T. Graham gave 0·0001645 for the **viscosity** of the gas at 0°, and 0·0001860 at 20° ; O. E. Meyer and F. Springmühl, 0·000168. H. Vogel studied this subject. A. Klemenc and W. Remi found 0·0001797 at 0°, and for Sutherland's constant, $C=162{\cdot}2$. O. E. Meyer gave 0·878 (oxygen unity) between 10° and 20°. T. Alty studied the surface phenomena of bubbles of nitric oxide in water. A. Masson found the **velocity of sound** in nitric oxide to be 325 metres per sec. ; W. Heuse, 323 metres per sec. A. Jaquerod and O. Scheuer found the divergence of the **compressibility** of the gas from Boyle's law is very slight. The value of a in $1-p_1v_1/p_0v_0=a(p_1-p_0)$ is 0·00097 for oxygen, 0·00117 for nitric oxide, and 0·01527 for ammonia. J. Batuecas gave 0·0000147 for the compressibility of the gas, and 1·00112 for the divergence from Avogadro's law, $1+\lambda$. J. Briner and co-workers observed :

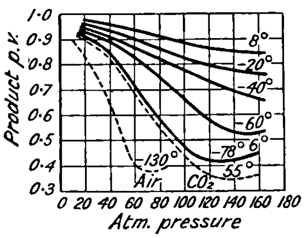

FIG. 70.—Isothermal pv Curves of Nitric Oxide.

	p . . .	30	50	70	90	110	130	150	160
$\dfrac{pv}{p_0v_0}$	9° .	0·9625	0·938	0·9135	0·892	0·862	0·8545	0·843	0·8375
	20° .	0·9475	0·9135	0·8805	0·8455	0·8135	0·787	0·767	0·758
	40° .	0·9365	0·8895	0·8385	0·789	0·7475	0·711	0·6745	0·659
	78·6° .	0·893	0·779	0·6420	0·520	0·441	0·424	0·4435	0·4525

The results are plotted in Fig. 70. When compared with the isotherms of nitrogen, oxygen, carbon dioxide, or ethylene, there is no indication of abnormal polymerization. The subject was studied by C. Schlatter. The **vapour pressure** of solid nitric oxide at —160·6° is 168 mm. According to K. Adwentowsky, the vap. press., p, at different temp. are as follow :

	Solid.			Liquid.				
	−174·4°	−169·2°	−161·0°	−160·6°	−157·8°	−154·1°	−150·9°	−150·2°
p mm.	23	55	158	168	353	519	664	760

and from this temp. on to the critical temp., —92·9° :

	−128·2°	−124·0°	−118·7°	−112·6°	−107·8°	−102·9°	−97·3°	−92·9°
p atm.	8·95	10·7	15·8	21·6	31·0	41·0	53·1	64·6

He said that the vap. press. curve of liquid nitric oxide is somewhat anomalous, and this is attributed to polymerization of the molecules at low temp. The fact that the vapour density at atmospheric press. is quite normal at these temp. indicates, however, that the dissociation of the polymerized mols. is practically complete at this pressure. The high density of the liquid at its b.p., 1·269, is cited as evidence in support of the view that the liquid mols. are associated. W. Nernst's value for the **chemical constant** is about 3·7 ; J. R. Partington's, 1·263 ; F. A. Henglein, and A. Langen, 0·92 ; and A. Eucken and co-workers gave 0·03 for the integration constant of the thermodynamic vap. press. equation ; and A. Eucken and F. Fried, 0·95 for the constant in the equilibrium equation for $2NO=N_2+O_2$.

For the constants in the **equation of state,** $(p+a/v^2)(v-b)=RT$, F. Guye and L. Friedrich gave $a=0{\cdot}00257$ and $b=0{\cdot}00115$ when in terms of the initial vol.; $a=1{\cdot}29\times10^{-6}$ and $b=25{\cdot}9$ if expressed in mols; and $a=1430$ and $b=0{\cdot}862$ if expressed in grams. M. F. Carroll studied the equation of state.

K. Adwentowsky found the coeff. of **thermal expansion** at 760 mm. between —140° and 0° is 0·0037074. H. V. Regnault's value for the **specific heat** of nitric oxide is $c_p=0{\cdot}231$ between 13° and 172°, and it increases with rise of temp. R. Threlfall held it possible that at low temp. some molecular complexes decompose, and they are resolved into the simple molecules at higher temp. G. Daccomo and V. Meyer said that at low temp., —70°, the gas is monomolecular. A. Eucken and E. Karwat gave for the **molecular heat:**

	−250·6°	−239·30°	−194·10°	−177·00°	−168·7°	157·6°	−156·0°
C_p . .	2·04	3·48	7·17	8·49	8·95	17·00	17·5
	Solid.					Liquid.	

K. Scheel and W. Heuse found for the mol. ht., $C_p=7{\cdot}23$; and $C_v=5{\cdot}25$ at 15°; and at —45°, —55°, —80°, W. Heuse obtained $C_p=7{\cdot}14$, 7·22, and 7·28 respectively; and $C_v=5{\cdot}15$, 5·24, and 5·29 respectively. A. Masson gave for the ratio of the two sp. hts., $\gamma=1{\cdot}399$ at 0°; and J. R. Partington and W. G. Shilling, 1·400 at 7·6°. W. Heuse obtained 1·38 at 15° and 1·38 at —80°. J. L. Pickering, and S. W. Saunders discussed the sp. ht. of nitric oxide. The sp. ht. of nitric oxide, calculated by E. E. Witmer from spectroscopic data, is $1{\cdot}33R$ at 50° K., where R is the gas-constant, 1·986 cals. per degree. W. G. Shilling gave:

T° K.	300°	500°	1000°	1500°	2000°	2500°	2700°
C_v . . .	5·00	5·06	5·30	5·73	6·26	6·66	6·73
C_p . . .	7·00	7·05	7·29	7·71	8·24	8·65	8·72
γ . . .	1·399	1·393	1·375	1·347	1·317	1·298	1·295

He also gave $C_v=5{\cdot}102-0{\cdot}0_3564T+0{\cdot}0_69554T^2-0{\cdot}0_91934T^3$.

Nitric oxide was not liquefied by M. Faraday at —110° and 50 atm. press.; but M. Berthelot liquefied it at —11° and 104 atm. press., but not at 8° under a press. of 270 atm. He therefore thought that the **critical temperature** is between —11° and 8°. On the other hand, K. Olschewsky found the critical temp. to be —93·5°, and the **critical pressure,** 71·2 atm.; and K. Adwentowsky gave respectively —92·9° and 64·6 atm. K. Olschewsky found the **boiling point** to be —153·6° at one atm. press., and in addition:

Press. .	71·2	49·9	20·0	10·6	5·4	1·0	0·182	0·023 atm.
B.p. .	−93·5°	−100·9°	−119·°0	−129°	−138°	−153·6°	−167·0°	−176·5°

A. Ladenburg and C. Krügel gave —142·4° for the b.p.; P. A. Guye and G. Drouginine, —142°; H. Goldschmidt, —151·13°; F. A. Henglein and H. Krüger, —150·6°; M. W. Travers, —149·9°; P. A. Guye and G. Drouginine, —150°; and K. Adwentowsky, —150·2°. K. Olschewsky found the **vapour pressure** at —176·3° to be 18·2 mm., and at 166·8°, 138·3 mm.; W. Ramsay and M. W. Travers gave 760 mm. at —149·7°; and K. Adwentowsky, 23 mm. at —174·2°; 107 mm. at —164·3°; 441 mm. at —155·4°; and 760 mm. at —150·0°. F. A. Henglein and H. Krüger found the vap. press., p mm., to be:

	−199·57°	−192·82°	−171·8°	−164·0°	−161·1°	−155·9°	−152·8°	−150·5°	−148·4°
p .	0·0229	0·210	35·5	157·1	221·6	413·9	609·1	761·0	949·6
	Solid.				Liquid.				

The observed results can be represented by $\log p=10{\cdot}1466-867{\cdot}4T^{-1}$ for the solid, and by $\log p=8{\cdot}4440-681{\cdot}1T^{-1}$ for the liquid. The relation dp/pdT is relatively large, meaning that there is a relatively large change in the vap. press. for a relatively small change of temp. H. Goldschmidt found that the vap. press.,

p mm., of liquid nitric oxide can be represented by $\log p = 6{\cdot}92669 - 0{\cdot}016801T - 1{\cdot}75 \log T - 778{\cdot}13T^{-1}$; and for the solid, $\log p = 6{\cdot}92669 - 0{\cdot}005985T - 1{\cdot}75 \log T - 837{\cdot}42T^{-1}$. There is much association among the liquid molecules. K. Adwentowsky gave −167° for the f.p.; A. Ladenburg and C. Krügel, 150·0° for the **melting point**; H. Goldschmidt, −163·21°; A. Eucken and E. Karwat, −110°; F. A. Henglein and H. Krüger, −163·6°; and K. Adwentowsky, −160·6°. H. Goldschmidt gave for the **triple point** −163·21°; the vap. press. at the triple point is 172·2 mm.; the **latent heat of vaporization** of the liquid is 3199 cals. at −151·13°; 3230 cals. at −155°; 3289 cals. at −160°; and 3324 cals. at −163·21°; and for the solid, 3863 cals. at −163·21°; 3872 cals. at −165°; 3885 cals. at −168°; 3902 cals. at −173°; 3912 cals. at −177°; and 3923 cals. at −183°. F. A. Henglein and H. Krüger gave 3080 cals. for the latent heat of sublimation and 3980 cals. for the latent heat of vaporization at the m.p. The **latent heat of fusion** at the triple point is 539 cals. A. Eucken and E. Karwat gave 552 cals. per mol; and F. A. Henglein and H. Krüger, 900 cals. The value for **Trouton's constant** is 24·7, the high value indicating an association of the liquid. J. Thomsen gave for the **heat of formation** of nitric oxide from its elements −21·575 Cals.; and from nitrous oxide and oxygen, −24·83 Cals. M. Berthelot gave −21·6 Cals. for the heat of formation from its elements. J. C. Thomlinson calculated what he called the thermochemical eq. of the nitrogen in nitric oxide—*vide infra.* R. T. Birge and H. Sponer calculated for the heat of dissociation of NO, 7·9 volts or 182,000 cals. from the band spectrum, and 8·3 volts or 191,000 cals. from chemical data. H. C. Urey gave 45·3 for the **entropy** of the gas; and E. D. Eastman, 46·6 to 49·3.

P. L. Dulong gave 1·000302 for the **index of refraction** of nitric oxide for white light, and E. Mascart, 1·0002971 for Na-light. C. Cuthbertson and E. P. Metcalfe gave 1·0002939 for light of wave-length $589{\cdot}3\mu\mu$; and C. and M. Cuthbertson, $1{\cdot}0_{3}29776$ for $\lambda = 480{\cdot}0\mu\mu$; $1{\cdot}0_{3}29622$ for $\lambda = 1{\cdot}0_{3}5209$; $1{\cdot}0_{3}29474$ for $\lambda = 576{\cdot}9\mu\mu$; and $1{\cdot}0_{3}29306$ for $\lambda = 670{\cdot}8\mu\mu$. They represented their results by $\mu - 1 = 3{\cdot}5210 \times 10^{27}/(12216 \times 10^{27} - \lambda^{2})$. For liquid nitric oxide, G. D. Liveing and J. Dewar gave 1·329 for the C-line; 1·3305 for the D-line; 1·3345 for the F-line; 1·3278 for the G-line; 1·3257 for the Li-Line, $\lambda = 670{\cdot}55\mu\mu$; and 1·3368 for the In-line, $\lambda = 450{\cdot}96\mu\mu$. The refractive power by $(\mu - 1)/D = 0{\cdot}2634$; and $(\mu^{2} - 1)/(\mu^{2} + 2)D = 1{\cdot}163$. J. Koch measured the dispersion. J. Cabannes and J. Granier discussed the polarization of light diffused laterally in nitric oxide. C. V. Raman and K. S. Krishnan observed no appreciable double refraction at 2 atm. press.; and none for Kerr's constant. K. S. Krishnan found no magnetic double refraction with nitric oxide, showing that the paramagnetic molecules of the gas do not orient, as a whole, in the magnetic field. W. H. Bair, and H. O. Kneser studied the **spectrum** of nitric oxide. The **absorption spectrum** of nitric oxide gas was examined by D. Brewster,[4] W. A. Miller, E. Robiquet, F. Holweck, E. Luck, J. Moser, H. Sponser and J. J. Hopfield, H. Kreusler, E. C. Kemble and F. A. Jenkins, R. S. Mulliken and co-workers, F. A. Jenkins and co-workers, M. Guillery, and J. N. Lockyer. The **ultra-violet spectrum** was examined by H. Kreusler; the **ultra-red spectrum** by E. Warburg and G. Leithauser; and the spectrum of soln. by A. Kundt, and D. Gernez. R. T. Birge and H. Sponer studied the heat of ionization of the gas. E. P. Metcalfe studied the ionization of nitric oxide. C. A. Mackay gave 9·4 volts for the **ionizing potential**; A. L. Hughes and A. A. Dixon, 9·3 volts; H. D. Smyth and co-workers, 9 volts; and T. R. Hogness and E. G. Lunn, and R. A. Morton and R. W. Riding studied this subject. H. Sponer said that the excitation potentials of the levels of the nitric oxide molecule are 5·44 and 13·96 volts; hence the ionizing potential must exceed 14 volts. T. R. Hogness and E. G. Lunn studied the positive ray analysis and ionization of nitric oxide, and of mixtures of that gas with argon and helium. W. G. Palmer examined the effect of nitric oxide on the coherer in detecting electric waves.

S. Zimmermann found the specific **electrical conductivity** of water saturated with nitric oxide to be $36{\cdot}2 \times 10^{-5}$. He considers that the soln. in water is in part a chemical process: $4NO+2H_2O=2HNO_2+H_2N_2O_2$. L. M. M. Smith and C. R. Daily found that the **dielectric constant** is nearly the same as that of air, being 1·00044 at room temp., and 760 mm. press. The value of this constant is not appreciably affected by a magnetic field of 10,000 gauss. The subject was discussed by L. Pauling. Nitric oxide is paramagnetic. G. Quincke found the **magnetic susceptibility** at 16° and 760 mm. to be $+0·053\times10^{-6}$; T. Soné gave $48·8\times10^{-6}$; and J. Schulmeister gave $0·0278\times10^{-6}$ and $0·0232\times10^{-6}$ for a magnetizing force of 668·3; and $0·0496\times10^{-6}$ and $0·0437\times10^{-6}$ for a magnetizing force of 2721·8. E. Bauer and co-workers, and P. Weiss and A. Piccard measured the coeff. of magnetization of nitric oxide; while P. Debye and A. Huber inferred that, in harmony with P. Ehrenfest's view, the molecules of this paramagnetic gas do not become oriented under the influence of a magnetic field; and A. Huber observed no electrical polarization with gaseous, liquid, or solid nitric oxide. E. C. Fritts, J. H. van Vleck, and N. W. Taylor and G. N. Lewis discussed this subject. G. Gehlhoff studied the cathode fall of potential of the gas in a vacuum tube. M. F. Skinker and J. V. White investigated the motion of electrons in nitric oxide.

The solubility of nitric oxide in different solvents.—According to H. Davy, one vol. of *water* absorbs $\frac{1}{10}$th vol. of gas at ordinary temp.; W. Henry said that one vol. of water absorbs $\frac{1}{10}$th vol. of gas, and J. Dalton, $\frac{1}{27}$th vol. G. Hüfner found that 100 c.c. of water at 20° absorb 4·706 c.c. of nitric oxide at 760 mm. L. W. Winkler obtained for the coeff. of absorption, β, or the vol. of gas reduced to n.p. θ, absorbed by one vol. of liquid when the press. of the gas without the partial press. of the liquid is 760 mm.; the solubility, S, or the vol. of gas reduced to n.p. θ, absorbed by one vol. of liquid at 760 mm.; and w, the weight of gas in grams absorbed by 100 grms. of solvent when the total press. is 760 mm.

	0°	5°	10°	15°	20°	40°	60°	80°	100°
β .	0·0738	0·0646	0·0571	0·0515	0·0471	0·0351	0·0295	0·0270	0·0263
S .	0·0734	0·0641	0·0564	0·0506	0·0460	0·0325	0·0237	0·0144	0·0000
w .	0·00984	0·00860	0·00757	0·00680	0·00618	0·00440	0·00324	0·00199	0·00000

According to J. Dalton, 100 vols. of *nitric acid* of sp. gr. 1·3 absorb 20 vols. of nitric oxide. He added that the amount of nitric oxide absorbed is proportional to the conc. of the acid, HNO_3; very dil. acid absorbs scarcely any more nitric oxide than does pure water. A. V. Schaposchnikoff measured the coeff. of absorption of nitric oxide by nitric acid expressed in litres of gas per litre of acid of different conc., N, at 25°:

Conc. HNO_3 .	N-	0·4N-	0·2N-	0·1N-	0·075N-	0·05N-	0·025N-
NO . .	0·3209	0·1448	0·0753	0·03803	0·02852	0·0195	0·00981

An acid of sp. gr. 1·517 at 15°/4° absorbs 0·88 per cent. of nitric oxide so that the coeff. of absorption is 12·5. The speed of absorption varies with the conc. of the acid. C. A. Winkler obtained no absorption of nitric oxide by the hydrate of *sulphuric acid;* and M. Berthelot said that nitric oxide is very slightly soluble in conc. sulphuric acid. O. Lubarsch made some observations on this subject. E. Desbassayns de Richemont said that if the sulphuric acid contains a little ferrous sulphate, nitric oxide imparts to it a red colour; and if copper sulphate, a violet colour. In the latter case, W. Manchot found that the coloration is due to the formation of an easily dissociated *copper nitrosylsulphate*, $CuSO_4.NO$—*vide infra.* For the corresponding compound with ferrous sulphate, *vide infra.* G. Lunge found that 1 c.c. of sulphuric acid of sp. gr. 1·84 absorbs 0·035 c.c. of nitric oxide, and an acid of sp. gr. 1·50, 0·017 c.c.; and O. F. Tower, v vol. of nitric oxide at 760 mm. absorbed by one vol. of acid 18° and H_2SO_4 per cent.

.	98	90	80	70	60	50
v . . .	0·0227	0·0193	0·0117	0·0113	0·0118	0·0120

J. Priestley said that nitric oxide is very soluble in aq. soln. of *ferrous sulphate*, and of other ferrous salts; J. Dalton, that a soln. of ferrous sulphate of sp. gr. 1·081, containing one part by weight of ferrous sulphate to six parts of water absorbs 6 vols. of nitric oxide. E. Péligot showed that 2 mols of the ferrous salt absorb one mol of nitric oxide. If v represents the number of litres of soln. containing one mol of ferrous sulphate ; and S number of litres of nitric oxide absorbed, then V. Kohlschütter found :

v . .	1·2	1·8	2·4	4·82	7·2	12·0	18·6	36·0
S . .	1·47	2·01	2·55	4·40	5·52	5·36	8·01	10·40

J. Gay showed that the amount of gas absorbed is proportional to the amount of iron present irrespective of the acid, or the conc. of the soln. The absorption is also dependent on the temp. and press. Thus, between 0° and 10°, about 2 mols of nitric oxide are absorbed per gram-atom of iron ; between 10° and 15°, in agreement with E. Péligot, one mol of nitric oxide for 2 gram-atoms of iron ; and at 25°, only one mol of nitric oxide per 2·5–3 gram-atoms of iron. The sp. gr. of the soln. is greater after the absorption of nitric oxide than it was before. The soln. are decomposed by heat, and at 100°, all the nitric oxide is expelled. The cooling or evap. of the soln. in an atm. of nitric oxide yields black crystals which contain very little nitric oxide. L. Moser and R. Herzner found that the most efficient soln. for analytical work contains 15 per cent. by wt. of anhydrous ferrous sulphate, 15 per cent. of 64 per cent. sulphuric acid, and 70 per cent. of water. S. Zimmermann found that soln. after the absorption of nitric oxide have a smaller conductivity than before, and the complex ion containing nitric oxide has a smaller transport number than the iron-ion. F. L. Usher found that owing to chemical interaction, neither the f.p. of the soln. nor the press. of the nitric oxide remained constant. The nitric oxide is reduced by soln. of ferrous sulphate so that the vol. of gas absorbed gradually increases with time. This interferes with the exact measurement of the solubility. G. von Hüfner gave for the coeff. of absorption, β, of 205·69 c.c. of a soln. containing w gram-atoms of iron, at 20·09° :

w . .	0·0221	0·0296	0·0409	10·0513	0·0663	0·099
β . .	0·06067	0·06505	0·06684	0·07981	0·08059	0·11661

He argued that the nitric oxide must be in some way attached to the metal because the amount of gas absorbed increases with the conc. of the salt soln. ; and he added that the connection is so " loose " that within certain limits of press., the absorption of the gas is in accord with Henry's law. W. Manchot and K. Zechentmayer showed that the absorption of nitric oxide by a ferrous salt results from the formation of a chemical compound containing Fe and NO in the proportion 1 : 1. Under all conditions, therefore, the limit of absorption is reached when 1 mol. of nitric oxide has been absorbed for each ferrous atom present, and corresponds with the conversion of Fe'' into Fe'''. The formation of the compound is a reversible reaction ; the degree of dissociation varies with the ferrous salt, but is dependent also on the press., temp., conc. of the ferrous salt, presence of indifferent solutes, and nature of the solvent, to an extent which is in agreement with the laws of chemical dissociation. W. Manchot and co-workers regarded the product of the reaction as **ferrous nitrosylsulphate,** $FeSO_4.NO$, which was isolated in red leaflets by W. Manchot and F. Huttner, W. Manchot, and I. Bellucci. J. Dalton said that a soln. of *ferric* sulphate does not absorb nitric oxide—presumably to any marked extent. W. Manchot and E. Linckh found that ferrous selenate behaves like ferrous sulphate in absorbing nitric oxide, and a similar ring test may be made with ferrous selenate and conc. selenic acid. The combination is similar to that in the case of ferrous sulphate, giving an equilibrium constant on the assumption that the combining ratio is 1 : 1. The equilibrium constant, 162, is rather smaller than that obtained with ferrous sulphate. Crystalline **ferrous nitrosylselenate,** $FeSeO_4.NO.4H_2O$, may be prepared by saturating a conc. aq. soln. of ferrous selenate, $FeSeO_4.5H_2O$, with nitric oxide in the presence of a little conc. selenic acid. On adding a large excess of absolute alcohol, also sat. with nitric oxide, with cooling in a freezing mixture, brownish-black crystals appear after some hours. The crystals are unstable, losing nitric oxide when kept in air, but the composition is that indicated above. W. Manchot found that a soln. of ferric sulphate in 90 per cent. sulphuric acid forms **ferric nitrosylsulphate,** $Fe_2(SO_4)_3.NO$. G. Hüfner also found that the coeff. of absorption for 205·69 c.c. of a soln. of *cobalt sulphate* with 0·0598 gram-atom of cobalt is 0·09146 at 20·09°; and for 205·69 c.c. of a soln. of *nickel sulphate* with 0·0506 gram-atom of nickel, it is 0·08311. For soln. of the same conc., F. L. Usher gave 0·048 at 20° with nickel sulphate, and 0·0245 for a soln. sat. at 20°; and for a soln. of cobalt sulphate sat. at 20°, 0·0288. Thus, while G. Hüfner found the coeff. of absorption of nitric oxide in cobalt and nickel sulphates to be high, F. L. Usher claimed that the presence of these salts diminishes the solubility of nitric oxide in water. L. Moser and R. Herzner studied the solubility from the point of view of analysis.

V. Kohlschütter and M. Kutscheroff found that v litres of water containing a mol of *ferrous chloride* absorb S litres of nitric oxide; thus:

v . . .	2·5	5·18	10·35	20·7	51·8
S . . .	3·30	4·83	6·56	8·32	11·89

The solubility of nitric oxide in presence of 10 per cent. hydrochloric acid is rather less than in an aq. soln. of the same conc., as W. Manchot and K. Zechtenmayer have observed, but with 30 per cent. hydrochloric acid, the solubility is approximately doubled. They also found that a soln. of a mol of ferrous chloride in 10·37 litres sat. with sodium chloride absorbed 6·549 litres of nitric oxide; and when the sodium chloride is replaced by ammonium chloride, 6·549 litres of nitric oxide are absorbed. According to V. Thomas, anhydrous *ferric chloride* absorbs nitric oxide at the ordinary temp., forming a brown complex **ferric nitrosylhexachloride,** $2FeCl_3.NO$; and at 60°, **ferric nitrosyldodecachloride,** $4FeCl_3.NO$. The same compounds are formed when nitric oxide is passed into soln. of ferric chloride. At the temp. of sublimation, ferric chloride is reduced by nitric oxide. These two salts are very hygroscopic, and could not be crystallized; they give off nitric oxide when in contact with water; and when heated in air, form ferric oxide. When nitric oxide is passed into ether sat. with ferric chloride, and the soln. evaporated over sulphuric acid, black needles of **dihydrated ferrous nitrosyldichloride,** $FeCl_2(NO).2H_2O$, are formed; and if the crystallization occurs at 60°, yellow crystals of anhydrous **ferrous nitrosyldichloride,** $FeCl_2(NO)$, are produced. This compound dissolves completely in water, without evolution of gas, and yields a pale yellow solution, the colour of which deepens when heated. On addition of alkalies out of contact with air, ferrous oxide is precipitated, but no gas is evolved. The solution gives other reactions of ferrous salts. V. Thomas found that these three nitrosyl compounds have no appreciable dissociation press. at ordinary temp., either in vacuo, or in a current of a dry inert gas. Water dissolves ferrous nitrosyldichloride without an evolution of gas, and no gas is evolved if the other two compounds are added to a large proportion of water; but if water is allowed to drop on the solid compounds, gas is liberated in large quantity. Potassium hydroxide or ammonia behaves similarly with all three compounds, and produces a greyish-white precipitate which rapidly becomes bluish-green and, finally, black. There is no liberation of gas, and the liquid contains neither a nitrate nor a nitrite, nor ammonia. When the black precipitate, produced by alkalis in solutions of the solid compounds, is placed in a vacuum, it gives off a considerable quantity of almost pure nitrogen. If a soln. of the nitrosyl dichloride is precipitated with silver nitrate, there seem to be indications of the formation of silver hyponitrite; but this supposition could not be confirmed, and the phenomena are not shown by the other two compounds. Nitric oxide is only very slowly absorbed by solutions of the ferrous nitrosyl chlorides, and seems to act as an oxidizing agent. W. Manchot and F. Huttner studied the equilibrium conditions of the reaction $FeCl_2+NO \rightleftharpoons FeCl_2.NO$, but I. Bellucci could not confirm the existence of ferrous nitrosyldichloride, although he did obtain W. Manchot's **ferrous nitrosylhydrophosphate,** $Fe(NO)(HPO_4)$. W. Manchot also prepared **copper nitrosylsulphate,** $Cu(NO)SO_4$; **copper nitrosylchloride,** $Cu(NO)Cl_2$; and **copper nitrosylbromide,** $Cu(NO)Br_2$; but the nitrosyl salts could not be obtained with copper fluoride, nitrate, acetate, tartrate, formate, and glycollate. V. Thomas found that at 10° soln. of *ferrous bromide* absorb nitric oxide and appear to form **ferrous dinitrosylhexabromide,** $3FeBr_2.2NO$; and at 15°–16°, **ferrous nitrosyltetrabromide,** $2FeBr_2.NO$. These results agree with those of J. Gay obtained with ferrous sulphate and chloride. W. Manchot studied the equilibrium conditions of the reaction $FeBr_2+NO \rightleftharpoons FeBr_2.NO$; but I. Bellucci doubts the existence of this nitrosylbromide. With *ferric bromide* the reduction occurs more readily than with ferric chloride, and the resulting ferrous bromide absorbs nitric oxide as just indicated. W. Manchot and E. Linckh, and H. I. Schlesinger and A. Salathe measured the absorption spectra of the nitrosyl copper and ferrous sulphates. W. Manchot and E. Linckh found that the absorption spectra of the nitrosyl compound in soln. of varying concentration are independent of the Cl'-, SO_4-, and SeO_4-anions, and are determined by the $(FeNO)'$-cation. The spectra of the green soln. of the ferrous nitrosyl chloride in alcohols, esters, or hydrochloric acid are quite similar, indicating that hydrogen chloride may replace alcohol or ester in the complex which causes the colour. The spectrum of red soln. of the ferrous nitrosyl sulphate in conc. sulphuric acid, or of the chloride in pyridine denotes that the colouring complex has a different structure. Soln. of cupric nitrosyl salts in conc. sulphuric acid, alcohol, or ethyl acetate were found by W. Manchot and E. Linckh to have closely similar absorption spectra resembling the green type of ferrous nitrosyl salts; and the colour appears to be due to the CuX_2NO complex. The red ferrous nitrosyl salts have no counterpart among the copper salts; nor do brown copper salts analogous to brown ferrous nitrosyl salts exist. H. I. Schlesinger and A. Salathe, and L. Cambi and L. Szego also studied the absorption spectra of soln. of the nitrosyl ferrous and copper sulphates. G. Hüfner found that at 20·09°, 205·69 c.c. of a soln. of *manganous chloride* containing 0·0697 grm. of manganese, had a coeff. of absorption 0·06111, and the solubility increased with increasing press. F. L. Usher found a soln. of this salt sat. at 20° had a coeff. of absorption of 0·0082. V. Kohlschütter and M. Kutscheroff found that at 23°, 3·25, 6·50, and 26·00 litres of soln. containing a mol of *ferrous nitrate,* absorb respectively 2·77, 4·16, and 6·61 litres of nitric oxide. They also obtained with 0·231, 0·277, and 0·371 litre of a soln. containing a mol of *cupric chloride,* an absorption of 0·120, 0·098, and 0·052 litre respectively of nitric oxide; with v litres of conc. hydrochloric acid containing a mol of cupric chloride, S litres of gas were absorbed.

v .	0·389	0·840	1·230	2·462	7·499	12·500	18·750	28·650

They also tried soln. of cupric chloride in acetic acid, formic acid, acetone, and methyl and ethyl alcohols. With 0·37, 0·62, and 0·925 litre of soln. with a mol of *cupric bromide,* 0·515, 0·120, and 0·000 litre of nitric oxide were respectively absorbed. They also tried soln. of cupric bromide in ethyl alcohol. E. Péligot found that nitric oxide is absorbed by aq. soln. of *stannous salts* (*vide infra*) and *chromous salts.* According to G. Chesneau, a soln. of *chromous chloride* absorbs nitric oxide in the ratio $CrCl_2 : NO = 3 : 1$, and the blue liquid becomes dark red. When heated, the nitric oxide is not expelled as in the case of ferrous salts, but the liquid becomes greenish-brown, and the nitric oxide is reduced to ammonia or hydroxylamine. The action of nitric oxide on soln. of chromous salts was also studied by V. Kohlschütter, and J. Sand and O. Burger.

Nitrosyl compounds of copper, manganese, iron, cobalt, nickel, and palladium are also known. W. Manchot and H. Schmid described the preparation of **potassium manganese nitrosylcyanide,** K_3MnCy_5NO, from the action of nitric oxide on a soln. of potassium cyanide and manganese chloride or acetate. W. Manchot and A. Waldmüller prepared **palladium dinitrosyldichloride,** $PdCl_2(NO)_2$, by the action of nitric oxide on a soln. of palladous chloride; with palladous sulphate, **palladium dinitrosylsulphate,** $PdSO_4(NO)_2$, is formed; and with palladium nitrate, palladium nitrite, $Pd(NO_2)_2$, is formed.

R. Bunsen found that S vols. of nitric oxide reduced to n.p.t. are absorbed by one vol. of absolute *ethyl alcohol* at 750 mm.,

	0°	5°	10°	15°	20°	24°
S . .	0·31606	0·29985	0·28609	0·27478	0·26592	0·26060

and L. Carius represented the results by $S=0·21606-0·003487\theta+0·000049\theta^2$ between 0° and 25°, and 760 mm. L. H. Friedburg found that nitric oxide is abundantly absorbed by *carbon disulphide.* Alkaline soln. of *pyrogallol* were shown by W. Lapraik, and G. Lechartier, to absorb nitric oxide, and by C. Oppenheimer to reduce it to nitrous oxide. R. A. Smith said that *charcoal* absorbs 12·66 times its vol. of nitric oxide; and C. Montemartini found that 4·441 grms. of *palladium* black absorbed 163·6 c.c. of nitric oxide in 2 days.

The chemical properties of nitric oxide.—Nitric oxide is not combustible, and it supports the combustion of a few substances, but not that of a candle. Nitric oxide is irrespirable since, in the presence of air, it forms brown fumes of nitrogen peroxide. L. Hermann[5] said that oxygenated blood is darkened when shaken with nitric oxide, and it seems to form a *nitrosylhæmaglobin.* W. Manchot discussed the compounds formed by nitric oxide with blood. F. Hatton showed that the bacteria which are connected with the putrefaction of meat extracts develop quite well in an atm. of nitric oxide.

The analyses of H. Davy, and J. L. Gay Lussac and L. J. Thénard show that nitric oxide has the empirical composition NO. This formula agrees with the physical properties of the gas. Oxygen is bivalent, hence the nitrogen in nitric oxide also behaves as a bivalent element: $O{=}N$; but nitrogen is usually ter- or quinque-valent, so that nitric oxide is usually considered to be an unsaturated compound. No evidence of the existence of $O{=}N{-}N{=}O$ has been observed. C. Weltzien considers that the radicle NO is sometimes univalent, and sometimes bivalent. J. C. Thomlinson's calculations of the thermochemical eq. of nitrogen in nitric oxide favoured the assumption that the oxygen is quinquevalent. E. Müller discussed this subject; and E. C. Stoner, and C. D. Niven, the electronic structure.

Nitric oxide is one of the most stable oxides of nitrogen. J. L. Gay Lussac[6] observed that when nitric oxide is passed through a red-hot tube, which contains platinum wire, it is decomposed into nitrogen and nitrogen peroxide; but W. R. E. Hodgkinson and F. K. S. Lowndes observed no decomposition when a platinum wire is electrically heated in an atm. of nitric oxide. M. Berthelot found that the gas begins to decompose when heated in a sealed tube at 520°, and in half an hour, about one-fourth of the gas is decomposed into nitrogen, nitrous oxide, and nitrogen tri- and per-oxides. K. Jellinek noted that decomposition can be detected at 689°, and that moisture has no influence on the reaction. For the equilibrium conditions, *vide supra,* the fixation of nitrogen. F. Emich, and C. Langer and V. Meyer noted that the gas is completely decomposed at about 1690°; at 700°, about 0·5 per cent. is decomposed; at 900°, one per cent.; and at 1200°, 60 per cent. The dissociation of nitric oxide: $2NO\rightleftharpoons N_2+O_2$, with rise of temp. has been discussed in connection with the fixation of nitrogen. E. Briner and N. Boubnoff studied the reaction over the range of press. from 50 to 700 atm., and over the temp. range from −90° to 300°. Nitrogen, nitric and nitrous oxides, and nitrogen trioxide and peroxide were among the products. It is inferred that the main reactions are: $2NO \rightleftharpoons N_2+O_2$; and $4NO=2N_2O+O_2$. The latter predominates. The other nitrogen oxides are supposed to be formed by the secondary action of oxygen on untransformed nitric oxide. The reaction was studied by W. Muthmann and H. Hofer, C. Meiner, W. Nernst, J. Brode, and P. A. Guye and F. Schneider—*vide supra.* E. Calberla said that at a bright red-heat, all the gas is decomposed in the presence of silver, but F. Emich could not verify this statement. While the reaction: $2NO=N_2+O_2$ is bimolecular in the gas phase, C. N. Hinshelwood and T. E. Green found that it is unimolecular on the surface of a heated platinum wire between 273° and 1531°. It is not influenced by nitrogen, but is retarded by oxygen. Thus, the velocity constant falls from $k=0{\cdot}0023$ with a 13 per cent. decomposition, to 0·0007 with 40 per cent. decomposition. M. Berthelot found that if mercury fulminate be exploded in nitric oxide, the gas is decomposed. J. Priestley observed that the gas is decomposed by the passage of electric sparks, forming, according to M. Berthelot, nitrogen, oxygen, and a trace of nitrous oxide. The decomposition of nitric oxide by electric sparks was noted by H. Buff and A. W. Hofmann, W. R. Grove, and T. Andrews and P. G. Tait. The decomposition of the gas by radiations of short wave-length was noted by E. Warburg and E. Regener. C. B. Bazzoni and A. T. Waldie said that at press. ranging from 0·1 mm. to 180 mm., nitric oxide is not dissociated either by heat radiation or by ultra-violet light; but D. Berthelot and H. Gaudechon observed that it is decomposed into nitrogen and oxygen by the light from a mercury quartz lamp, and that the oxygen unites with the remaining nitric oxide to form higher oxides. According to E. Briner and A. Wroczynsky, if nitric oxide be allowed to remain at a high press. in a sealed tube, drops of a blue liquid are first noticed at 28 atm. press.; $6NO=2N_2O_3+N_2$. E. Briner, and co-workers observed nitric oxide under prolonged compression decomposes, yielding a blue liquid which consists of a mixture of nitrous oxide and nitrous anhydride. Nitric oxide decomposes to give nitrous oxide and oxygen, the oxygen reacts with unchanged nitric oxide, yielding the peroxide, which in turn may react with nitric oxide to form the trioxide. The decomposition is very rapid at 700 atm. At lower press., the reaction is retarded by corrosion of the glass vessels by nitrogen peroxide. Freshly prepared and condensed nitric oxide is only very faintly blue in colour. Multiple liquefaction does not affect purification, since the blue colour gradually increases in intensity. Liquid nitric oxide is probably colourless and the blue tint is due to nitrous anhydride. E. Briner and co-workers studied the decomposition of nitric oxide at 700 atm. press.

C. L. Berthollet contradicted the statement of A. F. de Fourcroy, and T. Thomson that when a mixture of equal vols. of nitric oxide and **hydrogen** is passed through a red-hot tube, a detonation occurs. D. Waldie found that a mixture of nitric oxide and hydrogen burns with a white flame in air, without explosion, forming nitrogen peroxide; the hydrogen is said to be oxidized by the atm. oxygen, since a hydrogen flame is extinguished in nitric oxide. C. von Than determined nitric oxide by exploding a mixture of it with hydrogen by an electric spark: $2NO+2H_2=N_2+2H_2O$. H. Davy obtained no explosion by sparking a mixture of equal vols. of hydrogen and nitric oxide. S. Cooke said that it requires intense and long sparks to explode the 1 : 1 or 2 : 1 mixture of nitric oxide and hydrogen, while a mixture with more than 3 : 5 of hydrogen can no longer be exploded. C. von Than found that the reaction $2NO+2H_2=N_2+2H_2O$ can be completed by sparking the mixed gases. C. N. Hinshelwood and T. E. Green found that the homogeneous reaction between nitric oxide and hydrogen between 727° and 827° is termolecular, proceeding according to the ultimate reaction $2NO+2H_2=N_2+2H_2O$ at 826°, the value of K in $d[NO]/dt=K[NO]^2[H_2]$, ranges between $1{\cdot}08\times10^{-7}$ and $1{\cdot}60\times10^{-7}$ for considerable variations in the concentrations of hydrogen and nitric oxide expressed in mm. press., and the time in seconds. There is a small surface action which becomes more marked at lower press. The heat of activation is 44,000 cals. M. Faraday observed that a platinum plate in the mixture gradually induces combination. G. von Knorre and K. Arndt determined the nitric oxide in a gas from the contraction which occurs after passing a mixture of it with hydrogen over heated platinum sponge: $2NO+2H_2=N_2+2H_2O$. According to S. Cooke, a little hydrogen occluded in platinum reduces nitric oxide to nitrogen and nitrous oxide, but with more hydrogen, hydroxylamine, and ammonia are formed. L. Duparc and co-workers found that nitric oxide is reduced by hydrogen in the presence of platinum or rhodium to ammonia, while nitrous oxide always yields nitrogen. E. Ludwig and T. Hein found that with nascent hydrogen from tin and hydrochloric acid, hydroxylamine is formed (*q.v.*); J. H. Gladstone and A. Tribe, that with a copper-zinc couple, ammonia is produced; and R. S. Felgate, that nitric oxide is reduced to nitrogen by passing the gas through water with nickel reduced from the hydroxide by hydrogen. The nickel is at some time oxidized. A colloidal soln. of nickel does not produce the same result. P. Sabatier and J. B. Senderens observed no reduction when palladium sat. with hydrogen is surrounded by nitric oxide in the cold, but at 200°, the metal glows, forming water, ammonia, and a little nitrogen; nickel and copper at 180° also act as catalysts in this reaction; P. Neogi and B. B. Adhicary said that the reaction with nickel commences at 300° and then proceeds at 120° almost quantitatively; they also found that the reduction of nitric oxide in the presence of 3 times its vol. of hydrogen proceeds almost quantitatively in the presence of finely divided tin, iron, or zinc, whilst magnesium, mercury, and aluminium are inactive. Antimony and bismuth when freshly reduced from their oxides also exert a catalytic action. Gold, silver, or lead in the form of foil are almost inactive, but the freshly reduced metals in the form of powder cause the production of large quantities of ammonia. Gold acts best at 335°–345°; and silver at 430°. E. Briner and co-workers found that platinum with the alkaline earths as promoters was the most advantageous catalyst tried; and they found a parallelism between the catalytic efficiency and the electronic emission. P. A. Guye and F. Schneider represented the reduction of nitric oxide by nickel as the result of two consecutive reactions, one giving ammonia: $2NO+5H_2=2NH_3+2H_2O$, and the other nitrogen: $2NO+H_2=N_2+H_2O$. No nitrous oxide is produced. A temp. of 250°–300° is most suitable for the ammonia-reaction when 70 per cent. of the nitric oxide is transformed with ammonia. H. Gall and W. Manchot found that the NO-group of sodium nitroprusside was not reduced by hydrogen to the NH_3-group with aq. soln. and spongy platinum as catalyst. H. Moissan found that when **calcium hydride** is heated to dull redness in an atm. of nitric oxide the mass becomes incandescent and much ammonia is formed—*vide supra*, the formation of ammonia.

The early workers observed that when nitric oxide is brought in contact with **air** or **oxygen,** ruddy fumes of nitrogen peroxide are produced $2NO+O_2=2NO_2$. Numerous lecture experiments have been devised for illustrating this reaction—*e.g.* by G. Bruylants, etc.—*vide infra*, nitrogen peroxide, and *vide supra*, nitrosonitrogen trioxide for the action of oxygen on nitric oxide at very low temp. R. Pictet found that the reaction occurs very slowly at —80°, but at —120°, there is no reaction. H. B. Baker showed that if the gases be thoroughly dried, nitric oxide does not react with oxygen, although F. Emich did not succeed in the demonstration. According to J. L. Gay Lussac, and E. Péligot, in the cold, and in the absence of water and bases, nitrogen peroxide is the chief product; while P. L. Dulong, and J. J. Berzelius hold that nitrogen trioxide is formed. M. Berthelot said that in the presence of an excess of oxygen, nitrogen trioxide is first formed, and afterwards nitrogen peroxide is produced. This was confirmed by F. Raschig, who also suggested, without proof, that higher oxides are formed. He also stated that nitric oxide and oxygen unite in the fraction of a second to form nitrous anhydride: $(n+1)O_2+4NO \rightarrow nO_2+2N_2O_3$, and the anhydride, N_2O_3, then slowly oxidizes to the peroxide, N_2O_4. G. Lunge and co-workers claimed that with an excess of oxygen, nitrogen peroxide is first formed; and if nitric oxide be in excess, both nitrogen tri- and peroxides are formed, and at —21°, the nitrogen peroxide unites with nitric oxide, forming nitrogen trioxide (*q.v.*). If water is present, and the oxygen is in excess, only nitric acid is formed, and in the presence of sulphuric acid, nitrosylsulphonic acid is produced, but no nitrogen peroxide or nitric acid is formed. G. Lunge and E. Berl said that the reaction: $2NO+O_2=2NO_2$ is termolecular. The data were found by G. W. Todd to give sensibly constant values for the velocity coeff. at 20° with oxygen and nitric oxide; but with air, higher values are found in the earlier stages of the reaction. This is ascribed to the time required for mixing the reacting gases. F. Haber and W. Holwech, and F. Förster and A. Blich found that the oxidation of nitric oxide to nitrogen peroxide is a comparatively slow reaction, and the latter obtained a small negative velocity coeff. between 0° and 100°. They therefore assumed that a direct addition of oxygen to form a complex oxide occurs : $NO+O_2=NO.O_2$, which then reacts with a second molecule of nitric oxide to form nitrogen peroxide: $NO.O_2+NO=2NO_2$. The first reaction is reversible and the equilibrium state with a rise of temp. favours the dissociation of the complex oxide. The smaller conc. of the complex oxide at the higher temp. more than counteracts the increased velocity between the complex oxide and nitric oxide. The subject was discussed by J. Wiswald.

L. Francesconi and N. Sciacca showed that at the temp. of liquid air, the action of oxygen on nitric oxide results in the formation of nitrogen peroxide, whatever proportions of nitric oxide and oxygen be taken, provided the temp. be below —110°; only above —100° is nitrogen trioxide transformed by oxygen to nitrogen peroxide; and nitrogen peroxide is reduced by nitric oxide to nitrogen trioxide at temp. below —150°. According to A. Sanfourche, the first stage in the oxidation of nitric oxide: $4NO+O_2=2N_2O_3$, is practically instantaneous and independent of temp. between —50° and 525°. The second stage is a reversible process: $2N_2O_3+O_2\rightleftharpoons4NO_2$. The equilibrium is displaced from left to right up to 200°, but tends more and more from right to left as the temp. rises from 200° to 525°. The velocity of the oxidation has been measured by M. Bodenstein, the reaction is termolecular, and a rise of temp. lessens the speed of the reaction $dx/dt=kC_0C_1$, where C_1 denotes the conc. of nitric oxide, and C_0, that of oxygen. E. Briner and E. Fridöri said that over the interval of temp. 0°–60°, lowering the temp. 10° raises the velocity 10–20 per cent. The speed of the reaction was also studied by M. Trautz, E. Briner and co-workers, S. Dushman, and G. B. Taylor and co-workers. E. Wourtzel found that the reaction is of the third order, with a velocity—$dx/dt=kx^2p$, where x denotes the partial press. of the nitric oxide; and p, that of the oxygen. E. Briner and co-workers found that the third order of reaction becomes of the second order when a large excess of oxygen is present. A little nitrogen trioxide is formed: $NO+NO_2=N_2O_3$. According to A. Sanfourche, in the presence of water, nitric oxide is oxidized to nitrogen trioxide and not to the peroxide, the trioxide then being decomposed by the water, giving nitric acid and a partial regeneration of nitric oxide. In the presence of nitric acid (sp. gr. 1·5), however, the nitrogen trioxide is oxidized with the formation of the peroxide and water, according to the equation $2HNO_3+N_2O_3=H_2O+2N_2O_4$. This oxidation is first noticeable with nitric acid (sp. gr. 1·3), which has a concentration of approximately 50 per cent. but is not complete, and progresses further as the concentration of the nitric acid used is increased. E. Briner concluded that although water favours the reaction, its presence is not an essential condition for the reaction between oxygen and nitric oxide.

In 1846, I. T. Jullion patented the use of platinized asbestos for the oxidation of nitric oxide to nitric acid. C. L. Burdick found that between 0° and 100°, the oxidation of nitric oxide by oxygen is not catalyzed by ordinary porous materials —glass, pumice, or pumice impregnated with tungstic oxide—but with other agents—nickel, cobalt, or nickel, cobalt, or manganese oxides, platinized pumice or asbestos, coke, or charcoal—the reaction is accelerated. In the case of the highly absorptive varieties of charcoal, the reaction may be accelerated 500 times. The presence of water vapour in the gaseous mixtures greatly decreases the activity of the charcoal catalysts. An increase of temp. above the point at which the aq. vap. condenses counteracts this effect to some extent. The temp. coeff. of the velocity of reaction for both the catalyzed and uncatalyzed change is generally negative. In the presence of water vapour, the temp. coeff. of the catalyzed reaction is positive. This is probably due to the decreased absorption of water by the catalyst at elevated temp. The velocity of reaction increases greatly as the temp. is lowered, particularly at very low temp. The temp. coeff. of the velocity constant (defined as the ratio of the velocity constants at two temp. differing by 10°) decreases from 0·96 at 70° to 0·85 at —180°, in contrast to the values of 2–3 for ordinary reactions. The oxidation of nitric oxide is greatly facilitated by the cooling of the gases, particularly if the cooling takes place immediately the gases leave the arc. R. L. Hasche found that the reaction is accelerated by moisture, and the decrease in velocity observed when the interior of a glass vessel is coated with paraffin is attributed to a decreased film of moisture on the surface. The speed of oxidation can be reduced 30 per cent. by excluding water. There is a period of induction which is a function of the press. and of the humidity of the gas. The moisture is supposed to act as a catalytic agent: $NO+H_2O=NO.H_2O$; $NO.H_2O+NO=(NO)_2.H_2O$; and $(NO)_2.H_2O+O_2=N_2O_4(\rightleftharpoons 2NO_2)+H_2O$. The presence of sulphur dioxide, or of nitrogen peroxide, had no perceptible influence. M. Latshaw and W. A. Patrick studied the rate of oxidation of nitric oxide in an apparatus in which the changes of press. of the manometer were recorded on a photographic film mounted on the drum of a kymograph. R. L. Hasche observed that a period of induction occupying about 10 seconds occurs when the initial pressure of the mixed gases is below 14 mm. of mercury. J. L. Gay Lussac observed that a mixture of one vol. of oxygen with not more than four vols. of nitric oxide, in the presence of potash-lye, forms potassium nitrate; and T. Schlösing showed that if oxygen be in excess, the nitric oxide is converted completely into the nitrate. F. Fischer said that some nitrite is formed. W. A. Lampadius reported that if nitric oxide be added to oxygen standing over water at about 52° some nitric acid is formed. A. K. Brewer and F. Daniels showed that when nitric oxide is oxidized between oppositely charged electrodes a current of electricity passed through the gases. The current is of the order of 10^{-14} amperes for the oxidation of 50 c.c. of nitric oxide per minute reacting in a field of 450 volts per cm. This corresponds with about one ion for every million molecules reacting. The current is directly proportional to the voltage and to the number of molecules reacting. No evidence of a saturation current could be detected. A. Mandl and F. Russ found that the reaction with a mixture of 2 vols. of nitric oxide and one vol. of oxygen does not always go to an end. In some cases, only 97 per cent. of the nitric oxide is oxidized. Thus, electrolytic oxygen is said to be more active after passage over heated palladium. The retardation is possibly due to traces of hydrogen dioxide or ozone in the oxygen either directly or by the destruction of some catalyst necessary for the reaction. W. Holwech denied the phenomenon, and said that the speed of the reaction is the same with oxygen from all sources. For the reversibility of this reaction at high temp., *vide infra*, nitrogen peroxide. G. Kornfeld observed that the reaction with the two paramagnetic gases: $2NO+O_2=N_2O_4$, is slightly accelerated by a magnetic field.

A. Reis and O. Waldbauer obtained steady flames from mixtures of methane, nitric oxide, and oxygen; and the flames could be readily separated into two cones. If small percentages of nitric oxide are present, the gases from the inner cone contain ammonia, hydrogen cyanide, and acetylene. The proportion of hydrogen cyanide decreases with increasing height, while the proportion of ammonia rises to a maximum, and then falls. This shows that the ammonia is derived from the hydrogen cyanide. If a large proportion of nitric oxide is present, the inner cone has the appearance of substances burning in nitrogen peroxide. Here 90 per cent. of the nitrogen peroxide is transformed into nitric oxide, which then passes out of the inner cone unchanged; from 25–33 per cent. of the methane also escapes from the inner cone unchanged. The hydrogen is almost wholly oxidized, but the carbon monoxide is only slightly oxidized. Some formaldehyde is present in the gases between the two zones. The gases between the zones contain 40 per cent. of nitric oxide mixed with combustible gases and vapours. In this zone, too, the nitric oxide is only slightly decomposed, but the methane is unchanged ; and the conc. of the hydrogen increases upwards while the conc. of the carbon monoxide decreases. When the gases between the two zones contain sufficient oxygen, a new cone appears between the inner and outer cones, and in the middle cone, the combustible gases are burnt at the expense of the nitric oxide. A. Pinkus observed no sign of ionization in the oxidation of nitric oxide by oxygen ; but A. Pinkus and M. de Schulthess found that the reaction between conc. **ozone** and nitric oxide takes place with the evolution of light, and has the character of an explosion when the quantity of ozone present is small. A. K. Brewer noted ionization in the oxidation of nitric oxide by oxygen at 50° and 385°, and by ozone at 50°.

According to J. L. Gay Lussac, if a mixture of **water** vapour, oxygen, and nitric oxide be passed through a red-hot tube, containing some platinum wire, nitric acid is formed. According to P. Villard, at 0° and 10 atm. press., or at 12° and 43 atm. press., an unstable *hydrated nitric oxide* is formed. W. J. Russell and W. Lapraik found that if nitric oxide and water be heated for a long time in a sealed tube, nitrous acid, nitrous oxide, and nitrogen are formed. S. Cooke said that nitric oxide is gradually altered by prolonged contact with water, and if platinum be also present, there is a large contraction, and nitrous acid with some nitrogen and nitrous oxide are formed ; without the platinum, the reaction occupies nine months at ordinary temp. ; but at a higher temp., the reaction is faster. According to L. Moser, E. J. Joss, and S. Zimmermann, nitric oxide cannot be preserved over water without change, partly owing to the dissolved oxygen, and partly owing to hydrolysis : $4NO+2H_2O=2HNO_2+H_2N_2O_2$; as A. Hantzsch and L. Kauffmann have shown, the hyponitrous acid produces nitrous oxide and ammonium nitrite, which further decomposes into nitrogen. This product increases slowly with the length of time the gas remains over water. The moist gas can, however, be kept indefinitely over mercury without change. R. S. Felgate found that the reaction with hot water is accelerated by nickel with the production of nickel oxide and nitrogen. For the solubility, *vide supra.* The aq. soln. does not redden litmus. J. L. Gay Lussac, and W. J. Russell and W. Lapraik observed that when in contact with a conc. aq. soln. of **potassium hydroxide,** potassium nitrite and nitrous oxide are formed : $4NO+2KOH=N_2O+2KNO_2+H_2O$; and S. Cooke found that the reaction is speedier if platinum be present. G. Barr, and S. Cooke said that some nitrogen is also formed. F. Emich noted that at 112°–113°, solid potassium hydroxide reacts quickly with nitric oxide. O. Baudisch and G. Klinger represented the reaction : $4NO+O_2+4KOH=4KNO_2+2H_2O$, and utilized it in removing nitric oxide from gases for analysis. F. L. Usher also found that the gas is decomposed by potash-lye so that the solubility of the gas washed by potash-lye is greater than when washed by conc. sulphuric acid. According to C. F. Schönbein, **hydrogen dioxide** in excess converts nitric oxide into nitric acid, and if not in excess, some nitrous acid is formed ; if the soln. be shaken with ether, and the nitrous acid be removed by alkali-lye, the neutral ethereal layer, when treated with an acid, yields nitrous acid. L. Spiegel suggested that the acid is formed by the action of the ozonized ether on atm. nitrogen. H. Wilfarht determined nitric oxide by transforming it into nitrate by an alkaline soln. of hydrogen dioxide, and titrating back with a standard soln. of potassium permanganate.

H. Moissan and P. Lebeau [7] found that nitric oxide reacts immediately with **fluorine** with the production of a pale yellow flame, and when the nitric oxide is in excess no volatile compound of fluorine is obtained, but the heat developed by the reaction decomposes the nitric oxide into nitrogen and oxygen, the oxygen reacting with the excess of nitric oxide to form nitrogen peroxide. By the action of nitric oxide on excess of fluorine at the temp. of liquid oxygen, a white solid is obtained, nitroxyl fluoride, $4NO+F_2=N_2+2NO_2F$. According to J. L. Gay Lussac, a mixture of nitric oxide with half its vol. of **chlorine** at —15° to —20° forms a pale orange-yellow gas which condenses to a dark brown liquid which is a mixture of nitrosyl and nitroxyl chlorides. E. Davy, and C. F. Schönbein studied this reaction, and **bromine** and **iodine** were found to react similarly. M. Berthelot said that nitric oxide is soluble in bromine. H. H. Landolt found that bromine reacts with nitric oxide, forming bromonitrous acid, or bromonitric acid, NO_2Br_2 or $NOBr_3$; but O. Fröhlich said that only nitrosyl bromide, NOBr, is formed, and that H. H. Landolt's products were a mixture of nitrosyl bromide and bromine. C. F. Schönbein found that nitric oxide reacts on iodine suspended in water, forming hydriodic and nitric acids. M. Trautz and F. A. Henglein observed no signs of ionization during the reaction: $2NO+Cl_2\rightleftharpoons 2NOCl$, and the reaction $2NO+Br_2\rightleftharpoons 2NOBr$. A. Pinkus said that ionization occurs in the former case if the chlorine be in excess, but this could not be confirmed. W. H. Rodebush and T. O. Yntema observed that a mixture of **hydrogen chloride** and nitric oxide, when cooled to the temp. of liquid air, furnishes a purple solid; this melts to a purple liquid between —153° and —143°, when it has a sp. conductivity of 10^{-3} ohms, a value near that for $0{\cdot}01N$-KOH. The vap. press. of the purple liquid is near that for liquid nitric oxide. It is assumed that an unstable complex is formed between —153° and 143°, and is possibly $(NOH)^+Cl^-$, *hyponitrous chloride*. E. T. Champman found that boiling conc. **hydriodic acid** absorbs nitric oxide slowly, forming ammonia and iodine. A. J. Balard showed that the reaction with **chlorine monoxide** is explosive: $Cl_2O+NO=NO_2+Cl_2$; and with **hypochlorous acid** and **hypochlorites,** chlorine and nitric acid are formed. H. Davy observed that red fumes are formed when nitric oxide is brought in contact with **euchlorine.** H. Reinsch found that when nitric oxide is passed into a flask of **hydrogen chloride,** a yellowish-green oily liquid is produced along with some colourless crystals which decompose with effervescence when treated with water. Both solid and liquid slowly decompose and give off chlorine. E. Briner and A. Wroczynsky found that in sealed tubes at 50 atm., a mixture of nitric oxide and hydrogen chloride does not change, but at 500 atm. press., the mixture condenses in liquid air to deep reddish-violet solid, doubtless an additive compound. At the ordinary temp., the highly compressed mixture is a colourless gas, which after a time deposits two liquids, the layers gradually increasing from day to day. The pale red layer is nitrosyl chloride, and the pale yellow layer is water containing dissolved nitrosyl chloride. The action $4NO+4HCl\rightarrow 2NOCl+2H_2O+Cl_2+N_2$ is strongly exothermic. If the tube contains excess of nitric oxide, the two liquid layers are slowly converted into one deep green liquid of unknown composition. R. Weber said that nitric oxide has no action on **potassium iodide.** According to H. A. Auden and G. J. Fowler, **potassium chlorate** is attacked at ordinary temp. by nitric oxide, forming chlorine, nitrogen peroxide, potassium nitrate, and a trace of perchlorate; K. A. Hofmann and co-workers found that the reaction begins at 210° with the production of potassium nitrate, chlorine, and oxygen; the reaction is faster at 300°. The liberated oxygen oxidizes the nitric oxide to some extent and some nitrite is formed. H. A. Auden and G. J. Fowler found that **barium chlorate** behaves similarly; and **silver chlorate** gives silver chloride, etc.; **potassium iodate** at 80° gives iodine and potassium nitrate; **silver iodate** at 110° forms silver iodide; **potassium perchlorate** is attacked at 300°, forming potassium nitrate; and **barium periodate,** $BaIO_4$, at 388° liberates iodine.

The flame of burning sulphur is extinguished in nitric oxide. According to G. Chevrier,[8] the passage of electric sparks through a mixture of nitric oxide and sulphur vapour results in the formation of nitrous acid, sulphur dioxide, and the so-called chamber crystals. C. Leconte found that equal vols. of **hydrogen sulphide** and nitric oxide react in a few hours, forming some nitrous oxide and ammonium sulphide. T. Thomson said the dried gases act most rapidly, but C. Leconte, and G. Lunge said that the dried gases do not react at all. S. Cooke noted that a mixture of hydrogen sulphide and nitric oxide can be exploded by electric sparks. G. Ville found that when nitric oxide is mixed with an excess of hydrogen sulphide, and passed over heated soda-lime, ammonia is formed. J. Priestley, and H. Davy observed the reduction of nitric to nitrous oxide by the action of **potassium sulphide,** dry, or in aq. soln. H. Davy found that pyrophoric potassium sulphide inflames in nitric oxide. Heated **barium sulphide** removes the oxygen from nitric oxide. A. Klemenc studied the oxidation of sulphides by nitric oxide. According to J. Pelouze, nitric oxide mixed with half its vol. of **sulphur dioxide,** standing over water, forms nitrous oxide and sulphuric acid ; R. Weber said that the transformation is not complete in 14 days at 22·5° ; but G. Lunge said the reaction is complete in 48 hrs., and all the nitric oxide is reduced to nitrous oxide ; a mixture of nitric oxide, sulphur dioxide and oxygen in the presence of water always forms some nitrous oxide, even when the oxygen is in excess. F. Kuhlmann showed that nitric oxide is reduced by sulphur dioxide in the presence of platinum sponge, forming nitrous oxide and water. The reaction proceeds quickly—particularly if the mixed gases be warmed. A. Klemenc, and L. Moser and R. Herzner studied the oxidization of sulphites by nitric oxide—*vide* the manufacture of sulphuric acid by the chamber process. L. Moser and R. Herzner found that the best mixture for absorbing nitric oxide contains 11–15 per cent. by wt. of anhydrous sodium sulphate, one per cent. of sodium hydroxide, and 88–84 per cent. of water. E. Briner and A. Wroczynsky found that a mixture of nitric oxide and sulphur dioxide in a sealed tube at 50 atm. press. does not change, but at 500 atm. press., a pale green solid is formed which is thought to be a soln. of nitric oxide in sulphur trioxide formed by the reaction : $2NO+2SO_2=2SO_3+N_2$. A. Graire observed that nitrous oxide is formed by the slow interaction of sulphur dioxide and nitric oxide in the liquid phase—*e.g.* as in a soln. of $FeSO_4.NO$. The reduction is increased by diluting the soln. ; it is feeble with 35 per cent. H_2SO_4, and takes place readily with 25 per cent. H_2SO_4. Only traces of nitrogen are produced. J. Priestley observed that **alkali sulphites** at ordinary temp. form nitrous oxide and ammonia ; and J. Pelouze found that **ammonium sulphite** acts similarly above 0°, but below that temp., it forms a complex salt, **ammonium nitrosylsulphite,** $NO(NH_4SO_3)$. E. Divers and T. Haga also produced **sodium dinitrosylsulphite,** $Na_2SO_3.2NO$, by the action of nitric oxide on an alkaline soln. of **sodium sulphite ;** similarly, with potassium sulphite, they obtained **potassium dinitrosylsulphite,** $K_2SO_3.2NO$. W. Manchot found that at 60° **sulphur trioxide** reacts with nitric oxide forming **nitrosylsulphur trioxide,** $2SO_3.NO$; the same product is produced by the action of sulphur dioxide on nitrogen peroxide (*q.v.*). The product melts at 215°–220° ; it softens at 180°, and boils at 275° and 715 mm. When heated it decomposes into sulphur dioxide and nitrogen peroxide. It is readily decomposed by water into sulphuric acid and nitric oxide ; but it does not react with a soln. of ferrous or cupric sulphate in conc. sulphuric acid. A. Graire observed that **sulphuric acid** is reduced by nitric oxide —*vide supra* for the solubility of the gas in the acid.

J. L. Gay Lussac [9] observed that a mixture of nitric oxide and **ammonia** decomposes slowly at ordinary temp., forming nitrogen and nitrous oxide ; and the mixture explodes when sparked. G. P. Baxter and C. H. Hickey said that the reaction : $6NO+4NH_3=5N_2+6H_2O$, is completed only at an elevated temp.—say by passing the mixture over copper turnings heated in a hard glass tube. W. Ramsay and J. T. Cundall were not able to demonstrate that nitric oxide and **nitrogen peroxide** unite at ordinary temp. ; but H. B. Dixon and J. D. Peterkin inferred that on mixing these two gases there is a limited combination. G. Lunge and G. I. Porschneff observed no change in vol. and no combination on mixing these gases above 28° ; at −21° and below, nitric oxide is freely absorbed by liquid nitrogen peroxide, forming blue liquid nitrogen trioxide (*q.v.*). A similar result is obtained by cooling a mixture of the two gases. These results contradict the conclusions drawn by W. Ramsay, and C. W. Hasenbach. H. le Blanc and W. Nuranen said that there is a state of equilibrium between the two gases $NO+NO_2\rightleftharpoons N_2O_3$ which, at ordinary temp., is almost wholly in favour of the mixture indicated on the left side of the equation—*vide infra,* nitrogen trioxide. According to V. H. Veley, nitrous acid is formed when nitric oxide is passed into conc. **nitric acid,** for, as dry nitric oxide is passed into monohydrated nitric acid, the liquid becomes yellow, then orange-red, and soon a red oil separates out; later, the liquid becomes blue, forming nitrogen peroxide, and finally nitrous acid. L. Marchlewsky said that with an acid of sp. gr. 1·510, the colour is brown; sp. gr. 1·410, yellow; 1·320, greenish-blue; and acids with a smaller sp. gr. are not coloured by nitric oxide. P. T. Austen also discussed this reaction—*vide infra,* nitrous acid. A. V. Schaposchnikoff's observations on the equilibrium conditions in the reaction $2NO+HNO_3+H_2O \rightleftharpoons 3HNO_2$ are indicated below in connection with nitrous acid. A. Sanfourche said that nitric oxide reduces nitric acid, producing, with acid of 10 per cent. or lower concentration, nitrous acid only ($2NO+HNO_3+H_2O \rightarrow 3HNO_2$); when the concentration of the nitric acid is in the neighbourhood of 20 per cent. a second reaction ($NO+2HNO_3 \rightarrow H_2O+3NO_2$) also occurs. The latter predominates with increasing concentration of the acid; with 70 per cent. acid, the former ceases.

According to H. Davy,[10] and J. L. Gay Lussac, feebly burning **phosphorus** is extinguished by nitric oxide, but if vigorously burning, the combustion continues as brilliantly as in oxygen, forming nitrogen, and phosphorus pentoxide. According to J. Dalton, nitric oxide is reduced in a few hours by spontaneously inflammable **phosphine,** forming nitrogen and nitrous oxide. The mixture is ignited by electric sparks, or by the addition of a little oxygen, forming water, nitrogen, and phosphoric acid. H. Reinsch reported a compound of nitric oxide and **phosphoric acid**—namely, *nitrosyl phosphoric acid;* H. Davy, and J. L. Gay Lussac found that red-hot **arsenic** absorbs oxygen and leaves half a vol. of nitrogen. H. Reinsch reported a compound of nitric oxide and **arsenic acid**—namely, *nitrosylarsenic acid.* A. Gutmann found that nitric oxide reacts with **sodium arsenite:** $2NO+Na_3AsO_3=N_2O+Na_3AsO_4$; and the same change occurs when sodium arsenite is added to a soln. of nitric oxide in freshly prepared, strongly alkaline soln. of potassium sulphite. The reaction was also studied by A. Klemenc.

H. St. C. Deville and F. Wöhler showed that when heated with amorphous **boron,** nitric oxide forms nitrogen, boron oxide, and nitride. F. Kuhlmann reported compounds of nitric oxide with **boron fluoride**—namely, *boron nitrosylfluoride;* and **silicon fluoride**—namely, *silicon nitrosylfluoride.* The combustion of **charcoal** in nitric oxide is more brilliant than in air, and J. Dalton found that the reaction is that symbolized by $2NO+C=CO_2+N_2$. H. Moissan said that **calcium carbide** at a dull red-heat readily oxidizes in an atm. of nitric oxide, and the reaction is vigorous at a higher temp., forming fused lime, and nitrogen. F. Kuhlmann observed that some cyanide is formed when the vapour of ethyl nitrate is passed over platinum sponge at 400°; but C. Weltzien observed no trace of hydrogen cyanide after the passage of a mixture of nitrogen trioxide and ethane over red-hot chromic oxide. L. I. de Nagy Ilosva found some hydrogen cyanide is formed when nitric oxide mixed with air is burnt in an atmosphere of **coal-gas;** and A. K. Huntington, that hydrogen cyanide is found amongst the products of the explosion of a compressed mixture of nitric oxide and **acetylene.** E. Elöd and H. Nedelmann studied the synthesis of hydrogen cyanide in the reaction between nitric oxide and hydrocarbons—**methane,** acetylene, and **ethylene**—in the presence of a mixture of quartz and alumina as catalyst. W. Henry referred to the vivid combustion which occurs when an electric discharge from a Leyden jar is passed through a mixture of ethylene and nitric oxide (nitrous gas), but with a small spark without a condenser in circuit the mixture is not inflamed; he also said that a mixture of **carbon monoxide** and nitric oxide cannot be inflamed by electric sparks, although, as S. Cooke showed, there is a gradual reduction of the nitric oxide: $2NO+2CO=2CO_2+N_2$. E. Briner and A. Wroczynsky observed no reaction between nitric oxide and carbon monoxide at 50 atm. press., but at 500 atm. press., there is evidence of chemical change; likewise also with mixtures of nitric oxide and **methyl chloride.** G. Baume and A. F. O. Germann obtained evidence of the formation of **methyl ether** and nitric oxide, **methyl dinitrosyl oxide,** $(CH_3)_2{=}O{=}(NO)_2$, of m.p. −166·3°, on the fusion curve. J. J. Berzelius said that a mixture of nitric oxide with the vapour of **carbon disulphide,** gives *ein grosse, schön leuchtende grünliche Flamme,* which in brilliancy resembles that of burning zinc. The flame is very rich in actinic rays, and special arrangements have been made for burning the mixture. The subject has been studied by E. Sell and R. Bidermann, C. Zenghelis, A. B. Delachanal and A. E. Mermet, and M. Tiffereau. For the solubility of nitric oxide in carbon disulphide, *vide supra.* H. Delbrück found that **potassium carbonyl** reacts with nitric oxide at a red-heat, forming potassium cyanide. According to M. Berthelot, nitric oxide forms a blue compound with **nickel tetracarbonyl.** R. L. Mond and A. E. Wallis could not isolate the product in a high state of purity, but they believe it to be **nickel dinitrosyl,** $Ni(NO)_2$, which dissociates violently at 90°. The reaction with **cobalt tetracarbonyl** furnishes **cobalt nitrosyltricarbonyl,** $Co(CO)_3.NO$; there is only a very slight reaction between nitric oxide and **cobalt tricarbonyl**; and **ferric enneacarbonyl** furnishes **iron nitrosylpentadecacarbonyl,** $Fe_4(NO)(CO)_{15}$—*vide* **5.** 39, 27. O. Baudisch found that organic nitrogenous products are produced by the action of light on mixtures of **formaldehyde** and nitric oxide. A. Miolatti described a number of complex **cyanogen compounds.** Numerous compounds of nitrosyl with **organic radicles** have been reported.[11] W. Traube, G. W. MacDonald and O. Masson, and M. Stechoff investigated the action of nitric oxide on an alcoholic soln. of sodium ethoxide resulting in the formation of $CH_2\{N(NO).ONa\}_2$; W. Traube regarded the compound $CH_2(N_2O_2Na)_2$ as representative of a series of compounds which he called *isonitramines.* He added that sodium ethoxide soln. do not react with nitric oxide so long as they are undecomposed, but as soon as ketones are formed by the autodecomposition of the sodium ethoxide soln., reaction sets in. F. Garelli noted the tendency of nitric oxide to enter the solid phase when soln. in benzene, bromoform, nitrobenzene, and cyclohexane are frozen, and so lower the f.p. from 0·25° to 0·225°. R. Seeliger studied the absorption of nitric oxide by dehydrated chabazite.

According to J. L. Gay Lussac,[12] L. J. Thénard, F. Kuhlmann, J. W. Döbereiner, and R. Hare, **potassium** burns when heated in nitric oxide, forming nitrogen and potassium oxide, which later produces some nitrite. A. Joannis observed that a hyponitrite is formed by the action of nitric oxide on **sodammonium** or **potassammonium.** H. Moissan showed that calcium takes fire in nitric oxide below a red-heat, burning with *une lumière éblouissante,* and forming fused calcium oxide but no nitride. P. Sabatier and J. B. Senderens found that **copper** acquires a superficial film of oxide when exposed to the gas; and reduced copper at 200° forms red cuprous oxide. A mixture of nitric oxide and hydrogen acts on reduced copper at 180°. forming ammonia, water, and nitrogen. T. Gray, and F. Emich studied the action of nitric oxide on heated copper. E. Müller and H. Barck said that copper decomposes 99·7 per cent. of the gas at 500°, but at lower temp. the action depends on the purity of the metal. E. Schröder and G. Tammann studied the rate of oxidation of copper by nitric oxide. No effect was observed when **silver** is exposed to nitric oxide; this is also the case with other metals which are not oxidized in air—*e.g.* **platinum.** E. Müller and H. Barck observed that silver is without action up to 700°; while **calcium** and **magnesium** decompose the gas at 500°, forming the oxides and nitrides; **brass** is without action at 600°, and decomposes only 29 per cent. at 700°; **zinc** has no action below 350°; at 600°, the action is slow, but decomposition is complete. P. Sabatier and J. B. Senderens found that, in general, moist metal reducing agents change nitric into nitrous oxide. Zinc and **cadmium** become superficially coated with oxide when exposed to the gas. J. Priestley observed that zinc reduces moist nitric oxide to nitrous oxide and ammonia; N. H. Morse and J. White, and F. Emich studied the action of nitric oxide on heated zinc. The latter also examined the action with cadmium. P. Sabatier and J. B. Senderens found that **mercury** is not perceptibly oxidized by nitric oxide at 450°, and F. Emich observed no action at the b.p. P. Sabatier and J. B. Senderens found that **aluminium** filings are very little changed by nitric oxide ; F. Emich examined the action of nitric oxide on **tin** and **lead**—in the former case stannic oxide is formed, and in the latter, lead oxide. P. Sabatier and J. B. Senderens noted that lead quickly acquires a film of lead oxide. E. Müller and H. Barck said that tin has no action up to 400°, but then commences to act rapidly, forming a nitride which may be completely decomposed at 600°. They also found that **aluminium** has little action below 600° ; **chromium** has no action below 700° ; **ferrochrome**—with 60 per cent. chromium—decomposes 19 per cent. of the gas at 650° ; and **manganese** decomposes 68 per cent. of the gas at 400° and all of it at 500°, forming manganese nitride. F. Emich also observed the effect of nitric oxide on heated **titanium,** chromium, **molybdenum, tungsten, uranium,** and manganese. E. Müller and H. Barck found that **bismuth** decomposes 74 per cent. of the gas at 400°, forming bismuth trioxide. Vanadium trioxide is formed when **vanadium** is heated in an atm. of nitric oxide. P. Sabatier and J. B. Senderens observed that at ordinary temp., **iron** acquires a superficial film of oxide. I. Milner found that moist iron filings and nitric oxide form ammonia ; J. Priestley noted that nitrous oxide as well as ammonia is formed ; and P. Sabatier and J. B. Senderens obtained nitrogen, nitrous oxide, and a little hydrogen and ammonia. With moist iron filings and sulphur, C. L. Berthollet obtained 44 vols. of nitrogen from 100 vols. of nitric oxide. H. Buff and A. W. Hofmann found an electrically heated iron spiral burns in nitric oxide. According to P. Sabatier and J. B. Senderens, reduced iron at 200° glows and forms black ferrous oxide. E. Müller and H. Barck said that iron reduced in hydrogen decomposes nitric oxide better than copper. E. Schröder and G. Tammann studied the rate of oxidation of iron and **nickel** by nitric oxide. The action of nitric oxide on heated iron, **cobalt,** and nickel was studied by F. Emich, Reduced cobalt at 150° forms brown cobalt oxide ; and reduced nickel at 200° forms brown nickel oxide ; and reduced nickel at 200° forms yellowish-green nickel oxide. A mixture of nitric oxide and hydrogen in the presence of warm reduced nickel furnishes ammonia. From his observations on the action of nitric oxide on the metals, F. Emich concluded that the action closely resembles, but is much slower than, that of oxygen provided the temp. of the former gas is kept below the point at which dissociation occurs. Of the metals examined, only copper, lead, and vanadium give products different from those obtained with oxygen ; and mercury is not attacked by nitric oxide below its b.p. E. Schröder and G. Tammann compared the rates of oxidation of metals—copper, iron, and nickel—in oxygen, nitric oxide, and nitrous oxide. In general, C. B. Bazzoni and A. T. Waldie said that hot metals—*e.g.* nickel—decompose nitric oxide, forming the metal oxide and nitrogen.

B. C. Dutt and S. N. Sen found that when nitric oxide is passed into a suspension of **barium dioxide** in water, barium nitrite, not nitrate, is formed. P. Sabatier and J. B. Senderens observed no change when nitric oxide is passed over **cuprous oxide** at 500°. H. A. Auden and G. J. Fowler observed that dry nitric oxide and **silver oxide,** at ordinary temp., form silver and silver nitrate ; P. Sabatier and J. B. Senderens also obtained silver and silver nitrite by passing nitric oxide into water with silver oxide in suspension. C. F. Schönbein found **gold oxide** is reduced by moist nitric oxide, forming nitrous acid. P. Sabatier and J. B. Senderens found that **titanium sesquioxide** forms white titanic oxide when heated in an atm. of nitric oxide ; and that **stannous oxide** below 500° burns in an atm. of nitric oxide, forming stannic oxide. If nitric oxide be passed into water with **lead dioxide** in suspension, the water is coloured, and in about 3 hrs., lead nitrite and nitrate are formed, and later, rhombic crystals of a basic nitrite. B. C. Dutt and S. N. Sen said that the nitrate is formed by the action of the dioxide on the nitrite. Lead dioxide is reduced to lead oxide by nitric oxide at 315°, and H. A. Auden and G. J. Fowler found that the reaction begins at 15°, when a basic lead nitrite is formed ; the maximum speed of the reaction occurs at 130°. E. Müller and H. Barck observed that at room temp. lead dioxide absorbs nitric oxide, forming the nitrite ; on heating, the gas is liberated, but at 200°, oxygen is liberated as well, and nitrogen peroxide is formed ; **red-lead** has no action on the gas at room temp., but complete absorption occurs at 200° ; while **lead monoxide** is practically without action on nitric oxide even at 650°. P. Sabatier and J. B. Senderens observed that in an atm. of nitric oxide at a bright red-heat, **molybdenum sesquioxide** forms the dioxide ; **tungsten dioxide,** at about 500°, forms the blue higher oxide ; and **uranium dioxide** forms the pentoxide ; while **vanadium trioxide** is not attacked below 500°, but E. Müller and H. Barck observed that the gas at 500° is completely decomposed and vanadium tetroxide is formed. Manganous oxide, at a red-heat, forms brown Mn_3O_4 ; so also does **manganese dioxide** at 400°—H. A. Auden and G. J. Fowler said that the reaction is very slow at ordinary temp., and fast at 216°. C. F. Schönbein observed that manganese dioxide suspended in water slowly forms nitrite when in the presence of nitric oxide. I. M. Kolthoff observed that permanganates in acid soln. completely oxidize nitrous acid in 15 minutes. J. Gay observed that freshly precipitated ferrous oxide reduces nitric oxide to nitrogen.

The absorption of nitric oxide by soln. of **copper salts** has been previously discussed. E. Drechsel found that Fehling's solution is reduced to cuprous oxide by nitric oxide. A. Besson obtained **aluminium nitrosylhexachloride,** $2AlCl_3.NO$, by the action of nitric oxide on dry **aluminium chloride.** E. Ludwig and T. Heim found that nitric oxide is reduced by a hot, conc., acidified soln. of **stannous chloride,** forming hydroxylamine, but the metal and cold dil. acid give a better yield. E. J. Maumené also obtained hydroxylamine by the reducing action of stannous chloride. E. Divers and T. Haga said that part of the nitric oxide is reduced to nitrogen, and added :

> There is a remarkable fact about the reaction between nitric oxide and stannous chloride. At a temp. of fully 100°, there is no action between nitric oxide and acid stannous chloride soln. The stannous chloride remains unchanged for hours together, and neither nitrogen nor hydroxylamine is formed. The only thing we have noticed is always a trace of ammonia in experiments at 100°, and this, we are inclined to believe, is due to some other cause than this reaction alone. At 90°, the action is still exceedingly small, but as the temp. descends from about 80°, it becomes rapidly greater with the descent.

O. von Dumreicher did not agree with this ; he found that at 100°, both nitric oxide, and hydroxylamine are reduced to ammonia by an acidified soln. of stannous chloride. At room temp., the yield is poor with acidified stannous chloride although it is quantitative with tin and hydrochloric acid. F. Kuhlmann prepared a complex salt with **stannic chloride**—namely, *stannic nitrosylchloride,* $SnCl_4(NO)$—which is thought by R. Weber, and W. Hampe to be $SnCl_4.2NOCl$ —*vide infra.* O. von Dumreicher reduced nitric oxide by **stannous chloride,** forming hydroxylamine (*q.v.*), and ammonia (*q.v.*) ; and E. Divers and T. Haga obtained only hydroxylamine and nitrogen, no nitrous oxide or ammonia. With **potassium stannite** in alkaline soln., nitric oxide forms the hyponitrite (*q.v.*). H. Reihlen and A. Hake prepared a number of complex salts of **titanium tetrachloride** with organic nitro- and nitroso-compounds. Titanium tetranitrate, $Ti(NO_2)_4$, or chlorotrinitrate forms **titanium dinitrosylhexachloride,** $TiCl_6(N_2O_2)$, as a yellow, fuming salt. V. Thomas observed that if dry **bismuth chloride** be in contact with nitric oxide for a day, **bismuth nitrosyltrichloride,** $BiCl_3(NO)$, is formed. A. Besson obtained this product and also yellow crystals of **antimony nitrosyldecachloride,** $2SbCl_5.NO$, by the action of nitric oxide on anhydrous **antimony pentachlorde.** For the action of nitric oxide on **chromous chlcride,** *vide supra.* G. Chesneau observed that a blue soln. of chromous chloride reduces nitric oxide to hydroxylamine when the gas is run in rapidly, and to ammonia when run in slowly. V. Kohlschütter found that the nitric oxide is reduced to hydroxylamine in acidic soln., and to ammonia in neutral soln. This is in agreement with the general observations by M. L. Nichols and I. A. Derbigny that increased acidity lowers the reduction potential of most reducing agents faster than it increases the oxidizing power of nitrogenous gases. P. Sabatier and J. B. Senderens, and C. Böhmer found that chromic acid reacts with nitric oxide at ordinary temp. H. A. Auden and G. J. Fowler found dry **lead chromate** remains unchanged at 400°; and **silver chromate** at 300° forms silver, silver nitrate, and chromic oxide. A. Werner and G. Richter obtained **chromic nitrosyl tetrathiocyanatodiammine,** $[Cr(NH_3)_2(SCy)_4]NO$, by the action of 10 per cent. nitric acid on potassium or ammonium tetrathiocyanatodiammine. The dark brown, four-sided prisms are unstable, and they are decomposed by water, and alkali-lye. The vapour of **chromyl chloride** was found by V. Thomas to react with nitric oxide, forming a complex $Cr_5Cl_5O_7.2NO$, *chromium nitrosyloxychloride.* For the action of nitric oxide on **manganous chloride,** *vide supra.* C. F. Schönbein found that **permanganic acid** oxidized nitric oxide to nitric acid; alkaline soln. of **potassium permanganate** greedily absorb nitric oxide at ordinary temp., and manganese dioxide separates out. This reaction was studied by C. Böhmer, B. C. Dutt and co-workers, and A. Cavazzi. G. Lunge determined nitric oxide volumetrically by titration with permanganate: $10NO+6KMnO_4+9H_2SO_4=10HNO_3+6MnSO_4+3K_2SO_4+4H_2O$. Dry potassium permanganate was found by H. A. Auden and G. J. Fowler to react with nitric oxide at 190°, forming manganese dioxide and potassium nitrate; while **silver permanganate** at 80° forms silver, silver oxide and nitrate, and manganese dioxide.

The action of nitric oxide on **iron, cobalt, and nickel salts** has been previously discussed. Complexes with iron salts and nitrosyl have been discussed by W. Manchot[13] and co-workers, A. Werner, K. A. Hofmann and O. F. Wrede, C. Marie and R. Marquis, and I. Bellucci and D. Venditori. W. Manchot and A. Waldmüller obtained with **palladium salts** the complexes **palladous dinitrosylchloride,** $PdCl_2.2NO$, and **palladous dinitrosylsulphate,** $PdSO_4.2NO$. They are unstable salts giving off nitric oxide in the presence of water. Nitric oxide with palladous nitrate yields $Pd(NO_2)_2$. Hence, nitric oxide is known to form complexes with the salts of Cu, Mn, Fe, Co, Ni, and Pd.

In 1858, Z. Roussin[14] discovered that a definite compound, which he called *binitrosulfure de fer*, can be formed by the simultaneous action of an alkali nitrite and sulphide on an iron salt, just as a nitroferricyanide is formed by the joint action of an alkali nitrite and cyanide on an iron salt. Z. Roussin made this compound by adding a soln. of ferrous or ferric chloride slowly to a mixed soln. of potassium nitrite and ammonium sulphide, and then boiling the mixture for a few minutes. If ferric chloride is used some sulphur is formed. The filtered liquid furnishes black, rhombic needles of the so-called *Roussin's black salt.* This compound was also obtained by A. Porzczinsky by warming ammonium sulphide with a soln. of ferrous salt sat. with nitric oxide—*vide infra.* The black crystals were said by A. Porzczinsky to be monoclinic; and by J. O. Rosenberg, triclinic. The crystals were found by Z. Roussin to be stable in air when separated from alkaline soln., but if pure, A. Porzczinsky, and J. O. Rosenberg said that they easily give off nitric oxide when exposed to air. The crystals are stable at 100°; but at 110°, they were found by J. O. Rosenberg to begin to give off water of crystallization. Z. Roussin found that the salt begins to decompose when heated above 115° giving off red fumes, and forming sulphur, and ammonium sulphite and nitrite. At ordinary temp., 100 parts of water dissolve 0·893 part of salt, and at 100°, 50 parts of salt. The soln. is dark brown, one part of salt in 20,000 parts of water is distinctly coloured; the soln. has a styptic and bitter taste. The salt is precipitated from its aq. soln. by the addition of a soln. of potassium hydroxide, ammonia, or ammonium sulphide. At ordinary temp., chlorine, and iodine, as well as the mineral acids, decompose the salt, and this more quickly at a higher temp. The salt is not affected by organic acids; it is freely soluble in alcohol, and in ether; it is insoluble in chloroform, and in carbon disulphide. Many metallic salts decompose a soln. of the salt liberating nitric oxide; while potassium cyanide forms the nitroferricyanide. Z. Roussin's analysis of his *binitrosulfure de fer* corresponded with $Fe_3S_5H_2N_4O_4$; A. Porzczinsky's, with $Fe_3S_3N_4O_4.2H_2O$; and J. O. Rosenberg's, with $Fe_6S_5N_{10}O_{10}.4H_2O$. The products here analyzed were probably impure, because I. Bellucci and P. de Cesaris's, O. Pavel's, L. Marchlewsky and J. Sach's, and W. Manchot and E. Linckh's analyses correspond with $KFe_4(NO)_7S_3$. I. Bellucci and F. Carnevali found that the effect of the black sodium and potassium salts on the f.p. of water, and acetone, and of the potassium salt on the f.p. of nitrobenzene corresponds with a mol. wt. one-half the formula of **potassium ferroheptanitrosylsulphide,** $K[Fe_4(NO)_7S_3]H_2O$. This indicates that in dil. soln., the salt is completely ionized. The mol. conductivity of the black sodium salt also agrees with the assumption that the sodium salt is the salt of a monobasic acid. According to O. Pavel, and I. Bellucci and co-workers, when the sodium or potassium salt is treated with dil. sulphuric acid, it furnishes a brown, amorphous mass supposed to be **hydrogen ferroheptanitrosylsulphide,** $H[Fe_4(NO)_7S_3]$. O. Pavel showed that this compound is unstable; it is insoluble in water, alcohol, and ether; but soluble in chloroform, and in carbon disulphide.

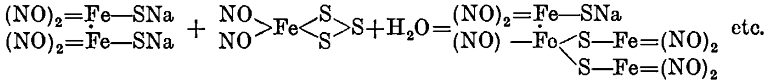
Z. Roussin found that if the black sodium salt be treated in the cold with a little acid, a yellowish-red flocculent precipitate of what he called *nitrosulfure sulfuré de fer*, $Fe_2S_3N_2O_2.4H_2S$, is formed; but if the soln. be boiling, when treated with an excess of acid, what he called *nitrosulfure de fer*, $Fe_2S_3N_2O_2$, is formed as an unstable, black precipitate. According to I. Bellucci and co-workers, when a $0{\cdot}1N$-soln. of sodium trisulphide is mixed with a soln. of ferrous chloride sat. with nitric oxide at about —2°, dark brown **ferrous dinitrosyltrisulphide,** $Fe(ON)_2S_3$, is formed:

$$\begin{matrix}\mathrm{NO}\\\mathrm{NO}\end{matrix}\!>\!\mathrm{Fe}\!<\!\begin{matrix}\mathrm{Cl}\\\mathrm{Cl}\end{matrix}+\begin{matrix}\mathrm{Na-S}\\\mathrm{Na-S}\end{matrix}\!>\!\mathrm{S}=2\mathrm{NaCl}+\begin{matrix}\mathrm{NO}\\\mathrm{NO}\end{matrix}\!>\!\mathrm{Fe}\!<\!\begin{matrix}\mathrm{S}\\\mathrm{S}\end{matrix}\!>\!\mathrm{S}$$

Sodium trisulphide gives a better yield than the mono- or the di-sulphide. Ferrous dinitrosyltrisulphide can be preserved under water. Z. Roussin observed that the evaporation of a soln. of *nitrosulfure de fer* in sodium sulphide furnishes red, prismatic crystals of *nitrosulfure de fer et de sodium*, $Fe_2S_4N_2O_2Na_2.H_2O$, a salt sometimes called *Roussin's red salt.* I. Bellucci and P. de Cesaris showed that the composition is $Fe_2S_4(ON)_4Na_2.4H_2O$, or $K[Fe(NO)_2S].2H_2O$—**potassium dinitrosylsulphide**—and they obtained it by treating ferrous dinitrosyltrisulphide with $0{\cdot}04N$-sodium sulphide. The first product of the reaction:

$$2\begin{matrix}\mathrm{NO}\\\mathrm{NO}\end{matrix}\!>\!\mathrm{Fe}\!<\!\begin{matrix}\mathrm{S}\\\mathrm{S}\end{matrix}\!>\!\mathrm{S}+\mathrm{S}\!<\!\begin{matrix}\mathrm{Na}\\\mathrm{Na}\end{matrix}=5\mathrm{S}+\begin{matrix}(\mathrm{NO})_2{=}\dot{\mathrm{F}}\mathrm{e}{-}\mathrm{SNa}\\(\mathrm{NO})_2{=}\dot{\mathrm{F}}\mathrm{e}{-}\mathrm{SNa}\end{matrix}$$

is Roussin's red salt, which immediately changes into Roussin's black salt:



$$\begin{matrix}(\mathrm{NO})_2{=}\dot{\mathrm{F}}\mathrm{e}{-}\mathrm{SNa}\\(\mathrm{NO})_2{=}\dot{\mathrm{F}}\mathrm{e}{-}\mathrm{SNa}\end{matrix}+\begin{matrix}\mathrm{NO}\\\mathrm{NO}\end{matrix}\!>\!\mathrm{Fe}\!<\!\begin{matrix}\mathrm{S}\\\mathrm{S}\end{matrix}\!>\!\mathrm{S}+\mathrm{H_2O}=\begin{matrix}(\mathrm{NO})_2{=}\dot{\mathrm{F}}\mathrm{e}{-}\mathrm{SNa}\\(\mathrm{NO})\,{-}\dot{\mathrm{F}}\mathrm{e}\!<\!\begin{matrix}\mathrm{S}{-}\mathrm{Fe}{=}(\mathrm{NO})_2\\\mathrm{S}{-}\mathrm{Fe}{=}(\mathrm{NO})_2\end{matrix}\end{matrix}\quad\text{etc.}$$

Roussin's red salt. **Ferrous dinitrosyltrisulphide.** **Roussin's black salt.**

There are thus two series of nitrosylsulphides: (i) Ferrous dinitrosyl-derivatives (Roussin's red salts); and (ii) Ferrous heptanitrosyl-derivatives (Roussin's black salts). If sufficiently conc. soln. of ferrous dinitrosyltrisulphide in alkali sulphide be used, the red salt crystallizes out before the black salt begins to form. This occurs, for instance, if N-Na_2S be used in place of the $0{\cdot}04N$-soln. The red salt is also produced by decomposing ferrous dinitrosyltrisulphide with a hot soln. of potassium hydroxide. The red salt is converted into the black salt under the influence of carbon dioxide, dil. acids, or ferrous chloride: $4K_2Fe_2(NO)_4S_2+2CO_2+2H_2O=2KFe_4(NO)_7S_3+2H_2S+K_2N_2O_2+2K_2CO_3$; and the black salt is converted into the red salt by treatment with alkali hydroxide: $2KFe_4(NO)_7S_3+4KOH=3K_2Fe_2S_3(NO)_4+Fe_2O_3+N_2O+2H_2O$, or else $2KFe_4(NO)_7S_6+6KOH=3K_2S_2(NO$

$+4Fe_2O_3+3H_2O+K_2N_2O_2$. If cadmium oxide be present, both the red and the black salts give off all their nitrogen as nitrous oxide which is formed by the oxidation of ferrous iron $2FeO+2NO=Fe_2O_3+N_2O$. When Roussin's black salt is heated with dil. sulphuric acid and silver sulphate, it gives off nitric oxide eq. to 4 gram-atoms of nitrogen per mol, and nitrous oxide eq. to 3 gram-atoms of nitrogen per mol. Under similar circumstances, Roussin's red salt yields the mixture $2NO+2N_2O$. The formation of nitrous oxide is due to the oxidation of ferrous iron as just indicated. If a mol. of potassium ferroheptanitrosylsulphide be treated with copper sulphate, seven mols. of nitric oxide are given off, and the cupric salt is reduced to the cuprous state. According to L. Cambi, if the ferroheptanitrosylsulphide be treated with silver nitrate, silver hyponitrite is formed: $2KFe_4(NO)_7S_3+26AgNO_3=2KNO_3+8Fe(NO_3)_3+6Ag_2S+7Ag_2N_2O_2$. I. Bellucci and P. de Cesaris found that when the compound is treated with potassium permanganate, the equivalent of 26 gram-atoms of oxygen are required to oxidize all the elements in a mol. of the ferroheptanitrosyltrisulphide. This is in agreement with the assumption that all the iron in the mol. is present in the ferrous condition. L. Cambi suggested that the ferroheptonitrosyltrisulphides are complexes of sulphides and hyponitrites, possibly of the form $K_2N_2O_2.2FeS_3.2Fe_2(N_2O_2)_3$; but a comparison of the behaviour of this salt with that of the complex sulphides $Fe_2S_3.K_2S$, and $2FeS.K_2S$, towards hydrochloric acid, was found by I. Bellucci and P. de Cesaris to be in agreement with the assumption that the three atoms of sulphur in the mol. are probably sulphidic, and combined directly with the iron atoms.

The ferroheptanitrosyl-derivatives or Roussin's black salts of the type: $R'[Fe_4(NO)_7S_3]$, are represented by the potassium salt indicated above. O. Pavel obtained the potassium salt by adding 400 c.c. of potassium sulphide—prepared from 44 grms. potassium hydroxide—to a boiling soln. of 35 grms. of sodium nitrite in 400 c.c. of water. After the addition of a few drops of dil. sulphuric acid, 159 grms. of ferrous sulphate dissolved in 1200 c.c. of water are slowly poured into the hot mixture. The liquid is heated in a water-bath for about half an hour, until a deposit begins to settle on the sides of the flask. It is then quickly filtered, and dil. potassium sulphide is added to the filtrate. After 48 hrs., the potassium salt crystallizes out. It is purified by recrystallization at 70° from water, containing a small quantity of potassium hydroxide. O. Pavel prepared **lithium ferroheptanitrosyltrisulphide** by the method emphasized for the potassium salt. O. Pavel, and I. Bellucci and co-workers prepared **sodium ferroheptanitrosyltrisulphide,** $Na[Fe_4(NO)_7S_3].2H_2O$, in an analogous manner. O. Pavel found that the sodium salt is completely decomposed by hot, conc. sulphuric acid, by silver oxide or sulphate, by hydrochloric acid, and by iodine. W. Manchot and E. Linckh studied the absorption spectra of soln. of the ferroheptanitrosyltrisulphides. They found that the absorption spectra bear no relation to that of the $FeSO_4.NO$-salts, and they assumed that the iron is univalent. On the other hand, L. Cambi and L. Szegö found the absorption spectra of dil. soln. indicate the presence of bivalent iron as in the case of $FeSO_4.NO$. O. Loew reported *sodium ferrohexanitrosylthiocarbonate*, $Fe_4(NO)_6CS_3$, to be formed by the action of ferrous sulphate on a mixture of sodium thiocarbonate and nitrite, but O. Pavel showed that the product is really sodium ferroheptanitrosyltrisulphide; and he prepared **ammonium ferroheptanitrosyltrisulphide,** $NH_4[Fe_4(NO)_7S_3].H_2O$, by the method employed for the potassium salt; it is less soluble than the potassium salt. Similarly with **rubidium ferroheptanitrosyltrisulphide**, which is less soluble than the ammonium salt; while **cæsium ferroheptanitrosyltrisulphide** is insoluble in cold water, and sparingly soluble in alcohol and ether. According to I. Bellucci and C. Cecchetti, a number of other salts can be prepared in stable, shining, black crystals, which can be crystallized from water, and remain unchanged for a long time if preserved in the absence of light. Thus, if the sodium salt be treated with hydrazine in acidic or alkaline soln., **hydrazine ferroheptanitrosyltrisulphide,**

$N_2H_4.H[Fe_4(NO)_7S_3]$, is formed; it is slightly soluble in water, and freely soluble in alcohol or ether. If hydroxylamine in acidic or alkaline soln. be employed in place of hydrazine, **hydroxylamine ferroheptanitrosyltrisulphide**, $NH_2OH.H[Fe_4(NO)_7S_3]$, is formed; it is readily soluble in water, alcohol, and ether.

I. Bellucci and F. Carnevali observed that if the sodium salt be treated with phenylhydrazine hydrochloride, **phenylhydrazine ferroheptanitrosyltrisulphide**, $C_6H_5.N_2H_3.H[Fe_4(NO)_7S_3]$, is obtained; it melts under hot water in which it is sparingly soluble; it is freely soluble in alcohol and ether, but sparingly soluble in benzene. Similarly, **carbazide ferroheptanitrosyltrisulphide**, $N_2H_3.CO.NH_2.H[Fe_4(NO)_7S_3]$, has been prepared; it is soluble in water, alcohol, and ether. They also prepared **tetramethylammonium ferroheptanitrosyltrisulphide**, $N(CH_3)_4[Fe_4(NO)_7S_3]$, which, in acetone soln., yields black, triclinic crystals with the axial ratios $a:b:c=0{\cdot}8648:1:1{\cdot}3125$, and $\alpha=87°\ 29'\ 34''$, $\beta=106°\ 7'\ 10''$, and $\gamma=93°\ 44'\ 10''$, and the sp. gr. 2·056 at 19°. It is sparingly soluble in water, and soluble in alcohol. Similarly, **tetraethylammonium ferroheptanitrosyltrisulphide**, $N(C_2H_5)_4[Fe_4(NO)_7S_3]$, furnishes black, triclinic crystals with the axial ratios $a:b:c=1{\cdot}0221:1:1{\cdot}0247$, and $\alpha=85°\ 8'\ 19''$, $\beta=97°\ 8'\ 2''$, and $\gamma=99°\ 17'\ 41''$, and sp. gr. 1·883 at 18°; it is sparingly soluble in water, alcohol, and benzene. These two salts are insoluble in ether, and are very stable, for they are not decomposed by boiling with a 50 per cent. soln. of potassium hydroxide. I. Bellucci and F. Carnevali also prepared **aniline ferroheptanitrosyltrisulphide**, $C_6H_5NH_2.H[Fe_4(NO)_7S_3]$, soluble in nitrobenzene, and aniline; moderately soluble in water, alcohol, ether, and benzene; and sparingly soluble in chloroform, and in benzene; **pyridine ferroheptanitrosyltrisulphide**, $C_5H_5N.H[Fe_4(NO)_7S_3]$, soluble in alcohol, ether, and acetone, and sparingly soluble in water; and *o*-**phenylenediamine ferroheptanitrosyltrisulphide**, $C_6H_4(NH_2)_2.H_2[Fe_4(NO)_7S_3]_2$, soluble in water, alcohol, acetone, and ether.

O. Pavel prepared **calcium ferroheptanitrosyltrisulphide** by the method employed for the potassium salt. It is freely soluble in water; similarly also with **barium ferroheptanitrosyltrisulphide**, and with **magnesium ferroheptanitrosyltrisulphide.** These salts are decomposed by heat in the presence of air, forming ammonium sulphate, ferrous sulphide, etc.; and if air be excluded, no ammonium sulphate is produced. O. Pavel, and L. Marchlewsky and J. Sachs prepared **thallium ferroheptanitrosyltrisulphide**, $Tl[Fe_4(NO)_7S_3].H_2O$, by the action of thallium sulphate on an aq. soln. of the alkali salt, and crystallized the product as rapidly as possible from alcohol in vacuo. It is sparingly soluble in water, and is decomposed by a protracted heating with water. I. Bellucci and F. Carnevali prepared **cobalt hexamminoferroheptanitrosyltrisulphide**, $Co(NH_3)_6[Fe_4(NO)_7S_3]_3$, soluble in water, alcohol, ether, and acetone.

The ferrodinitrosyl-derivatives or Roussin's red salts of the type $R'[Fe(NO)_2S]$ are represented by **potassium ferrodinitrosylsulphide**, $K[Fe(NO)_2S].2H_2O$, prepared, as indicated above, by the action of hot, dil. soln. of potassium hydroxide on the ferroheptanitrosyltrisulphides. O. Pavel prepared **sodium ferrodinitrosylsulphide**, $Na[Fe(NO)_2S].4H_2O$, in a similar way. These dark red coloured salts are unstable; they are, with the exception of the iron compound, insoluble in ether, chloroform, and carbon disulphide. They are decomposed by potassium ferricyanide, which does not attack ferroheptanitrosyltrisulphides. These salts decompose violently when heated, giving ammonium and alkali sulphates, etc. When the potassium salt is treated with dil. sulphuric acid, hydrogen ferrodinitrosylsulphide, $H[Fe(NO)_2S]$, is formed. This soon decomposes into hydrogen sulphide, nitrous oxide, nitrogen, and hydrogen ferroheptanitrosyltrisulphide. W. Manchot and E. Linckh studied the absorption spectra of soln. of ferrodinitrosylsulphides. O. Pavel prepared monoclinic crystals of **ethyl ferrodinitrosylsulphide**, $C_2H_5[Fe(NO)_2S]$, soluble in ether, benzene, chloroform, ethyl iodide, and carbon disulphide; while K. A. Hofmann and O. F. Wiede prepared tabular crystals of **phenyl ferrodinitrosylsulphide**, $C_6H_5[Fe(NO)_2S]$, melting at 179°, and giving, by the cryoscopic method, a mol. wt. corresponding with the doubled mol. If nitric oxide is passed into a soln. of ferrous sulphate and potassium thiosulphate for about 10 hrs., reddish-brown crystals of **potassium ferrodinitrosylthiosulphate**, $K[Fe(NO)_2(S_2O_3)].H_2O$, are formed. The crystals are soluble in water. Similarly with **sodium ferrodinitro-**

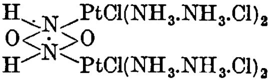
sylthiosulphate, and with **ammonium ferrodinitrosylthiosulphate**—the latter is more soluble than the former.

J. Sand and O. Genssler[15] obtained a series of complex salts by the action of nitric oxide on ammoniacal soln. of cobalt salts. They considered the products to be formed by the addition of two mols. of the cobalt pentammines. Thus, **cobalt nitrosylpentamminodichloride,** $[Co(NO)(NH_3)_5]Cl_2$, furnishes black crystals supposed to be constituted $Cl_2[(NH_3)_5Co.NO.NO.Co(NH_3)_5]Cl_2$ or $[Co_2(N_2O_2)(NH_3)_{10}]Cl_4$.

There is also a series of red salts supposed to have a different constitution. Thus, **cobalt nitrosylpentamminodinitrate,** $[Co(NO)(NH_3)_5](NO_3)_2.\frac{1}{2}H_2O$. This yields the complex salts *cobalt dinitrosyldecamminodinitratotetranitrate,* $[Co_2\{N_2O_2(NO_3)_2\}(NH_3)_{10}](NO_3)_4$; *cobalt dinitrosyldecamminosulphatotetranitrate,* $[Co_2\{N_2O(SO_4)\}(NH_3)_{10}](NO_3)_4$; *cobalt dinitrosylenneamminoiodotetraoxalate,* $[Co_2\{N_2O(C_2O_4)\}(NH_3)_9(H_2O)](H.C_2O_4)_4$; *cobalt dinitrosyldecamminodinitratotetraperchlorate,* $[Co_2\{N_2O(NO_3)_2\}(NH_3)_{10}](ClO_4)_4$; *potassium cobalt dinitrosyldecamminodiiododinitratoiodide,* $[Co_2(N_2O_2)(NH_3)_{10}](NO_3)_2I_2.KI$; *silver cobalt dinitrosyldecamminotetranitratonitrate,* $[Co_2(N_2O_2)(NH_3)_{10}](NO_3)_4.AgNO_3$; *lead cobalt dinitrosyldecamminotetranitratonitrate,* $[(Co_2(N_2O_2)(NH_3)_{10}](NO_3)_4.\frac{1}{2}Pb(NO_3)_2$.

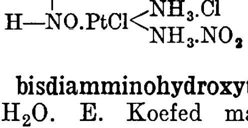
E. Koefed[16] prepared a number of complexes of nitric oxide and **platinum salts.** Thus, **platinous tetramminodichloronitrosylhydrochloride,** $Pt(NH_3)_4Cl_2.NO.HCl$, was considered by E. A. Hadow to have the formula $2Pt(NH_3)_4Cl_2.N_2O_3.2HCl$. It is obtained in green octahedral crystals by the action of nitrogen trioxide on a hydrochloric acid soln. of platinous tetramminodichloride; by the action of sodium nitrite on an ammoniacal soln. of potassium chloroplatinite; by passing nitric oxide into a hydrochloric acid soln. of potassium chloroplatinite; or by adding a soln. of ferrous sulphate sat. with nitric oxide into a hydrochloric acid soln. of platinous tetramminodichloride. The constitution is considered to be represented by one of the following schemes:

$$\begin{array}{l} H—\dot{N}O.PtCl(NH_3.NH_3.Cl)_2 \\ H—\dot{N}O.PtCl(NH_3.NH_3.Cl)_2 \end{array}$$



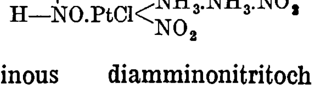
E. Koefed made **platinous tetramminodichlorodinitrosylhydrosulphate,** $[Pt(NH_3)_4Cl_2](NO)_2H_2SO_4$; **platinous tetramminodichloro-dichloronitrosylhydrochloride,** $[Pt(NH_3)_4Cl_2]Cl_2.NO.HCl$; and **platinous tetramminodinitratonitrosylhydronitrate,** $Pt(NH_3)_4(NO_3)_2.NO.HNO_3$.

S. Koefed prepared apple-green crystals of **platinous diamminonitritochloronitrosylhydrochloride,** $Pt(NH_3)_2(NO_2)Cl.NO.HCl.\frac{3}{4}H_2O$, by heating platinous tetramminodichloride with sodium nitrite and dil. hydrochloric acid on a water-bath, and drying the product at 100°. The constitution of the salt without water of hydration, is represented:



$$\begin{array}{l} H—NO.PtCl<\begin{smallmatrix}NH_3.Cl\\NH_3.NO_2\end{smallmatrix} \\ \quad\ \ | \\ H—NO.PtCl<\begin{smallmatrix}NH_3.Cl\\NH_3.NO_2\end{smallmatrix} \end{array}$$

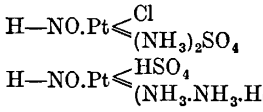
There is also a **platinous bisdiamminohydroxytriiodo-bisnitrosylhydroiodide,** $Pt_2(NH_3)_4(OH)I_3.2(NO.HI).6H_2O$. E. Koefed made bluish-green crystals of **platinous diamminodinitritonitrosylhydrochloride,** $Pt(NH_3)_2(NO_2)_2.NO.HCl$, by the action of sodium nitrite on platinous diamminodichloride. Its constitution was represented:



$$\begin{array}{l} H—NO.PtCl<\begin{smallmatrix}NH_3.NH_3.NO_2\\NO_2\end{smallmatrix} \\ \quad\ \ | \\ H—NO.PtCl<\begin{smallmatrix}NH_3.NH_3.NO_2\\NO_2\end{smallmatrix} \end{array}$$

There is also **platinous diamminonitritochloronitrosylhydronitrate,**

$Pt(NH_3)_2(NO_2)Cl.NO.HNO_3$; and **platinous hexamminosulphatodihydrosulphatodinitrosylhydrosulphatodihydrochloride**, $Pt_2(NH_3)_6(HSO_4)_2SO_4.2NO.H_2SO_4.HCl$, supposed to be constituted



$$\begin{array}{l} H—NO.Pt\leqslant^{Cl}_{(NH_3)_2SO_4} \\ H—NO.Pt\leqslant^{HSO_4}_{(NH_3.NH_3.HSO_4)_2} \end{array}$$

Complex salts of platinum ammines were also made with dimethylamine, diethylamine, pyridine, and diethylsulphine.

§ 36. Nitrogen Trioxide

E. Luck[1] found that the absorption spectrum of the so-called **nitrogen trioxide,** N_2O_3, is identical with that of nitrogen peroxide, NO_2, and he therefore inferred that nitrogen trioxide does not exist in the gaseous state. H. B. Dixon and J. D. Peterkin believed that there is a slight union when nitric oxide and nitrogen peroxide are brought into contact ; and E. Wourtzel said that with a stoichiometrical mixture of nitric oxide and nitrogen peroxide, the contraction corresponds with the formation of about 2·5 per cent. of the trioxide ; W. Ramsay and J. T. Cundall, A. Geuther, and O. N. Witt said that the yellowish-red or brown vapour produced by the evaporation of liquid nitrogen trioxide is a mixture of nitric oxide and nitrogen peroxide : $N_2O_3 \rightleftharpoons NO + NO_2$. G. Lunge, at first, maintained that the dissociation is not complete, and that nitrogen trioxide can exist as a gas even at 150° ; but later, in conjunction with G. I. Porschneff, he showed that in the gaseous state, the dissociation is virtually complete—*vide infra.* The different modes of preparation of nitrogen trioxide gas really give a mixture of nitric oxide and nitrogen peroxide which forms nitrogen trioxide only when condensed to the liquid state.

C. W. Hasenbach, and P. L. Dulong made nitrogen trioxide by passing a mixture of nitric oxide and oxygen through a heated tube. F. Birhans dried nitric oxide and oxygen by passing them separately over pumice moistened with sulphuric acid, and then over baryta and lime. The gases were then strongly cooled, and allowed to mix in a receiver cooled to —54°. One vol. of oxygen to 6–8 vols. of nitric oxide was used in order to avoid the formation of nitrogen peroxide. The trioxide thus appears as a blue liquid. L. Francesconi and N. Sciacca found that (i) liquid nitric oxide and oxygen or gaseous oxygen and liquid or solid nitric oxide, or gaseous nitric oxide and liquid oxygen, mixed in all proportions, even with the oxygen in large excess, always yield nitrogen trioxide. (ii) Gaseous nitric oxide and oxygen, the latter being in excess, also give nitrogen trioxide if they react at a temp. lower than —110°. (iii) When subjected to the action of oxygen, nitrogen trioxide is transformed into nitrogen peroxide only at temp. above —100°. (iv) The reduction of nitrogen peroxide to nitrogen trioxide by nitric oxide commences at —150°. (v) Nitrogen trioxide is stable under the ordinary pressure up to a temp. of —21°. E. Luck purified liquid nitrogen trioxide by adding ice-water until the liquid is indigo-blue ; decanting off the upper layer, and rectifying it repeatedly at 5° to 10°.

E. Péligot said that nitrogen trioxide is formed when nitric oxide is passed into liquid nitrogen peroxide. This subject has been previously discussed. N. M. Wittorff studied the fusion curves of mixtures of these two oxides, and his results are shown in Fig. 71. On saturating liquid nitrogen peroxide with nitric oxide and subsequently cooling the solution, dark blue crystals of nitrogen trioxide melting at —103° separate ; no other compound is formed. The eutectic mixture of N_2O_4 and N_2O_3 melts at —112°. It is probable

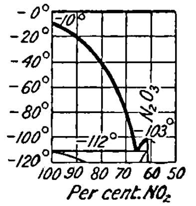

FIG. 71. — Fusion Curvo of Mixtures of Nitrogen Peroxide and Nitric Oxide.

that nitric oxide does not dissolve nitrogen trioxide. G. Baume and M. Robert found the m.p. which falls from —11·5° with 100 per cent. nitrogen peroxide to —107° with 86·3 per cent.; with 91·8 per cent. the temp. is again —107°, and with 97 per cent., —100°. According to L. S. Bagster, $5N$-HNO_3 or $6N$-HNO_3 acts on copper giving a gas with the empirical composition of nitrogen trioxide. A more conc. acid gives some nitrogen peroxide which increases proportionally with the conc. of the acid. J. Fritzsche allowed 45 parts of water to run gradually into 92 parts of nitrogen peroxide cooled to —20°; and heated the product in a retort with a receiver surrounded by a freezing mixture until the b.p. rose to 28°. C. F. Rammelsberg, and J. J. Streiff obtained a regular stream of gas by the action of water on nitroxylsulphonic acid: $HO(NO_2)SO_2+H_2O=H_2SO_4+HNO_2$; $2HNO_2=H_2O+(N_2O_3)$, which condensed to nitrogen trioxide. A similar stream of gas contaminated with other nitrogen oxides is produced by gradually dropping nitric acid on powdered glassy arsenic trioxide. G. Lunge found that with nitric acid of sp. gr. 1·20, nitric oxide is the main product; with an acid of sp. gr. 1·25, there is much nitric oxide and a little nitrogen trioxide; with an acid of sp. gr. 1·30, there is more nitrogen trioxide than nitric oxide; with an acid of sp. gr. 1·35, there is scarcely any nitric oxide mixed with the nitrogen trioxide; with an acid of sp. gr. 1·40 there is a mixture with nitrogen trioxide and peroxide in the molar proportion 100 : 126; and with an acid of sp. gr. 1·45, this proportion is 100 : 903. The reaction was also examined by A. Geuther, C. W. Hasenbach, E. Luck, C. W. G. Nylander, and O. N. Witt. A similar gas was prepared by E. Péligot, J. von Liebig, O. N. Witt, and G. Lunge by the action of nitric acid on starch. The composition of the product depends on the conc. of the acid. The last-named found that with nitric acid of sp. gr. 1·20, there is scarcely any action; with an acid of sp. gr. 1·33, the nitrogen trioxide is contaminated with a little nitric oxide; with an acid of sp. gr. 1·40, the product contains nitrogen trioxide and peroxide in the molar proportion 4 : 1; and with an acid of sp. gr. 1·50, this proportion is 5 : 3.

D. Helbig passed an electric current at 3000–4000 volts through liquid air and obtained a sky-blue powder of solid nitrogen trioxide. F. Fischer and F. Brähmer worked with an arc between platinized copper poles and obtained both nitrogen trioxide and ozone. O. Scarpa considered that in the region of the arc small amounts of oxygen and nitrogen formed by the evaporation of liquid air combine to form nitric oxide; and in the boiling air the reaction is $2NO+O=N_2O_3$. The nitrogen trioxide so produced is solid, and below its dissociation temp., so that under favourable conditions the reaction may proceed to an end. J. Fritzsche obtained a blue liquid by electrolyzing conc. nitric acid. The gas liberated by warming the blue liquid, when condensed and rectified, furnished liquid nitrogen trioxide. T. E. Thorpe and A. E. H. Tutton found that nitrogen trioxide is liberated when nitrogen peroxide is reduced by phosphorus trioxide; and D. Huizinga said that the gas is produced by the action of carbon dioxide on ammonium nitrite—though E. F. von Gorup-Besanez was unable to confirm this.

The physical properties of nitrogen trioxide.—C. W. Hasenbach said that nitrogen trioxide at —10° is an indigo-blue liquid which becomes paler as the temp. rises; and at ordinary temp., according to J. Fritzsche, the yellowish-green liquid becomes dark blue when cooled again. J. W. Mallet and R. H. Gaines found that the gas condenses to a dark green liquid when cooled to —14·4° at 755 mm. press., and if spongy platinum is present in the condensing vessel there is no perceptible difference in the temp. of liquefaction. If a very little water be present, the green liquid becomes blue; and the blue liquid does not readily mix with the green liquid. Both F. Birhans, and W. Ramsay described nitrogen trioxide at a low temp. as a blue liquid. G. Lunge and G. I. Porschneff consider the blue liquid is nitrogen trioxide, and the green one a soln. of nitric oxide in nitrogen peroxide. From observations on the thoroughly dried trioxide, B. M. Jones inferred that while liquid N_4O_6 is blue, both N_2O_3 and N_4O_6 are colourless in the gaseous state; and that ordinary liquid nitrogen trioxide is green owing to the admixture of blue N_4O_6 with a relatively large amount of moist nitrogen peroxide. The blue liquid N_2O_4 gives a brownish-red vapour, owing to the formation of NO_2 in the dissociation of the gaseous N_4O_6. At very low temp., all specimens of nitrogen trioxide, very dry or slightly wet, become quite blue. This would be due to the fact that at these temp. any "wet" NO_2 mols. would completely associate to give colourless N_2O_4 mols., which would then no longer produce a green colour with the blue N_4O_6. H. B. and M. Baker said that the liquid changes from green to indigo-blue when cooled below —2°, and that the sp. gr. of the liquid is about 1·11; but A. Geuther found the sp. gr. to be 1·4640 at —8°; 1·4555 at —4°; 1·4510 at —1°; 1·4490 at 0°; 1·4485 at 1°; and 1·4470 at 2°. E. Rabinowitsch gave 53 for the mol. vol. A. Geuther gave 3·5° for the b.p.; P. A. Guye and G. Drouginine, 2°; and C. W. Hasenbach, 2°. F. Birhans solidified the liquid at about —82°, but W. Ramsay did not freeze it at —90°. If a small quantity of nitrogen peroxide is present, the liquid freezes at —52° to —54°. D. Helbig gave —111° for the m.p.; P. A. Guye and G. Drouginine —111°; and N. M. Wittorff, —103°, see Fig. 73. D. Helbig said that when suspended in liquid air, the solid looks like green chromic hydroxide, but when the liquid air is evaporated off, the solid appears as a blue amorphous mass. N. M. Wittorff said that the solid furnishes dark blue crystals.

W. Ramsay and J. T. Cundall, and G. Lunge and G. I. Porschneff showed that the brown gas obtained by the vaporization of liquid nitrogen trioxide has a sp. gr. corresponding with that required for a mixture of nitric oxide and more or less polymerized nitrogen peroxide. The dissociation of the trioxide on vaporization is confirmed by J. Moser's observation that the spectrum of the gas is identical with that of nitrogen peroxide. L. Francesconi and N. Sciacca said that the liquid trioxide is stable at —21°; P. A. Guye and G. Drouginine found the vap. press., *p* mm., to be:

	0°	—6·2°	—10·4°	—18·1°	—20·0°	—25·2°	—80°
p . .	608	496	443	179	156	116	0

and W. Ramsay and co-workers, and G. Lunge and G. I. Porschneff found that the liquid is unstable, and can exist only in the presence of its products of dissociation. D. Gernez found that mechanical agitation favoured the decomposition of the liquid. G. Baume and M. Robert found that pure nitrogen trioxide can only exist at very low temp. in the solid state or in the liquid state under press. of nitric oxide. At temp. above —100°, it dissociates. It is not possible to distil it in a vacuum because of the immediate formation of an atmosphere of nitric oxide at temperatures at which distillation is possible. The blue liquid has no definite b.p., and by interpolation from the vap. press. curves between —80° and 35°, it is inferred that the b.p. is —27° at 760 mm. By prolonged drying over phosphorus pentoxide, H. B. and M. Baker found that the temp. could be raised to 43° before any sign of ebullition appeared. They also found that just as the dissociation of ammonium chloride does not occur if the compound be thoroughly dried, so is the dissociation of nitrogen trioxide hindered by thoroughly drying the liquid. This was shown by the vigorous absorption of the dried gas by conc. sulphuric acid, whereas an eq. mixture of nitric oxide and nitrogen peroxide is absorbed comparatively slowly. The subject was discussed by A. Smits—*vide* nitrogen peroxide.

The relative density of the gas dried for varying periods of time varied from 38·1 to 62·2. The theoretical value for undissociated nitrogen trioxide being 38, and 27·8 for dissociated nitrogen trioxide at 22°, it is therefore inferred that the dried gas contains varying amounts of polymerized nitrogen trioxide probably in the form of N_4O_6. W. Herz studied the mol. vol. Directly a minute trace of moisture is added to the nitrogen trioxide, dissociation occurs, and its density falls to about 28 at 22°. The dried liquid suffers no change of colour as it boils away, but with the moist liquid, the green colour soon changes to yellow. H. B. and M. Baker found that mol. wt. determinations of soln. nitrogen trioxide in dry benzene showed no signs of any more polymerization than is exhibited by the dried gas. The mol. wt. varied from 83 to 95—theory for N_2O_3 being 76. W. Ramsay also found the mol. wt. of ordinary nitrogen trioxide in acetic acid to be between 80·9 and 92·7. B. M. Jones found that for the dried gas, the equilibrium constant, *K*, in the reaction: $N_4O_6 \rightleftharpoons N_2O_3 + NO_2 + NO$, is:

	20°	40°	60°	80°	100°	120°	140°
K . .	513·4	144·6	46·97	15·97	5·15	2·86	0·915

M. Berthelot gave for the heat of formation: $(N_2.3O) = -22·2$ Cals. in the gaseous state, and −8·4 Cals. in soln. J. Thomsen gave −6·82 Cals in aq. soln. B. M. Jones gave for the heat of formation of N_4O_6, 12·933 Cals. The identity of the absorption spectrum of the gas with that of nitrogen peroxide has been emphasized by W. Ramsay, and J. Moser. The spectrum was also examined by D. Brewster, E. Luck, J. N. Lockyer, W. H. Bair, and J. Chappius. H. Wieland said that nitrogen trioxide between platinum electrodes 0·1 mm. apart showed no conductivity with a potential difference of 20,000 volts. T. Soné gave $-0·21 \times 10^{-6}$ for the sp. magnetic susceptibility of liquid nitrogen trioxide which is thus diamagnetic.

The chemical properties of nitrogen trioxide.—As just indicated the analyses and mol. wt. determinations agree with the formula N_2O_3, on the assumption that a small proportion is polymerized to N_4O_6. The formula usually employed to represent the constitution is O=N—O—N=O with both nitrogen atoms tervalent. R. Günsberg suggested that one nitrogen atom is quinquevalent, and wrote:

$$\begin{matrix}O\\O\end{matrix}\!\!\geqslant N-N=O$$

This view is supported by H. Wieland, who said that the formula O : N.O.N : O is not in keeping with its intense blue colour, which is characteristic of the nitroso-derivatives, O : $N.NO_2$—*vide infra*, nitrous acid. H. Reihlen and A. Hake obtained a colourless complex with stannic chloride in carbon tetrachloride at −40°, and it is supposed to be derived from a colourless tautomeric form, O : N.O.N : O. C. D. Niven discussed the electronic structure. G. le Bas said that the molecule has the structure:

$$\begin{matrix}O=N\\O=\ddot{N}\end{matrix}\!\!>O$$

L. Francesconi and N. Sciacca, and D. Helbig showed that below −110° oxygen is without action on nitrogen trioxide, which may be preserved solid in liquid air. Above −100°, oxygen attacks the trioxide, forming nitrogen peroxide. According to G. Lunge and G. I. Porschneff, with an excess of oxygen, nitrogen trioxide is oxidized wholly to the peroxide during its evaporation. The gases, however, consist of nitrogen peroxide and nitric oxide so that the observed effect is an oxidation of the latter. The reaction was also discussed by M. Berthelot, G. Lunge, and C. W. Hasenbach. According to H. B. and M. Baker, nitrogen trioxide is insoluble in water, and forms nitric oxide and nitrogen peroxide, which dissolves in the water. As usually prepared, however, nitrogen trioxide with a little water forms a bluish-green liquid, which above 0° evolves nitric oxide, and when diluted evolves nitric oxide. E. Frémy found that in the presence of oxygen and water, nitrogen trioxide forms nitric acid. With much water, nitrogen trioxide forms nitrous acid, and it is accordingly regarded as nitrous anhydride, the parent oxide of this acid—*vide infra*. A. Sanfourche observed that nitrous anhydride, or the gaseous mixture of the same composition which reacts as the anhydride, acts on water with production of nitrous acid, which decomposes, yielding two-thirds of the original nitrogen in the form of nitric oxide. Dil. nitric acid behaves towards the anhydride in a similar manner to water, but acid of 50 per cent. and greater concentration is reduced with formation of nitrogen peroxide, which dissolves in the acid. Both reactions take place simultaneously with acids of intermediate concentrations. E. K. Rideal found that the equilibrium constant in the reaction $2HNO_3+N_2O_3 \rightleftharpoons H_2O+2N_2O_4$ at ordinary temp. is $K=0{\cdot}81$. By agitation with oxygen, the trioxide is converted into nitrogen peroxide. According to C. Weltzien, no trace of hydrogen cyanide is formed when nitrogen trioxide mixed with ethane is passed over red-hot chromic oxide. Nitrogen trioxide is absorbed by soln. of the alkali hydroxides, much more rapidly than is the case with nitrogen peroxide or nitric oxide. According to G. Klinger, the absorption is quantitative. Hence, M. le Blanc suggested that the gas really contains a little nitrogen trioxide in equilibrium with the nitric oxide and nitrogen peroxide : $N_2O_3 \rightleftharpoons NO+NO_2$; and that it is the nitrogen trioxide which is absorbed when the gas is in contact with alkali-lye. This view is supported by F. Förster, and O. Schmidt and R. Böcker. H. Wieland said that F. Raschig's observation that the trioxide is almost completely absorbed as nitrite by dil. soda-lye, when, from a completely dissociated mixture of nitric oxide and nitrogen peroxide, only the latter should react to form nitrite and nitrate while the nitric oxide remains unchanged, may be explained by assuming that nitric oxide and nitrogen peroxide carry opposite charges $N_2O_3 \rightleftharpoons NO^{\cdot}+NO'_2$, so that the $Na^{\cdot}$-ion reacts with NO'_2 and the OH'-ion with $NO^{\cdot}$, consequently, with an excess of alkali-lye, only the nitrite would be formed. This view is supported by F. Förster and A. Blich's observation that nitrogen trioxide is absorbed instantaneously by a soln. of sodium hydroxide at −22°, but liquid nitrogen peroxide is absorbed quite slowly. From the contraction which occurs on mixing nitric oxide with oxygen and with nitrogen peroxide, E. Wourtzel inferred that the gaseous mixture $N_2O_3 \rightleftharpoons NO+NO_2$ contains about 2·5 per cent. of nitrogen trioxide. F. Garelli and E. Monath observed no appreciable lowering of the f.p. of stannic chloride by the dissolution of nitrogen trioxide ; and H. Reihlen and A. Hake said that the trioxide reacts with stannic chloride, not in the ordinary blue form, but in the colourless form producing an unstable $3SnCl_4.4NO_2$.

K. A. Hofmann and A. Zedtwitz found that when mixed oxides of nitrogen, prepared from sodium nitrite and 68 per cent. nitric acid, are passed into conc. perchloric acid (a mixture of dihydrate and monohydrate), colourless, doubly refracting leaflets separate ; when these are drained and dried over phosphoric oxide in an atm. of nitrogen oxides, and finally in a vacuum, a 20–30 per cent. yield of **nitrosyl perchlorate,** $NO.O.ClO_3,H_2O$, is obtained. By evaporating the mother-liquor at 140°, and again passing nitrogen oxides, a further yield is obtained. Nitrosyl perchlorate only absorbs moisture from the air very slowly. A little water decomposes it, forming a green solution. Methyl alcohol forms methyl nitrite, and ethyl alcohol, acetone, or ether ignite with explosion. Violent explosions occur with primary aromatic amines, probably owing to the formation of diazonium perchlorates. Phenols give colorations with conc. sulphuric acid ; B. Liljensztern and L. Marchlewsky also found that nitrosyl sulphuric acid is formed. The soln. of nitrogen trioxide in chloroform was found by A. Pictet and G. Karl to react with sulphur trioxide, forming mixed anhydrides—*vide infra*. According to W. Ramsay, if nitrogen pentoxide be added to liquid nitrogen trioxide, the blue colour disappears, and liquid nitrogen peroxide is formed. A. Geuther and A. Michaelis observed that nitrogen trioxide reacts with well-cooled phosphorus trichloride, forming pyrophosphoric chloride, $P_2O_3Cl_4$, phosphorus pentoxide, phosphoryl and nitrosyl chlorides, nitrogen, and a little nitric oxide ; and with phosphorus tribromide, phosphorus pentoxide and oxychloride are formed. H. B. and M. Baker found that dry nitrogen trioxide does not react with dry benzene. Many reactions of nitrogen trioxide are discussed in connection with nitrous acid. F. Kuhlmann reported the formation of *stannic nitrochloride,* $SnCl_4.N_2O_3$, as a non-crystalline, orange-yellow mass by the action of dry nitrogen trioxide on stannic chloride, but the product is thought by R. Weber, and W. Hampe to be a nitrosyl complex, $SnCl_4.2NOCl$.

§ 37. Nitrous Acid

In 1774, C. W. Scheele[1] in his memoir: *De magnesia nigra*, showed that when potassium nitrate is kept in a state of fusion for half an hour at a red-heat, "it acquires phlogiston"; otherwise expressed, it loses oxygen, or is reduced. The acid contained in the salt is quite different from what it was before the fusion. The product "deliquesces in air although there is no evidence of any superabundant alkali." The new acid in the ignited nitre is so feeble, said T. Bergman, that it can be displaced by vinegar, and he called it *phlogisticated nitric acid*. In 1772, J. Priestley observed the different colours assumed when nitric acid is treated with nitric oxide, and found that the colour which is at first orange-yellow finally becomes a blue or green, forming what was later shown to be the phlogisticated nitric acid. These facts were not appreciated until J. J. Berzelius had demonstrated that there are at least two definite acids concerned in these reactions—nitrous acid, and nitric acid—and he established the fact that nitrous acid is a specific acid which forms with the saline bases a series of salts—the nitrites—with properties quite distinct from those of the nitrates. In 1802, J. L. Proust concluded from his observations on the action of lead on a boiling soln. of lead nitrate that the yellow crystals obtained represented a salt of lead in a lower state of oxidation; but J. J. Berzelius' observations showed that the yellow crystals were a nitrite and not a nitrate of lead. Similar results were obtained by the action of silver on silver nitrate. The additional observations of J. L. Gay Lussac,[2] and of P. L. Dulong in 1816, and the work of E. Péligot in 1841, proved that while nitric acid has the composition HNO_3, nitrous acid has the composition HNO_2. The name **nitrous acid** recommended by R. Chenevix is used at the present day, and the salts of the acid are called **nitrites.**

The occurrence of nitrous acid and nitrites in atm. air has already been discussed. The air of the best ventilated rooms where gas is burnt contains nitrites. L. I. de Nagy Ilosva found that nitrites are exhaled from the lungs in breathing, and C. Wurster, and T. Cramer believe that the depressed feeling and uneasiness experienced in crowded rooms is due to the presence of nitrites. J. Chabrier found from 0·75 to 4·52 mgrm. N_2O_3 per kgrm. in many soils. The presence of nitrites in soils has been treated by C. F. Schönbein, L. Carius, A. Houzeau, F. A. Haarstick, A. Müntz and T. Schlösing, R. Warington, L. Spiegel, E. Schaer, F. H. Storer, S. W. Johnson, etc.—*vide* the fixation of nitrogen. J. Chabrier also found nitrites in saltpetre prepared artificially; E. Bödtker found small traces of nitrites in sea-water; and J. E. Enklaar, in ordinary water. The presence of nitrites in spittle was detected by R. Böttger, C. Wurster, P. Griess, and R. N. Musgrave. The last-named found 0·4 to 2·0 parts of nitrous acid per million. The presence of nitrites in urine was discussed by C. F. Schönbein, F. Goppelsröder, H. B. Jones, and C. Jaffé. H. Struve found ammonium nitrite in expired air. G. Bertoni and C. Raimondi found nitrites in blood after poisoning with hydroxylamine. C. F. Schönbein, and P. Genadius found nitrites in the juices of some plants—*Boletus luridus, Leontodon taraxacum, Spinacia oberacea,* etc.

The preparation of nitrous acid and the nitrites.—Nitrous acid is found in the blue solution formed when nitrogen trioxide, N_2O_3, is dissolved in cold water: $N_2O_3+H_2O=2HNO_2$; and a mixture of nitrous and nitric acids is formed when nitrogen peroxide, N_2O_4, is dissolved in water: $N_2O_4+H_2O=HNO_2+HNO_3$. This acid is formed, according to D. Waldie, when a mixture of hydrogen and nitric oxide is burnt in air. Nitrous acid, however, is so unstable that it is usually studied when combined with the bases in the form of salts. Pure nitrous acid has not been isolated. A soln. of nitrous acid can be made by adding hydrochloric or sulphuric acid or acetic acid to a soln. of the nitrite: $NaNO_2+HCl=NaCl+HNO_2$. Some nitric oxide and nitric acid may be formed at the same time. According to C. W. Hasenbach, and J. Fritzsche, if nitrogen trioxide be passed into water, at 0°, a blue liquid is formed. The aq. soln. of the acid at low temp.—say −10°—is an indigo-blue colour which becomes yellowish-green at room temp.; the blue colour returns on re-cooling the soln., but it is rather paler than before owing to loss by decomposition. If the temp. be higher than this, nitric oxide is evolved, and nitric acid is formed: $3N_2O_3+H_2O=4NO+2HNO_3$. E. Frémy found that nitrogen trioxide, with a little water, forms nitric oxide and nitric acid, but with much water, the soln. does not decompose and is fairly stable. H. Reinsch considered that in cold water, nitrogen trioxide forms hydrated nitrous acid; and since an aq. soln. prepared out of contact with air conducts electricity, L. Marchlewsky inferred that a hydrated nitrous acid is present. H. Reinsch also found that an aq. soln. of nitrogen peroxide contains some nitrous as well as nitric acid. A. V. Saposchnikoff found aq. soln. of nitrous acid to be stable below 0°; but could not obtain a constant value for the distribution of nitrous acid between water and chloroform.

(1) *By the action of nitrogen oxides on alkaline hydroxides*—*vide* E. Turpin.—J. L. Gay Lussac, P. L. Dulong, J. Fritzsche, F. Emich, M. Berthelot, and T. Thomson found that a mixture of oxygen and a large excess of nitric oxide, say (1 : 4), in contact with a soln. of potash-lye forms potassium nitrite; and E. Péligot said that when nitric oxide comes in contact with mercurous oxide, mercurous nitrite is formed. C. F. Schönbein, and P. Sabatier and J. B. Senderens obtained nitrites by the action of nitric oxide on barium dioxide; C. F. Schönbein, on hydrogen dioxide, or manganese dioxide, or silver oxide. The nitrites are formed when nitrogen trioxide or nitrogen peroxide is passed into a soln. of potassium or sodium

hydroxide. With nitrogen peroxide, the corresponding nitrate is formed at the same time as the nitrite, and the two can be more or less cleanly separated by fractional crystallization; if the nitrogen trioxide is mixed with a slight excess of nitric oxide, NO, very little nitrate is formed. Commercially, the nitrous fumes obtained by passing an electric discharge in air (*vide supra*) at a temp. of about 300° are passed into the alkali-lye, and fairly pure nitrite is formed. The nitric oxide formed by the electric discharge does not oxidize further than N_2O_3 when the temp. does not fall below 300°.

(2) *By the reduction of the fused nitrates or their aqueous solutions.*—B. Moore found that ordinary tap-water which has stood for a day in darkness contains no nitrites, but if it has been exposed to the sun for an hour or two, nitrites are formed. Nitrates are thus reduced to nitrites when exposed to sunlight. Ordinary running water, or dew, may contain nitrites for a similar reason. According to S. Cooke, dil. nitric acid in the presence of spongy platinum is reduced by hydrogen with the formation of ammonium nitrite. J. J. Berzelius showed that when a soln. of lead nitrite is boiled with lead, the latter is oxidized at the expense of the nitrate, and lead nitrite is formed. C. F. Schönbein obtained it by reducing aq. soln. of the nitrates or nitric acid by stirring them with a cadmium or zinc rod, or by the addition of potassium-, sodium-, lead-, or zinc-amalgam—but not of iron-, aluminium-, or tin-amalgam; E. Müller and J. Weber, by the electrolysis of a soln. of a nitrate with silver or copper electrodes when the nitrate is almost wholly reduced to the nitrite before the latter commences to be reduced to ammonia. F. Gantter obtained nitrites by reducing nitrates by phosphorous acid; G. Flick, by the action of sulphur dioxide in the presence of lime which fixes the sulphuric acid simultaneously formed: $NaNO_3+CaO+SO_2=CaSO_4+NaNO_2$; G. Arth, and E. Divers, by the action of zinc, iron, etc., on the product of the action of ammonia on ammonium nitrate; H. Morin, by the action of cadmium on a soln. of ammonium nitrate; M. Goldschmidt, by the reducing action of carbon monoxide, formic acid or the formates; and J. Priestley, and J. L. Gay Lussac, by passing nitric oxide into nitric acid. V. H. Veley showed that the reaction between nitric oxide and nitric acid: $2NO+HNO_3+H_2O\rightleftharpoons3HNO_2$, is reversible, when the soln. is sufficiently dil. and the temp. low. For equilibrium, the ratio of the quantities of nitric acids is about 9 : 1. With more conc. acids, and at higher temp., the chemical changes taking place are more complicated. In soln. containing both nitric and nitrous acids, the rate of change at any moment is proportional to the mass of the nitrous acid present, and is dependent on the ratio of the masses of nitrous and nitric acid, being the more rapid the greater the proportion of the former to that of the latter. In the particular case of the liquids prepared from nitric oxide and nitric acid, the rate of change was found to vary with the temp. according to the equation $v_t=vk^{t-t_1}$. Nitrous-nitric acid soln. prepared in different ways behave in a similar manner as regards the diminution of the mass of the nitrous acid, but in other respects, such as the evolution of gases and action on metals, they are dissimilar. E. Divers showed that nitrites as well as nitrates are formed when the metals (*q.v.*) copper, silver, mercury, and bismuth are dissolved in nitric acid, but only nitrates and ammonia, or hydroxylamine, are formed when the alkali metals, magnesium, zinc, cadmium, aluminium, tin, lead, and iron, are similarly treated. The subject is discussed in connection with specific metals—*e.g.* copper. According to W. J. Russell, E. Divers, and V. H. Veley, many metals dissolve in nitric acid only when nitrous acid is present, and this has been attributed to the formation of nitrites which are attacked by the nitric acid, or else to the nitrous acid acting as a depolarizer. W. D. Bancroft holds that the nitrous acid acts catalytically to activate the nitric acid, possibly through the dynamic equilibrium: $3HNO_2\rightleftharpoons HNO_3+2NO+H_2O$. As already indicated, it was known in the middle of the eighteenth century that sodium or potassium nitrate decomposes when heated, forming a new salt, which was later shown to be the alkali nitrite. N. W. Fischer recognized that the reaction is difficult to control, and he found that better results

are obtained if the molten nitrate be treated with hydrogen, or preferably mixed with a reducing agent like charcoal, or lead. Thus, when a mixture of lead filings and an equal weight of sodium nitrate is heated in a crucible to about 420°, oxygen is slowly transferred from the nitrate to the lead; the main reaction is represented: $3Pb+4NaNO_3=Pb_3O_4+4NaNO_2$, or $Pb+NaNO_3=PbO+NaNO_2$. The temp. developed during the reaction is not sufficient to decompose much of the nitrite to sodium oxide—indeed, a 90 per cent. yield of nitrite can be formed under manufacturing conditions. The fused mass is digested with water, filtered, and the soln. evaporated when a crop of crystals of sodium nitrite separates on cooling. The lead oxide can be recovered and sold as litharge, while the unconverted lead can be recovered and used over again. J. Milbauer and O. Vogel said that the reaction $Pb+NaNO_3=NaNO_2+PbO$ proceeds completely to the right if a 15 per cent. excess of lead is employed, at about a hundred degrees above the m.p. of sodium nitrate—*viz.* 315°. The yield of lead oxide is less than the theoretical because of the dissociation of the nitrate into nitrite and oxygen. G. Tacchini recommended heating sodium nitrate with barium oxide or manganese dioxide. Several reducing agents have been recommended—thus, G. A. le Roy employed barium or calcium sulphide; A. Étard, alkali sulphite; and L. G. Paul, sodium hydroxide and sulphur—either the yield of nitrite is not so good as with lead, or the resulting nitrite is not so readily freed from impurities—sulphates, etc.—formed during the reaction. Nitrates were produced by E. Müller and co-workers, J. Weber, and W. J. Müller by the electro-reduction of nitrates.

(3) *By the reduction of nitric acid.*—E. Abel and D. Harasty studied the reaction: $HNO_3+H_2O+2NO=3HNO_2$, which occurs when nitric oxide is bubbled through nitric acid—*vide supra*, nitric oxide; and *infra* for the reverse reaction. The reaction is heterogeneous (the velocity of reduction is decreased by decreasing the glass surface of the apparatus) and is autocatalyzed by the nitrous acid, which acts as a superposed positive and negative catalyst; it accelerates the reduction when its conc. is small and retards it as the conc. becomes larger. The velocity increases with increasing velocity of the nitric oxide stream and with decreasing vol. of the soln. of the reactants. The latter effect is mainly due to change in the hydrogen-ion conc. of the nitric acid; the nitrate-ion conc. has only a small influence. Sodium sulphate retards the reaction and in moderately large conc. practically stops it. J. H. Gladstone and A. Tribe, and E. Müller and J. Weber found that nitrous acid is the first reduction product of nitric acid. According to K. Boresch, certain insoluble ferruginous substances—*e.g.* finely powdered ferromagnesian minerals, iron ores, and basic slag—can reduce neutral, aq. soln. of nitrates to nitrites. The reduction is favoured by the presence of ammonium salts which are themselves oxidized to nitrites. The ferrous oxide appears to act as a catalyst. The formation of nitrites from nitrates and ammonium salts is an incomplete bimolecular reaction. Only an insignificant amount of nitrite is formed by the action of manganese compounds. These reactions play a part in the changes suffered by nitrogenous compounds in soils.

(4) *By the oxidation of nitrogen, ammonia, and nitrogen-hydrogen compounds.*—C. F. Schönbein, O. Löw, and M. Zabelin said that ammonium nitrite is formed when water is evaporated or distilled in air; R. Warington found that nitrites are produced during the evaporation of water in vessels exposed to air, but not in closed vessels; and A. von Lösecke said that the amount produced is greater the lower the temp. On the other hand, L. Carius, E. Bohlig, P. Freda, and N. Smith failed to confirm the observation when care is taken to use air free from nitrites. According to C. F. Schönbein, P. Zöller and E. A. Grete, H. Struve, A. W. Hofmann, M. Zabelin, O. Löw, H. B. Jones, H. Kolbe, R. Böttger, J. D. Boeke, A. R. Leeds, L. T. Wright, C. Than, and L. I. de Nagy Ilosva, nitrous acid or ammonium nitrite is formed in traces when hydrogen, coal, carbon monoxide, wax, coal-gas, alcohol, and various hydrocarbons are burnt in air, and, added F. Fischer and F. Brähmer, this occurs even when the temp. is very low, for nitrous acid is

produced by the combustion of carbon monoxide, acetylene, carbon, wood, and sulphur in liquid air—*vide supra,* fixation of nitrogen. C. F. Schönbein, M. Berthelot, M. Zabelin, and G. Meissner reported on the production of nitrites during the slow oxidation of phosphorus in air; S. Kappel, by passing air over magnesium in contact with potassium hydroxide; E. Reichardt, by shaking water with manganic hydroxide and magnesium carbonate—but P. Zöller and E. A. Grete could not confirm this; A. A. Bonnema, by shaking ferric hydroxide in air—but F. Sestini denied this; M. Berthelot, and R. Pohl, by sparking a mixture of nitrogen and steam obtained ammonium nitrite, and S. M. Losanitsch and M. Z. Jovitschitsch obtained a similar result by the silent discharge. L. I. de Nagy Ilosva observed the formation of nitrous acid when a current of air is passed over reduced iron at 190°–250°.

The oxidation of ammonia has been previously discussed. O. Löw, L. T. Wright, and H. N. Warren observed the formation of ammonium nitrite when ammonia and air are passed over warm platinized asbestos. C. F. Schönbein, and S. Kappel obtained a similar result with reduced copper, nickel, or iron. F. Sestini said that ferric hydroxide can oxidize ammonia to the nitrite. When copper is oxidized in the presence of ammonia, the latter is simultaneously oxidized to a nitrite; this reaction was examined by C. F. Schönbein, E. Péligot, M. Berthelot and L. P. de St. Gilles, and D. K. Tuttle. C. F. Schönbein, and C. Kraut observed the formation of nitrites when a spiral of platinum, copper, or nickel wire is heated in ammoniacal air. According to F. Bayer, nitrous acid and not nitric acid is formed when a mixture of air or oxygen and ammonia is passed over ferric oxide or copper oxide at a temp. exceeding 650°. C. F. Schönbein obtained ammonium nitrite by passing electric sparks through aq. ammonia in the presence of air. C. F. Böhringer, and C. Couchet and co-workers reduced nitrates to nitrites by the electrolysis of aq. soln. with a mercury cathode. A nitrite is formed by the electrolysis of a soln. of ammonia in soda-lye in the presence of cupric hydroxide, and W. Traube and A. Biltz using a current of 5–15 amps., and platinum or iron electrodes, showed that virtually all the anode oxygen is used in oxidizing the ammonia to nitrite before the latter is converted into nitrate. E. Müller and F. Spitzer studied the nature of the anode material on the electro-reduction of nitrates to nitrites. According to C. F. Schönbein, aq. ammonia is oxidized to the nitrite by hydrogen dioxide, and by potassium permanganate, particularly when agitated in the presence of platinum-black, and the reaction was found by L. P. de St. Gilles to be quicker in the presence of formic acid. The reaction was investigated by F. Wöhler, W. Weith and R. Weber, F. Hoppe-Seyler, and H. Tamm. Various organic compounds were found by E. Donath to be energetically oxidized to nitrous acid by treatment with potassium permanganate. C. M. Tessié du Motay found that a mixture of oxygen and ammonia is oxidized to nitrite, nitrate, or free nitric acid when passed over lead manganate, permanganate, or dichromate at 350°–550°.

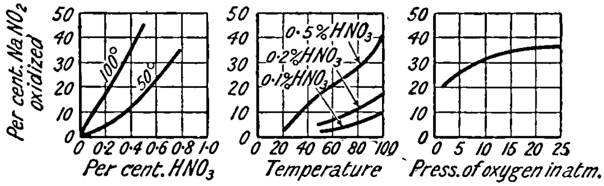
(5) *Biological processes.*—Nitrites are formed during the putrefaction and decay of nitrogenous substances. The oxidation of ammonia by bacteria has been discussed in connection with the fixation of nitrogen. Observations on the subject were made by C. F. Schönbein, F. Schür, P. F. Frankland and co-workers, E. Laurent, T. Schlösing, T. Leone, A. Müntz, S. Winogradsky, etc. The reverse action, *denitrification* of nitrates by bacteria, whereby nitrites are formed was probably observed by C. F. Schönbein in 1868; and the subject has been discussed by O. Baudische, E. Baur, M. W. Beyerinck, P. A. Boncquet, F. Bordas and co-co-workers, H. von Caron, J. Chukevich, M. Chwilewsky, E. Crespolani, A. Dieudonné, F. Duchacek, P. F. Frankland, U. Gayon and G. Dupetit, V. Griessmayer, L. Grimbert and L. Ficquet, C. A. Herter, B. Horowitz, H. Jensen, A. Jorissen, M. Klaeser, H. Kühl, E. Laurent, W. T. Logie, M. Lunkewitsch, A. Maassen, P. Mazé, L. Mazzetti, E. Meusel, E. Müller and F. Spitzer, E. Pelz, R. J. Petri, W. Seifert, A. Springer, J. Stoklasa, W. B. Wherry, etc. *Vide infra* for the reduction to ammonia and nitrogen.

The properties of nitrous acid and the nitrites.—The aq. soln. of the alkali nitrites were found by J. J. Berzelius to decompose slowly in boiling: $3KNO_2+H_2O=KNO_3+2KOH+2NO$—*vide infra* for ammonium salts. The aq. soln. when boiled in air, were also found to absorb oxygen, so as to form nitrates. G. Lunge showed that aq. soln. slowly pass into nitrates. According to E. Frémy, the aq. soln. at 0° is fairly stable, above that temp. it decomposes if in conc. soln. Indifferent powders like sand, gypsum, and charcoal accelerate the decomposition. A. V. Saposchnikoff found aq. soln. of nitrous acid to be stable below 0°; but he could not obtain a constant value for the distribution of nitrous acid between water and chloroform. According to C. Montemartini, an aq. soln. of the acid decomposes according to the rule for unimolecular processes, and judging by the final products, the simplest equation: $3HNO_2 \rightleftharpoons 2NO+HNO_3+H_2O$, is a termolecular process. This shows that the decomposition involves at least two operations—a slow unimolecular process and an immeasurably quicker process. The reaction is probably reversible because it is hindered in a marked way by increasing the press. of the nitric oxide. A. V. Saposchnikoff represented the velocity of the reaction by $K=(1/x_t) \log \{x_t(a-x)/a(x_t-x)\}$, where a denotes the initial conc. of the nitrous acid; x_t, the conc. at the time t; and x, the conc. after 300 hrs. when the soln. has been agitated energetically. He found that for nitric acid varying from N- to ^{1}N-conc., the equilibrium constant is 159; and for $0{\cdot}05N$-HNO_3, 232; this is taken to indicate that with low conc., the reaction proceeds very slowly and does not reach a final stage of equilibrium. G. N. Lewis and A. Edgar found for the equilibrium constant $K=[HNO_2]^3/[H^{\cdot}][NO'_3]$, in the reaction $3HNO_2 \rightleftharpoons 2NO+H_2O+H^{\cdot}+NO'_3$ to be $K=0{\cdot}0267$ at 25°; A. V. Saposchnikoff's value 0·0175 becomes 0·0208 if the same data are employed in the two cases. The water is assumed to be constant, and the nitric oxide being always present at the same press. is also constant. P. C. Ray, M. L. Dey and J. C. Ghosh found that the measurements of the rate of decomposition agree with those required for a unimolecular change, and the velocity coeff. at 0°, 21°, and 40° are respectively 0·00014, 0·00022, and 0·00057. A. Klemenc and F. Pollak showed that the decomposition $3HNO_2=HNO_3+2NO+H_2O$ depends on the velocity at which nitric oxide is removed from the soln. Undissociated nitrous acid possesses a considerable press. of nitric oxide, and, in consequence, the velocity of decomposition is proportional to the conc. of undissociated nitrous acid. The conc. of free nitric oxide in aq. soln. may be regarded as approximately the same as that of the undissociated nitrous acid. When nitrogen, or another inert gas, is led through a soln. of nitrous acid the velocity of decomposition is increased, and the velocity constant increases with the increasing rate at which the nitrogen is passed through. The speed of the direct decomposition of nitrous acid is in all probability immeasurably rapid. Nitrous acid decomposes spontaneously into nitric oxide, and the hydroxyl radicle and its transitory existence in aq. soln. is due to a mutual action between it and the solvent. The presence of mineral acids increases the velocity of decomposition. V. H. Veley showed that the reaction is probably reversible, and A. V. Saposchnikoff showed that the reverse change is very slow with dil. soln. of nitric acid. According to T. W. J. Taylor and co-workers, the reaction is at first rapid, and it subsequently slows down. If the nitrous acid be mixed with sodium sulphate, and kept under a layer of paraffin, the decomposition is considerably retarded. The first stage of the decomposition is represented by a state of equilibrium: $2HNO_2 \rightleftharpoons N_2O_3+H_2O$, and the complicated nature of the subsequent changes arises from the behaviour of the anhydride; that this latter exists in soln. is supported by the observations of A. V. Saposchnikoff on the ease with which organic solvents will dissolve it from soln. of the acid. It is not the anhydride itself which escapes as gas from the soln., for, if this were so, the soln. would contain eventually less nitric acid than the quantity corresponding to the equation of decomposition: $3HNO_3=HNO_2+2NO+H_2O$, and experiment showed that in every case under paraffin the theoretical amount of nitric acid remained. The facts are explained by the assumption that another state of equilibrium exists, namely, $N_2O_3 \rightleftharpoons NO + NO_2$. In a completely stable soln., the conc. of water being assumed to be constant, the function $[NO][NO_2]/[HNO_2]^2$ would have a fixed value at any one temp.; but the conc. of nitric oxide cannot exceed a certain limit because of its slight solubility, and the limit will depend on the press. No completely stable soln., however, can exist, even in a sealed bulb where the press. of nitric oxide can become high, since the nitrogen peroxide is continually hydrated and removed from the equilibrium. During the "slow" decomposition of the nitrous acid, two factors come into play: the rate of escape of nitric oxide, and the rate of hydration of the peroxide. The conc. of the latter is probably extremely small, and thus the quantity hydrated in unit time is small, and consequently the second factor under normal conditions is of less importance. Any factor tending to facilitate the escape of the nitric oxide, such as increased area of contact with the gas phase, addition of sand or charcoal or reduction of press., will increase the rate of decomposition.

N. R. Dhar showed that the decomposition of nitrous acid into nitric acid and nitric oxide is hindered by mild reducing agents; and K. B. Mukerji and N. R. Dhar, that the velocity coeff. in both the light and the dark increases slowly with increase of conc. of the nitrous acid. The velocity coeff. are considerably greater—from 200 to 400 per cent.—when the reaction is carried out in open vessels than when closed vessels are employed. This is attributed to a displacement of equilibrium owing to the removal of nitric oxide under the former conditions. The velocity of the reaction is markedly accelerated by light, and to a greater extent when closed vessels are used. The following substances act as positive catalysts for the reaction: ferric nitrate, cobalt nitrate, nickel nitrate, chromium chloride, copper sulphate, nitric acid, potassium chlorate, potassium nitrate, sulphuric acid, ferric hydroxide sol, molybdic and titanic acids, bromocamphor, thiocarbamide, dinitrophenol, carbamide, phthalic anhydride, citric, tartaric, and formic acids, potassium oxalate, potassium formate, boric acid, and tartar emetic. The following act as negative catalysts: sucrose, dextrose, glycerol, alcohol, hydrogen dioxide, ethyl ether, quinol, phenol, brucine, strychnine, narcotine, and quinine sulphate. Manganese nitrate and barium sulphate are without effect. The results indicate that reducing agents retard reactions involving auto-oxidation and reduction processes. The subject was also investigated by V. H. Veley, A. Jacob, J. Knox and D. M. Reid, and R. Abegg and H. Pick. A. Jacob found that the first stage of the reaction is probably $2HNO_3 = H_2O + N_2O_3$. According to J. Thomsen, the heat of formation (2N,3O,aq.) is $-6{\cdot}82$ Cals.; (2NO,O,aq.), $-36{\cdot}33$ Cals.; $(H,N,O_2,aq.)+30{\cdot}77$ Cals.; and $(NO,O,H,aq.)+52{\cdot}35$ Cals. M. Berthelot gave 9·1 Cals. for the heat of neutralization with ammonia; and 10·6 Cals. with baryta. A. Jacob calculated for the reaction $3HNO_2aq. \rightleftharpoons HNO_3aq. + 2NO + H_2O - 17{,}900$ cals. From the conductivity of the mercury salt, H. Ley and H. Kissel concluded that nitrous acid is rather stronger than acetic acid—*vide infra*, silver nitrite.

A. A. Blanchard calculated from the effect of carbon dioxide on soln. of potassium nitrite the ionization constant, $K=[H^{\cdot}][NO'_2]/[HNO_2]$, to be 0·00040; M. Schümann gave 0·00045; P. C. Ray and co-workers, 0·00060 at 0°; and E. Bauer, 0·00064. C. Matignon and G. Gire found that the electrical conductivity and the progressive displacement of nitrous acid by sulphuric in a dil. soln. of sodium nitrite indicate that nitrous acid is a stronger acid than the second acid function of phosphoric acid—the ionization constant for nitrous acid is 6×10^{-4}, and for the second acid function of phosphoric acid, $1{\cdot}9\times10^{-7}$. They also examined the effect of different indicators. E. Bauer found the transport number of the NO'_2-ions to be 58; M. Schümann gave 64·5; H. Pick, 63; N. R. Dhar and D. N. Bhattacharyya, 67·9 at 25° and infinite dilution; S. von Niementowsky and J. von Roszkowsky, 72·3 (when that for NO'_3-ion is 65·1); and F. Vogel, 61·7. According to R. Abegg and H. Pick, when heated in a closed vessel above 40°, soln. of silver nitrite were decomposed according to the equation $2AgNO_2 \rightleftharpoons Ag + NO + AgNO_3$, or, on the ionic theory, $2Ag^{\cdot} + 2NO'_2 \rightleftharpoons Ag + Ag + NO + NO'_3$; the action is a reversible one. If p denotes the partial press. of the nitric oxide, the constant $k=p[NO'_3]/[Ag^{\cdot}][NO'_2]^2$ has the value $1{\cdot}9\times10^5$ at 55°, the pressure of nitric oxide being expressed in atm. and the conc. of the other substances in mols. per litre. From this it is calculated that the intensity of the oxidation reaction $2NO'_2\rightarrow NO+NO'_3$ is $-0{\cdot}43$ volt, the potential of the hydrogen electrode being taken as zero; in other words, when the substances taking part in the equilibrium are present in unit concentration, the nitrite ion is, by 0·43 volt, a less powerful reducing agent than hydrogen, but the reducing action of the former is greatly increased when the nitric oxide conc. is small. According to R. Ihle, if the oxidation of the hydrogen ions in a Grove's cell is not sufficiently rapid, polarization occurs, and the e.m.f. falls considerably. This oxidation velocity is largely dependent on the conc. of the acid, and is increased by the addition of small quantities of nitrous acid. Thus, although polarization with a pure acid occurred when the conc. was 35 per cent., by the addition of 5 drops of nitrite soln. the acid could be further diluted to 20 per cent. without any polarization. Owing to this action of nitrous acid, urea and strong oxidizing agents, such as potassium permanganate, have a retarding effect on the oxidation velocity, which may further be increased by some reducing agents. The potential of the nitric acid increases with the conc., the values 1·23 volt, at 6 per cent., and 1·52 volt, at 95·5 per cent., being obtained. Nitrous acid, however, lowers the potential, and its effect in this respect was found to be a logarithmic function of its conc. The potential of nitrous acid itself was found to be lower than that of nitric acid. It was inferred that nitrous acid is the real depolarizer in Grove's cell. H. Pick, and A. Klemenc and P. Gross studied the anodic behaviour of nitrous acid. A. Klemenc showed that when a platinum electrode is in contact with the system: HNO_2–HNO_3–NO, in equilibrium, the reaction in approximately 3*N*-soln. is $NO+2H_2O\rightarrow4H^{\cdot}+NO'_3$; but in more dil. soln., the reaction: $NO+H_2O\rightarrow2H^{\cdot}+NO'_2$ also comes into play.

According to L. I. de Nagy Ilosva, nitrous acid can act both as an oxidizing and as a reducing agent. Thus it has a *reducing action* when it is oxidized to nitric acid—*e.g.* when treated with ozone or hydrogen dioxide, and in the latter case, added C. F. Schönbein, sunlight accelerates the change. K. B. Mukerji and N. R. Dhar estimated that the photochemical action of light persisted only $4{\cdot}2\times10^{-9}$ secs. M. Busch said the oxidation with hydrogen dioxide is complete in acid soln. The reactions were also studied by W. Weith and R. Weber, A. Perrot, R. Böttger, and H. Buff and A. W. Hofmann after exposure. C. F. Schönbein found that nitrous acid also reduces lead or manganese dioxide, and the brown soln. of silver dioxide in cold nitric acid. H. Zieler examined the oxidation of sodium nitrite or nitrous acid. Since the oxidizing action of nitric acid usually ceases when it has been reduced to nitric oxide; and the reaction: $4NO+3O_2+2H_2O=4HNO_3$ involves a decrease in vol., oxidations can be effected by oxygen under press. with nitric acid as catalytic agent. Thus, while neutral soln. of sodium nitrite are not oxidized by oxygen under a press. of 20 atm., in soln. acidified by nitric acid, the oxidation to nitrate is quantitative. The rate of oxidation increases with increase in the acidity, with the dilution of the soln., with the temp., and to a less extent with oxygen press. The results are summarized in Figs. 72 to 74—*vide infra*, sodium nitrite. A. W. Francis studied the speed of oxidation of sodium nitrite by bromine-water. R. C. Banerji and N. R. Dhar found that the reaction with iodine is bimolecular: $NaNO_2+I_2+H_2O=NaNO_3+2HI$, in darkness,



FIGS. 72 to 74.—The Effect of the Concentration of Nitric Acid, the Temperature, and the Pressure of the Oxygen on the Oxidation of Nitrous Acid or Sodium Nitrite.

but in light, the semimolecular formula gives better results for the velocity constant for the consumption of iodine. N. A. E. Millon said that chloric acid is reduced to chlorous acid, and H. Toussaint reduced it to hydrochloric acid. A. Schwicker, and W. Feit and K. Kubierschky found that it reduces bromic acid to bromine, forming nitric acid, but iodic acid, on the other hand, is not attacked in cold, conc. soln. A. Kurtenacker examined the velocity of the reduction of iodic acid by nitrous acid, and found that the reaction is best represented as occurring in two stages: (i) $IO'_3+2NO'_2=IO'+2NO'_3$; and (ii) $2IO'+NO'_2+2H^{\cdot}=I_2+NO'_3+H_2O$. The velocity of the second reaction is much less than that of the first. There may possibly be three stages (i) $IO'_3+NO'_2=IO'_2+NO'_3$; (ii) $IO'_2+NO'_2=IO'+NO'_3$; and (iii) $2IO'+NO'_2+2H^{\cdot}=I_2+NO'_3+H_2O$. The velocity of reduction of the iodate is found to be directly proportional to the conc. of the iodate, nitrite, and hydrogen ions, and is catalytically accelerated by the hypoiodous acid formed in the reaction. In the presence of potassium chloride, bromide, and nitrate, the nitrate ion slightly retards the velocity of reduction of the iodate, whilst the presence of chlorine or bromine ions exerts a marked accelerating effect, the influence of the bromine ion being about twenty times greater than that of the chlorine ion. For small conc. the catalytic action of the halogen ions is directly proportional to their conc.; with large conc., however, the accelerating influence falls off, owing to the conversion of hypoiodous acid into iodine monochloride or monobromide, which exert no catalytic action on the reduction of the iodate. The reaction with bromic acid occurs in three stages: (i) $BrO'_3+3NO'_2=Br+3NO_3$; (ii) $BrO'_3+5Br'+6H^{\cdot}=3Br_2+3H_2O$; and (iii) $Br_2+NO'_2+H_2O=2Br'+NO'_3+2H^{\cdot}$. The reaction is of the first order with respect to the bromate. The reaction is very slightly influenced by the conc. of the nitrite, and only when the relation of the conc. of bromate to nitrite is very large or equal to unity. With large conc. of nitrite the velocity is independent of the nitrite conc., and in this case the reaction is of the first order. The velocity is strongly accelerated by acetic acid. The behaviour of the nitrite and the acetic acid is explained by the assumption that the reaction which has been measured consists in the interaction of bromic acid, and nitric oxide, and in which the nitrous acid is only so far active as it produces the nitric oxide as fast as it is used up. Consequently, it is very probable that the first stage proceeds (i*a*) $3NO'_2+2H^{\cdot}=2NO+NO'_3+H_2O$; and (i*b*) $BrO'_3+2NO+H_2O=Br'+2NO'_3+2H^{\cdot}$. Diminution of press. decreases the reaction velocity, owing to decrease in conc. of nitric oxide. The extent of the decrease is scarcely so great as would be expected, possibly owing to an increased instability of nitrous acid, due to the lower press. The effect of temp. on the velocity of the reaction is that which would be expected if oxidation affects the nitric oxide. The reaction with chloric acid, in the presence of potassium hydrosulphate, can be expressed by the formula $dx/dt=(K_1+K_2S)[ClO'_3][HNO_2]$, where K_1 is the velocity coeff. of the uncatalyzed action, K_2 the acceleration coeff. of the acid, and S the conc. of the latter. Very marked differences are found in the mechanism of the action with chloric, bromic, and iodic acids respectively; the greatest abnormality is observed with bromic acid, which, in contrast with its position in the natural series, acts much more rapidly than either chloric or iodic acid. C. F. Schönbein, E. Frémy, L. P. de St. Gilles, and W. Kubel reduced permanganates in the presence of sulphuric acid with the formation of manganese sulphate: $2KMnO_4+5HNO_2+3H_2SO_4=K_2SO_4+2MnSO_4+5HNO_3+3H_2O$. In volumetric analyses, where the nitrite is titrated with standard permanganate, in order to avoid a decomposition of the nitric acid by the sulphuric acid, it is necessary to use a dil. soln. containing at least 5000 parts of water for one of nitric acid. Hence, L. P. de St. Gilles determined nitrites in dil. acid soln. by titration with permanganate. A. Kurtenacker found that the speed of reduction of permanganate by nitrous acid is greater than in the case of dichromates, chlorates, bromates, or iodates. G. A. Barbieri reduced ceric sulphate, $Ce(SO_4)_2$, quantitatively with nitrous acid; and L. L. de Koninck, potassium chromate or dichromate. A. Kurtenacker found that the reduction of dichromate by nitrous acid, in the presence of potassium hydrosulphate, can be represented by $dx/dt=(K_1+K_2S^2)[H_2Cr_2O_7][HNO_2]$—*vide supra.* In all probability it is the undissociated nitrous acid, and not the nitrite ion, which takes part in the change. Similar, the catalytically accelerating action of the added acid, $KHSO_4$, $CH_3.CO_2H$, is probably to be attributed to the undissociated mols. (or HSO'_4 ions), and not the hydrogen ions. E. Frémy reduced osmic acid with nitrous acid; and N. W. Fischer, soln. of auric chloride and mercurous nitrate.

As an *oxidizing agent,* W. Zorn, P. Zechlin, J. D. van der Plaats, S. M. Tanatar, E. Divers, E. J. Maumené, P. de Wilde, etc., showed that it reacts with nascent hydrogen, forming nitric oxide, nitrous oxide, and nitrogen, as well as hydroxylamine and ammonia. B. Suler studied the electrolytic reduction of nitrites. Nitrous acid oxidizes hydriodic acid or potassium iodide liberating iodine: $2HI+2HNO_2=2H_2O+2NO+I_2$—this reaction was studied by C. Aeby, A. Bömer, R. Böttger, C. Ekin, F. Fischer, E. Frémy, C. R. Fresenius, H. Hager, H. Kämmerer, J. König, A. R. Leeds, F. Musset, P. C. Plugge, C. F. Schönbein, and A. D. Tschirikoff. According to M. Lombard, if the reaction with iodides occurs in the presence of oxygen, the nitrous acid is regenerated as fast as it disappears. Nitrous acid precipitates sulphur from hydrogen sulphide. C. A. Winkler, E. Frémy, A. Claus, E. Divers and T. Haga, A. Lidoff, F. Raschig, and R. Weber found that sulphurous acid is oxidized to sulphuric acid; F. Raschig, nitrous oxide, to nitric oxide; and F. Hefti and W. Schilt, hydrogen sulphide, to thiosulphate, sulphur—and ammonia. N. R. Dhar studied the induced reaction involving the effect of nitrites on the reduction of mercuric chloride by oxalic acid.

N. W. Fischer, L. Ernst, and A. Piccini and F. M. Zuco found that manganous and ferrous salts form nitric oxide and hydrogen: $2FeSO_4+H_2SO_4+2HNO_2=2H_2O+2NO+Fe_2(SO_4)_3$; O. Baudisch and P. Mayer found that nitrites are reduced quantitatively by an excess of ferrous hydroxide in neutral and alkalinc soln.; and on boiling soln. made alkaline with carbonates, the chief products are ammonia and nitrous oxide; in boiling alkali-lye, the nitrite is reduced quantitatively to ammonia. Alkali nitrates are also reduced quantitatively to ammonia by ferrous hydroxide in neutral soln., and in alkaline soln. containing 28 per cent. of sodium hydroxide. P. Falciola said that if a litre of water containing 0·0001 per cent. of sodium nitrite is treated with about 2 c.c. of sulphuric acid and then with excess of thiocyanate and about 0·1 grm. of ferrous sulphate, an orange coloration is readily developed; if only 0·00001 per cent. of the nitrite is present, the colour appears more slowly. O. von Dumreicher found that stannous chloride is oxidized by nitrous acid with the formation of nitrous oxide. I. M. Kolthoff observed that the oxidization of a nitrite to nitrate by potassium permanganate does not occur in alkaline soln. Good results are obtained by adding the nitrite soln. to a considerable excess of permanganate in presence of 4*N*-sulphuric acid, and after 15 minutes, titrating the excess with iodide and thiosulphate. I. Bellucci said that in the presence of fluorides, the permanganate yields its oxygen $Mn_2O_7\rightarrow Mn_2O_3+4O$; and in its absence, $Mn_2O_7\leftarrow 2MnO_2+3O$. A. Claus, and C. Ludwig and A. Kromayer showed that urea is oxidized; according to N. A. E. Millon; $CO(NH_2)_2+N_2O_3=CO_2+2N_2+2H_2O$; or, according to F. Wöhler and J. von Liebig, in the cold and in conc. soln., $2CO(NH_2)_2+N_2O_3=(NH_4)_2CO_3+2N_2+CO_2$. For the reduction of nitrous acid by stannous chloride to nitrous oxide, hyponitrous acid (*q.v.*), and hydroxylamine (*q.v.*), *vide infra,* constitution. M. Coblens and J. K. Bernstein found that nitric oxide, and no ammonia, is formed when a sodium nitrite soln. is added drop by drop to an acid soln. of titanous chloride; and hydroxylamine is formed with an acid soln. of stannous chloride. The reducing action of titanous chloride on nitrous acid does not get fully to work because of the escape of the gaseous intermediate products of the action—*vide supra,* nitrous oxide. O. Baudisch and P. Mayer found that nitrites are reduced quantitatively by excess of ferrous hydroxide in neutral and alkaline soln. In boiling soln. made alkaline with carbonates, nitrous oxide and ammonia are chiefly formed. In boiling alkali hydroxide soln., the nitrite is quantitatively reduced to ammonia. O. Baudisch said that the formation of nitrate from nitrite by complex iron salts is probably due to the unsaturated tervalent nitrogen atom of the nitrite attaching itself to the central iron nucleus by secondary valencies, and it is subsequently decomposed, forming nitric oxide. The reduction of alkali nitrite by potassium ferrocyanide and oxygen is said to occur by the displacement of a CN-radicle from the inner sphere of the complex by oxygen and a molecule of an alkali taking its place, the nitrite then decomposes, giving off nitric oxide which is displaced by oxygen. The decomposition of alkali nitrites by complex iron salts can be effected in daylight at ordinary temp. For the action with arsenious and sulphurous acids, *vide* the respective acids.

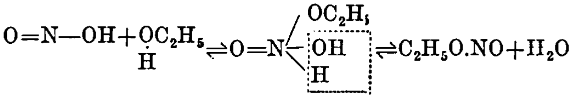
Nitrous acid is also employed as a *nitrating agent* in organic chemistry. Thus, M. F. Aitken and T. H. Reade studied its action on *p*-iododimethylaniline, and obtained nitro-derivatives; J. Reilly and P. J. Drumm, its action on substituted *p*-phenylenediamines; and F. Bettzieche, and R. H. A. Plimmer, its action on amides and other amino-compounds. Nitrogen trioxide was found by H. Reihlen and A. Hake to form an unstable complex with stannic chloride—possibly $3SnCl_4.4NO_2$. Nitrogen trioxide reacts with stannic chloride not in the ordinary blue but in the colourless form. A. Klemenc and R. Schöller studied the partition of nitrous acid between ether and water. The poisonous qualities of nitrous acid have been discussed by A. Purcell,[3] etc.

Some reactions of nitrous acid and the nitrites of analytical interest.—Many of the characteristic reactions of the nitrites depend on a change of colour attending oxidation or reduction. The salts are decomposed in the cold by sulphuric acid with the liberation of nitric oxide which gives brown fumes in air; the conc. acid acts more vigorously. Nitrates give brown fumes only when heated with the conc. acid. The test is not conclusive if chlorides or bromides be present. **Potassium iodide** is not decomposed by pure dil. nitric acid; whereas, a soln. of a nitrite, when acidified with dil. sulphuric or acetic acid, becomes yellow or brown owing to the separation of iodine. If a little starch paste be present, the soln. will be coloured blue. According to R. Böttger,[4] the reaction is sensitive to about one part of nitrous acid in about 10,000,000 parts of water. Many other oxidizing agents give the same coloration—ozone, hydrogen peroxide, chlorine, and ferric salts. Nitrates give the same coloration if a little zinc be added to the acidified soln. owing to the reduction of the nitrates to nitrites. A sensitive test for the nitrates is based upon the oxidation of **ferrous salts** by nitric acid: $6FeSO_4+3H_2SO_4+2HNO_3=3Fe_2(SO_4)_3+4H_2O+2NO$; and by nitrous acid; $2FeSO_4+H_2SO_4+2HNO_2=Fe_2(SO_4)_3+2H_2O+2NO$. In the cold, the nitric oxide forms a dark brown compound with the excess of ferrous salt. To apply the test, dissolve the nitrate in as little water as possible. Add a cold sat. soln. of ferrous sulphate slightly acidified with sulphuric acid. Pour conc. sulphuric acid down the side of the tube. If nitric acid be present, the zone of contact will be coloured dark brown. With nitrites, the conc. sulphuric acid need not be added. A warm, acidified soln. of **potassium permanganate** is decolorized by nitrous acid, but not a neutral soln. P. H. Hermans found that to 2 c.c. of the soln. to be examined a few drops of glacial acetic acid should be added and then 2 c.c. of 5 per cent. potassium oxalate soln., 1 c.c. of 5 per cent. **manganous sulphate** soln., and a few drops of 3 per cent. hydrogen peroxide. A red coloration indicates nitrite. A gram of sodium nitrite per litre can be detected in this way. If a nitrite be added to a dil., almost colourless soln. of **potassium ferrocyanide** acidified with acetic acid, G. C. Schäffer showed that a dark greenish-yellow colour appears—detectable if one part of nitrite is present in 600,000 parts of soln., owing to the conversion of ferro- to ferricyanide: $K_4FeCy_6+NaNO_2+2CH_3.COOH \rightarrow K_3FeCy_6+CH_3.COOK +CH_3COONa+H_2O+NO$. This reaction distinguishes nitrites from nitrates. The reaction was examined by C. M. van Deventer and co-workers, E. W. Davy, and T. M. Chatard. According to C. D. Braun, nitrites with potassium cyanide, cobalt chloride, and a little acetic acid give a reddish-orange colour. **Cobalt salts** with an excess of potassium nitrite and acetic acid give a yellow precipitate of potassium hexanitritocobaltate, $[Co(NO_2)_6]K_3$. According to E. Lenssen, W. Kalle and W. Prickharts, and P. Sabatier, **cuprous salts** in fuming hydrochloric acid soln. are coloured blue by nitrites. The colour vanishes when the soln. is warmed, or when alkalies are added. Nitrates may be distinguished from nitrites by the addition of hot concentrated sodium hyposulphite, the former remains unaltered, the latter evolves nitrogen. P. Falciola found that the addition of **sodium thiosulphate soln.** of about 0·5*N*-conc., drop by drop to an alkali nitrite soln. acidified with sulphuric acid, yields a transitory yellow coloration, more or less intense according to the proportion of nitrite present; this reaction is perceptible with 0·0001*N*-nitrite soln. With moderately conc. nitrite soln., use may be made of sodium thiosulphate test-paper, which is dipped first into the nitrite soln., and then into dil. sulphuric or acetic acid.

Several alkaloids are coloured by nitrites. In 1841, J. B. Berthemot found that **brucine** (0·02 grm.) in conc. sulphuric acid gives a red coloration with a soln. of nitrous acid mixed with 3–4 times its vol. of sulphuric acid. According to E. Nicholson, one part of nitric acid in 10,000,000 parts of water gives a perceptible pink coloration. The reaction was examined by G. Lunge, L. W. Winkler, and P. Pichard. Nitrous acid does not give the coloration in the presence of an excess of concentrated sulphuric acid. Aq. soln. of nitrites nearly always contain some nitrate, and consequently nitrites may appear to give the coloration. Nitrous acid in the presence of nitrates can be destroyed by treatment with dil. sulphuric acid and a concentrated solution of urea; or by boiling an alkaline soln. of ammonium nitrite with ammonium chloride—in both cases a trace of the nitrous acid is also converted into nitric acid. Chlorates react like the nitrates in the brucine test. A whole series of organic compounds give colour reactions with the nitrites or nitrates, and the intensity of the coloration is often proportional to the amount of, say, nitrite in a known vol. of soln., so that if the colour is matched in a colorimeter with a mixture containing a known amount of the nitrite, similarly treated, an estimate of the amount of nitrite in the given soln. can be made. For example, P. Griess showed that **m-phenylenediamine** gives a brown coloration with the nitrites—the equivalent of one part of nitrite in 10,000,000 parts of soln. gives a perceptible yellow colour. According to A. Longi, one part of nitric acid in 1,500,000 parts of water can be thus recognized. Other oxidizing agents like chloric acid, selenic acid, ferric chloride, chromic acid, vanadic acid, hypochlorites, hydrogen dioxide, etc., may give a similar coloration. The reaction was studied by E. M. Harvey.

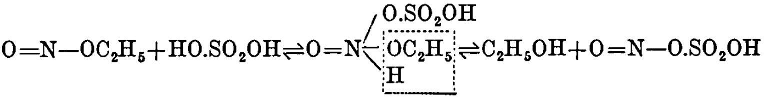
L. I. de Nagy Ilosva found that a mixed soln. of **sulphanilic acid and α-naphthylamine** gives a pink coloration when one part of nitrite is present in 1,000,000,000 parts of soln. E. Riegler observed that a mixture of **naphthionic acid** with a little conc. hydrochloric acid gives an intense rose coloration with nitrite soln. to which 20–30 drops of ammonia have been added—one gram in 10,000,000 c.c. can be so detected. H. Sprengel showed that when a few cubic centimetres of **phenol** dissolved in conc. sulphuric acid are poured over the dry mixture containing a nitrate, and after standing a moment, water is added, and the mixture is made alkaline with potassium (sodium, or ammonium) hydroxide, a yellow colour—due to the formation of tripotassium nitrophenol-disulphonate—develops if a nitrate be present. E. C. Woodruff found a dil. mixture of 2 drops of **dimethylaniline** and 0·2 grm. of *p*-toludine in 10 c.c. of sulphuric acid gives a blood-red colour with a nitrate in the presence of chlorates, bromates, or iodates; with chlorates it gives a strong brown colour. One drop of a 5 per cent. soln. of potassium nitrate in ten drops of the soln. of dimethylaniline gives an intense crimson in a few moments, and with one drop of a 0·001 per cent. soln. under similar conditions, a pale yellow. A. Tingle has shown that the following test for nitrates is not affected by the presence of halides. When a soln. of the nitrate is warmed with a 7 per cent. sulphuric acid soln. of **salicylic acid,** nitrosalicylic acid is formed, and when the soln. is made alkaline, a yellow or orange colour is produced. A. Jorissen, and A. Vogel found that **fuchsine** is coloured violet, blue, green, and finally yellow by nitrous acid; J. von Liebig, C. F. Schönbein, H. Trommsdorff, and H. Struve noted that **indigo** soln. is decolorized by nitrous acid; C. F. Schönbein, and M. Rosenfeld, **pyrogallol** is coloured brown; **resorcin,** by A. Novelli, E. Barbet and E. Jandrier, and G. Denigès; and P. Griess, **diamidobenzoic acid** is coloured yellow, orange-red, or brown. Colour reactions with 1 : **3-toluylene-diamine,** by P. Griess; **indol,** by O. Bujwid, and L. Spiegel; **phenol,** by C. P. Plugge; **diphenylamine,** by E. Kopp, and P. Soltzien; **aniline sulphate,** by T. M. Chatard, and G. Denigès; **aniline phosphate,** by P. Falciola; **p-amidobenzolazodimethylaniline,** by R. Meldola; **diphenyl-o-toluidine,** by C. Haussermann and R. Bauer; ammoniacal soln. of **cochineal,** by C. F. Schönbein; **antipyrine,** by M. C. Schuyten; **guaiacol,** by L. Spiegel; etc.

The constitution of nitrous acid and the nitrites.—The formula HNO_2 has been confirmed by analyses of the salts; by the electrical conductivity of the sodium salt; and by the effect of the acid on the f.p. of water. J. W. Brühl [5] considered that the refraction and dispersion of the aq. soln. corresponded with the presence of the hydrate $HNO_2.H_2O$, or of *orthonitrous acid,* $N(OH)_3$; the ordinary acid is then *metanitrous acid,* and the ordinary salts *metanitrites.* Salts are known corresponding with a theoretical pyronitrous acid, $N_2O(OH)_4$, obtained by the condensation of two mols of orthonitrous acid accompanied by the loss of a mol of water. There is some difference of opinion which of the formulæ $O_2{\equiv}N{-}H$; $O_2N{-}H$; or $O{=}N{-}OH$ represents nitrous acid. The last formula is generally accepted on the assumption that (i) the acid probably contains a hydroxyl group; and (ii) the nitrogen atom is tervalent. The first two formulæ are representative of formulæ in which the hydrogen atom is directly united to the nitrogen atom; and in the other type of formula, an oxygen atom intervenes; the former was suggested by R. Günsberg to explain the fact that silver nitrite, when gradually heated, forms nitric oxide with the simultaneous formation of metallic silver and silver nitrate; while if it be strongly heated, nitric peroxide and the metal are alone formed; hence, he argued that silver nitrite has the formula $Ag{-}NO_2$ where the silver atom is directly united to the metal. It is supposed that when silver nitrite is decomposed at a high temperature: $AgNO_2 \rightarrow Ag+NO_2$, and that at the low temp., the secondary reactions $Ag+2NO_2 \rightarrow AgNO_3+NO$, and also $AgNO_2+NO_2 \rightarrow AgNO_3+NO$, occur. The test on silver nitrite with phosphorus oxychloride for hydroxyl groups fails because no nitrogen oxychloride can be detected among the products of the reaction, and, even if such were formed, it is probable, as A. Exner has observed, that it would be decomposed by silver nitrite. A. von Bäyer and V. Villiger suppose that nitrous acid can unite with water or alcohol, forming addition compounds of the type:



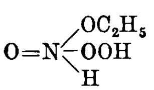
$$O{=}N{-}OH+\underset{H}{OC_2H_5}\rightleftharpoons O{=}N\begin{matrix}\diagup OC_2H_5\\ -\boxed{\begin{matrix}OH\\ H\end{matrix}}\\ \diagdown\end{matrix}\rightleftharpoons C_2H_5O.NO+H_2O$$

The unstable addition compound readily breaks down into ethyl nitrite and water: similarly, during the saponification of ethyl nitrite by dil. sulphuric acid, $HO.SO_2OH$, A. von Bäyer and V. Villiger suppose that

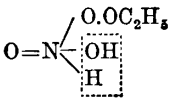


$$O{=}N{-}OC_2H_5+HO.SO_2OH\rightleftharpoons O{=}N\begin{matrix}\diagup O.SO_2OH\\ -\boxed{\begin{matrix}OC_2H_5\\ H\end{matrix}}\\ \diagdown\end{matrix}\rightleftharpoons C_2H_5OH+O{=}N{-}O.SO_2OH$$

and that the nitrosulphonic acid, $O{=}N{-}O.SO_2OH$, passes into the tautomeric form, $O{=}NO{-}O.SO_2OH$. The fact that ethyl nitrite reacts with hydrogen dioxide, forming nitric acid and alcohol, while nitrous acid and ethyl peroxide, $C_2H_5O.OH$, give ethyl nitrate and water shows that the addition products in the two cases are not the same; the hydrogen dioxide does not break into the two hydroxyl groups, but behaves like sulphuric acid, $H.O,SO_2OH$ as if it were $H.O.OH$, and similarly with ethyl peroxide, so that the addition compounds are respectively:



$$O=N\begin{smallmatrix}OC_2H_5\\OOH\\H\end{smallmatrix}$$



$$O=N\begin{smallmatrix}O.OC_2H_5\\OH\\H\end{smallmatrix}$$

This hypothesis explains very well the curious behaviour of the nitrites on the assumption that the molecule is O=N—OH. V. Meyer's experiments showed that when ethyl iodide, C_2H_5I, acts upon silver nitrite, both *ethyl nitrite*, $C_2H_5O.NO$, boiling at 18°, and *nitroethane*, $C_2H_5NO_2$, boiling at 114°, are formed. The fact that the reduction of ethyl nitrite with hydrogen sulphide, or with zinc and hydrochloric acid, produces ethyl alcohol, C_2H_5OH, and ammonia, is taken to mean that the ethyl group, C_2H_5, is not directly united to the nitrogen atom; otherwise, said A. Geuther, the ethyl radicle would stick to the nitrogen atom, and the reduction would give ethylamine, $C_2H_5NH_2$. On the other hand, it can also be argued that because methyl iodide, CH_3I, yields only nitromethane, CH_3NO_2, while the higher alkyl iodides give larger and larger propositions of alkyl nitrites, and are additively associated with the nitrous acid, forming alkyl nitrites, the formula for the nitrites is probably $H—NO_2$. The formation of the alkyl nitrites in these reactions may be considered as a secondary effect. The nitroparaffins are less stable than the alkyl nitrites when heated; and more stable in the presence of water. The fact that while silver nitrite in soln. forms metallic silver and nitric acid, silver nitrate is quite unaffected, is taken by E. Divers to mean that while hydrogen can separate silver from oxygen, it cannot separate it from nitrogen, and that in the nitrites silver must accordingly be directly united with hydrogen, $H.N : O_2$, and in the nitrates with oxygen, $HO.NO_2$. V. von Richter favoured the same hypothesis. P. C. Ray and P. Neogi have also shown that nitrites of potassium, sodium, barium, or calcium with ethyl alcohol and sulphuric acid give ethyl nitrite, $C_2H_5O.NO$, and nitroethane, $C_2H_5.NO_2$. With the alkali salts traces of *nitrobutane*, $C_4H_9.NO_2$, are also formed. This is taken to mean that the **metal nitrites have both a nitronic or imidic structure, M.N : O_2, and a hydroxylic structure, MO.N : O, that is, the salts are desmotropic.** F. Raschig found that when nitrous acid, or rather sodium nitrite, is reduced by stannous chloride, about 90 per cent. furnishes nitrous oxide, and 10 per cent. hyponitrous acid and hydroxylamine; the nitrite soln. contains

$$Na—N\Big\langle\begin{smallmatrix}O\\O\end{smallmatrix}\rightleftharpoons NaO—N=O$$

about 10 per cent. of the former, and 90 per cent. of the latter. H. Burgarth, H. Remy, and H. Henstock discussed the electronic structure.

§ 38. The Nitrites

The occurrence of **ammonium nitrite**, NH_4NO_2; and its formation during the combustion of many substances in air; during the evaporation of water; by the oxidation of ammonia in air in the presence of a catalytic agent; by electrical discharges in moist air; by oxidizing ammonia with hydrogen dioxide or potassium permanganate; and during the decay of organic substances in air, have been previously discussed. J. J. Berzelius[1] prepared ammonium nitrite by treating lead nitrite with ammonium sulphate, or silver nitrite with ammonium chloride. M. Berthelot used barium nitrite and ammonium sulphate; and he also obtained it from ammonia, nitric oxide, and oxygen. P. Neogi and B. B. Adhicary obtained ammonium nitrite in fairly large quantities by evaporating and subliming in vacuo a very conc. soln. of a mixture of ammonium chloride and sodium or potassium nitrite. N. A. E. Millon obtained ammonium nitrite, mixed with the nitrate, by passing the gases obtained in the thermal decomposition of lead nitrate into aq. ammonia. The filtrate in all these cases can be evaporated in vacuo over quicklime. O. L. Erdmann, and S. P. L. Sörensen have discussed the preparation of this salt.

In their process, the mixture of nitrogen oxides evolved during the action of arsenic trioxide on nitric acid is passed over coarsely powdered ammonium carbonate kept cool by ice. The half liquid mass is treated with alcohol, the unchanged carbonate filtered off, and the ammonium nitrite precipitated by the addition of ether. The nitrite so obtained is of 90–94 per cent. purity, and may be purified by re-solution in 96 per cent. alcohol and reprecipitation with ether.

Ammonium nitrite furnishes white, needle-like crystals which are very deliquescent. M. Berthelot said that the aq. soln. has a neutral reaction; and he gave for the heat of formation, $(2N,4H,2O)=64{\cdot}8$ Cals.; and J. Thomsen, $(N_2,2H_2O) = -71{\cdot}77$ Cals. P. C. Ray and co-workers found that ammonium nitrite gradually changes into nitrate; even during the process of crystallizing the aq. soln., traces of the nitrate are formed, and this the more the higher the temp. According to M. Berthelot, the solid salt decomposes very slowly in winter, and rapidly in summer: $NH_4NO_2=N_2+2H_2O$, and it cannot therefore be preserved in a sealed glass tube; S. P. L. Sörensen said that the purified dry salt can be safely kept in an atm. of hydrogen, and in the presence of ammonium carbonate and calcium oxide. It is best kept and transported under dry ether, free from alcohol. M. Berthelot observed that when the solid is heated on a water-bath, it appears quiescent for a few moments, and then detonates violently; it also detonates by percussion. If gradually heated on platinum foil, it volatilizes very quickly; and if placed on a hot foil, it burns with a pale flame. Although when heated in the ordinary way, the salt decomposes into nitrogen and water, there is a side reaction, for, as noted by Lord Rayleigh and W. Ramsay, some ammonia is formed, presumably: $3NH_4NO_2=NH_4NO_3+2NO+2NH_3+H_2O$; and the nitrate yields nitrous oxide as indicated by J. J. Berzelius. P. C. Ray and co-workers noticed that when heated under reduced press., the salt begins to sublime at about 32°–33°, and the temp. can be safely raised to 60° without the substance undergoing decomposition. The sublimate appears as a transparent, compact mass of crystals. They found that the sublimed salt is quite colourless, and absolutely devoid of the green tint. It is less hygroscopic, and far less liable to decomposition than the ordinary salt. When kept open in a desiccator the sublimed substance does not change, even after the lapse of five or six days, but slowly diminishes in weight from day to day. When kept, however, in a vacuum sealed tube, the salt can be preserved for any length of time. The crystals in the vacuum tube can be made to pass from one part to another by the application of gentle heat. The pure salt can be resublimed in a vacuum without any decomposition or residue of ammonium nitrate, provided the temp. of the bulb does not exceed 60°. Ammonium nitrate under similar conditions does not vaporize or decompose. This difference in property has been utilized in completely separating ammonium nitrite from the nitrate, with which it is often more or less admixed. Although there is a little decomposition, the vap. density can be determined, and it yields 32·0–35·0 when the theoretical value is 32·0.

M. Berthelot reported that the conc. aq. soln. decomposes more rapidly than the solid, and when shaken froths like champagne; and J. J. Berzelius said that the dil. aq. soln. decomposes at 50° into nitrogen and water so that the liquid retains its neutrality. The salt is readily soluble in water, and, added S. P. L. Sörensen, with the development of heat; it is readily but slowly dissolved by alcohol, and is precipitated from this soln. by ether, chloroform, or ethyl acetate. The conc. aq. soln. decomposes explosively like the solid when heated to 60°–70°, and with an acidified soln., the decomposition sometimes occurs at ordinary temp. N. A. E. Millon found that the decomposition is slow or fast according as the soln. is alkaline or acid. A single drop of ammonia added to the neutral soln. is sufficient to render the decomposition gradual, while a single drop of hydrochloric, nitric, or sulphuric acid causes it to take place suddenly. K. Arndt said that soln. of ammonium nitrite, prepared from silver nitrite and ammonium chloride, become alkaline after a certain time owing to the formation of ammonia; but V. H. Veley denied this. K. Arndt found that the addition of ammonia retards the decomposition, and V. H. Veley, that the decomposition is retarded or stopped by oxides, like calcium oxide, which liberate ammonia in the soln. It is also retarded by aliphatic or aromatic amines, by hydrazines, and to a less degree by amines. The decomposition is accelerated temporarily by the aliphatic amides, but not by other amides; it is also accelerated by benzoic sulphimide. E. Bohlig showed that very dil. soln. may be evaporated on the water-bath without decomposition; and A. Schöyen added that a soln. with one hundred-thousandth part of salt can be half distilled without the salt decomposing; a soln. with one five-hundredth part of salt when half distilled has 8·6 per cent. in the distillate and 82 per cent. in the retort, and 9·4 per cent. has decomposed. O. Löw found that the presence of platinum-black causes the dil. aq. soln. to decompose at ordinary temp.—a trace of nitric oxide is formed in the early stages of the decomposition. F. E. Brown measured the equilibrium press. V. H. Veley said that the addition of finely-powdered barium sulphate temporarily favours the evolution of gas. A. Angeli and G. Boeris said that the addition of salts with a common ion—say, sodium nitrite or ammonium chloride—accelerates the evolution of nitrogen, and hence inferred that the stability of very dil. soln. on the assumption that the salt is all ionized; but R. Wegscheider said that the inference might also be made that the reaction takes place between the two ions: $NH^{\cdot}_4+NO'_2=2H_2O+N_2$. A. A. Blanchard working with this hypothesis found that the only agents which accelerate decomposition are hydrogen ions and free nitrous acid. The presence of the acid involves a secondary reaction, in which nitric oxide is liberated, but the primary decomposition of nitrite is found to be independent of this. The gas evolved in the decomposition of the nitrite contains no nitrous oxide. The rate of decomposition is proportional to the concentration of $NH^{\cdot}_4$ and NO'_3, but it is probable that two independent processes go on simultaneously, each resulting in the liberation of nitrogen. V. H. Veley found that the start of the decomposition is very slow, owing, presumably, to the retention in the soln. of nitrogen gas; the reaction then rapidly increases to a maximum and afterwards decreases in accord with the unimolecular law $\log \{a/(a-x)\}=kt$, whether the reaction follows its normal course, or is accelerated by the addition of another substance. W. Biltz and W. Gahl showed that the reaction, apparently unimolecular in the presence of other salts, may be bimolecular with a soln. of ammonium nitrite alone; and they add that the change takes place between ammonium nitrite and the nitrous acid produced by the hydrolysis of the salt. P. C. Ray and S. C. Mukherjee observed that with dilutions 18·0 and 20·0 litres the degree of ionization of the salt is 0·91 and 0·81 respectively; and P. C. Ray and N. R. Dhar found the eq. conductivities of the soln. at dilutions $v=20{\cdot}7$, 62·1, 186·3, and 558·9 litres, are respectively 96·72, 104·54, 107·69, and 110·92, and the value at infinite dilutions is 126·3 at 20°. T. J. Pelouze examined the action of sulphuric acid on ammonium nitrite. N. R. Dhar showed that copper, zinc, etc., dissolve copiously in a soln. of ammonium nitrite, or in a soln. of a soluble nitrite and an ammonium salt, and that the result is not due as K. A. Hofmann and G. Buhk supposed to the hydrolysis of the nitrite and the formation of free nitrous acid, because the metal is attacked even in the presence of urea which destroys the nitrous acid, and soln. of nitrite which are hydrolyzed—*e.g.* zinc, nitrite —do not attack copper. The action is attributed to the instability of ammonium nitrite and its ready decomposition into nitrous oxide and water. D. Berthelot and H. Gaudechon said that a soln. of ammonium nitrite is decomposed when exposed to ultra-violet light, and that nitrogen is in consequence evolved. M. Holmes was unable to confirm this. The very slight difference in the results with soln. exposed to ultra-violet light and kept in darkness for 9 hrs. is fully explained as purely thermal effects. P. C. Ray and J. N. Rakshit described a number of alkylammonium nitrites.

According to C. Paal, **hydroxylamine nitrite** is formed in aq. soln. when a 2 per cent. aq. soln. of hydroxylamine chloride is treated with silver nitrite at 0°. No evolution of gas occurs. It will be observed that hydroxylamine nitrite, $NH_3OH(NO_2)$, and ammonium nitrate, NH_4NO_3, are isomeric. A. P. Sabanéeff and co-workers observed a number of analogous cases. When hydrazine is treated with nitrous acid, T. Curtius showed that the nitrite primarily formed decomposes: $N_2H_4+HNO_2=N_3H+2H_2O$—*vide* hydrazoic acid. According to A. W. Browne and O. R. Overman, potassium nitrite oxidizes hydrazine sulphate in sulphuric acid with the formation, under comparable conditions, of larger yields of azoimide and of much smaller yields of ammonia than are obtained by the action of hydrogen peroxide on hydrazine sulphate. B. B. Dey and H. K. Sen found that soln. of the metal nitrites react vigorously with hydrazine sulphate, even at 0°, evolving 2 vols. of nitrous oxide and one vol. of nitrogen; this agrees neither with the assumed existence of hydrazine mononitrite nor dinitrite. F. Sommer pointed out that the failure of B. B. Dey and H. K. Sen to prepare hydrazine nitrite from barium nitrite and hydrazine sulphate is due to the normal sulphate usually containing some disulphate as impurity, and it then behaves as an acid salt. Normal **hydrazine nitrite,** $N_2H_5NO_2$, was obtained by mixing solutions of barium nitrite and neutral hydrazine sulphate, stirring to convert the thick, gelatinous barium sulphate into the crystalline form, and filtering by means of a vacuum. The stable solution is then evaporated in a vacuum over phosphoric oxide. The oil thus obtained does not crystallize spontaneously, but does so on inoculating with a small quantity of solid obtained by extracting a portion with methyl alcohol, partly precipitating with ether, and cooling in ether and solid carbon dioxide. The solid salt is almost white, but becomes yellow on fusion. It is hygroscopic, and dissolves readily in alcohol, but not in ether, and may be obtained from a mixture of these in large, probably monoclinic, prisms. It explodes violently with a blow, less vigorously if rapidly heated. Hydrazine nitrite decomposes according to the equation $N_2H_5NO_2=NH_3+N_2O+H_2O$, and this decomposition is very greatly accelerated by nitrous acid. The preparation of **hydrazine dinitrite,** $N_2H_6(NO_2)_2$, in aq. soln., is thus impossible, as the weakly basic character of hydrazine would cause the salt to be so far hydrolyzed that much nitrous acid would be present in the solution. If hydrazine disulphate and barium nitrite react together, the products are ammonium nitrite and nitrous oxide. The decomposition of hydrazine nitrite is thus due to the action of nitrous acid on the undissociated compound, and is autocatalytic. The secondary reaction, the formation of hydrazoic acid from hydrazine and nitrous acid, is due to the action of nitrous acid on the N_2H_5 ion.

Methods for the preparation of the alkali nitrites have been indicated in connection with nitrous acid. J. J. Berzelius,[2] E. Mitscherlich, N. W. Fischer, and J. Lang described the preparation of **potassium nitrite,** KNO_2, or of **sodium nitrite,** $NaNO_2$, by keeping the nitrates in a state of fusion for some time alone, or mixed with lead (W. Hampe, S. Feldhaus, and A. Stromeyer). The process was discussed by A. Lottermoser, and E. W. Albrecht. According to J. Milbauer, the reduction of sodium nitrate to nitrite is best effected by heating the salt with an excess of 15 per cent. of granulated lead. The reaction commences at the m.p. of the nitrate, and, after 2 hrs. at 420°, complete reduction is obtained, but less lead than the theoretical amount is oxidized owing to a certain proportion of the salt being decomposed thermally with the evolution of oxygen. Other reducing agents can be employed—*e.g.* iron (O. L. Erdmann, and Balzer and Co.) ; copper (J. Persoz) ; ferrous oxide (Chemische Fabrik Grünau) ; manganous, chromic, or arsenious oxide in the presence of free alkalies or alkaline earths (C. Huggenberg) ; sulphur (L. G. Paul) ; sulphur or pyrites (Chemische Fabrik Leopoldshall) ; calcium sulphide (J. Grossmann) ; barium sulphide (G. A. le Roy, and Y. Okae) ; zinc blende (L. Elsbach and B. Pollini) ; galena (H. N. Warren, and M. Bartsch and M. Harmsen) ; anhydrous sulphites (Chemische Fabrik Gränau, and A. Étard) ; carbon (A. Knop) ; calcium carbide (E. Jacobsen) ; starch (R. Warington). G. Tacchini compared the results by using manganese dioxide, ferric oxide, barium oxide, cobalt oxide, nickel oxide, cerium dioxide, and thorium dioxide, and obtained the best results by heating the sodium nitrate with 25 per cent. of barium oxide or manganese dioxide at 650°. Molten alkali nitrate was also reduced to nitrite by exposure to carbon monoxide (M. Goldschmidt) ; or producer gas (G. de Bechi and A. Thibault) or hydrogen (E. T. Chapman). A. Müller reduced an aq. soln. of sodium nitrate by electrolysis with an amalgamated copper cathode ; C. Stahlschmidt reduced an aq. soln. of potassium nitrate with zinc. J. L. Gay Lussac, and J. Fritzsche passed nitrogen trioxide or peroxide gases into alkali-lye. E. Divers recommended this process, and said that it is a mistake to suppose that the soln. contains much nitrate. It can be made with so little nitrate that the impurity can scarcely be detected.

Avoiding, so far as practicable, the use of cork and caoutchouc, nitrous gases, from nitric acid and starch or arsenious oxide, are passed into the concentrated soln. of the hydroxide or carbonate until the alkali is quite neutralized. Sodium carbonate alone is somewhat inconvenient, because of its sparing solubility, but this may be circumvented by adding it, finely divided and in sufficient quantity, to its own saturated soln., just before passing the gases and by often shaking the vessel during their absorption. To prevent free access of air, the nitrite is prepared in a flask with its mouth kept loosely closed while the gases are passing ; it is not necessary to cool the flask. The strength of the nitric acid and the temperature of the generator of the nitrous gases must be regulated that just a little nitric oxide is in excess of the nitric peroxide, and therefore is passing unabsorbed, as a guarantee that the latter does not act on the soln. in absence of its equivalent of the former and thus produce some nitrate. To free the gases from volatilized nitric acid, they may be passed through a bottle or tube, either empty or packed loosely with cotton.

The finished soln. must be almost neutral, and if acid must be boiled until neutral, before exposing it to the air. A conc. soln. of alkali nitrite dissolves a little nitrous acid without decomposing it, as water alone would. To obtain the salt in the solid state or to crystallize out the sodium nitrite where it is necessary to be sure of absence of all nitrate in it, the soln. may be freely evaporated, even at boiling heat, without decomposing or oxidizing it.

The production of the nitrites by the arc process of nitrogen fixation has been previously discussed. H. K. Benson made sodium nitrite from the gases obtained in the arc process of nitrogen fixation ; and the Nitrum Aktien-Gesellchaft, from the gases obtained in the oxidation of ammonia. G. A. le Roy prepared alkali nitrite by the action of nitric oxide on barium dioxide followed by treatment with an alkali salt. H. N. Warren obtained the nitrite synthetically by passing a mixture of ammonia and oxygen over platinized asbestos and then into alkali-lye. J. J. Berzelius, and J. Lang treated barium or lead nitrite with potassium carbonate, or silver nitrite with potassium chloride ; H. Schwarz saponified amyl nitrite with alcoholic potash. J. Lang obtained **lithium nitrite,** $LiNO_2$, by the action of lithium chloride on silver nitrite ; and F. Vogel, and W. C. Ball and H. H. Abram, by the action of lithium sulphate on barium nitrite.

The sodium salt was analyzed by C. H. Hess, J. Lang, W. Hampe, M. Oswald, and E. Divers, and it is anhydrous ; but J. Lang, and W. Hampe found the magma of crystals of potassium nitrite dried in vacuo to be **hemihydrated potassium nitrite,** $KNO_2.\frac{1}{2}H_2O$. E. Divers, M. Oswald, and P. C. Ray, however, found the air-dried salt to lose about one per cent. in weight by fusion, and hence inferred that this salt, too, is anhydrous. J. Lang, and F. Vogel say that **hemihydrated lithium nitrite**, $LiNO_2.\frac{1}{2}H_2O$, is formed when the salt is dried in a current of dry hydrogen. M. Oswald obtained this salt and also **monohydrated lithium nitrite,** $LiNO_2.H_2O$; the transition temp. is 49°, and the conditions of equilibrium are illustrated by Fig. 77. P. C. Ray, and W. C. Ball and H. H. Abram found that it crystallizes as the *monohydrate*, $LiNO_2.H_2O$, in white, flat, needle-shaped crystals from its aq. soln. All the alkali nitrites can be dehydrated in vacuo, over phosphorus pentoxide, without undergoing decomposition.

All these alkali nitrites furnish crystalline masses. E. Divers said that sodium and potassium nitrites are a faint yellow colour, and give yellow soln. with water. W. C. Ball and H. H. Abram, and M. Oswald said that the lithium salt is white. The lithium and sodium salts are deliquescent, and the potassium salt is very much so. Potassium nitrite furnishes small, thick, prismatic crystals, and sodium nitrite often gives large flat prisms, which, according to A. Fock, belong to the rhombic system, and have the axial ratios $a : b : c = 0{\cdot}6399 : 1 : 0{\cdot}9670$. M. Oswald gave 1·912 at 0°/0° for the sp. gr. of potassium nitrite which has been fused ; 2·168 at 0°/0° for the sodium salt ; and 1·615 at 0°/0° for monohydrated lithium nitrite. The sp. gr. of a soln. of potassium nitrate with 10 per cent. of salt is 1·049 ; with 30 per cent., 1·208 ; with 50 per cent., 1·377 ; and with 70 per cent., 1·599. J. G. Bogusky said the change in the sp. gr. of a soln. with conc. can be represented by a straight line being at 19·23°/19·23°, for 2·63, 20·11, and 48·89 per cent. soln. respectively 1·0174, 1·1401, and 1·3451. A sat. soln. of the potassium salt has a sp. gr. 1·6464 at 17·5°, it contains 74·5 per cent. of salt, and its b.p. is 132° at 758·5 mm. ; that of the sodium salt has a sp. gr. 1·3585 at 20°, it contains 45·8 per cent. of salt, and its b.p. is 128° at 761·5 mm. ; and that of the lithium salt has a sp. gr. 1·3186 at 19°, and it contains 48·9 per cent. of anhydrous salt. P. Rehbinder found at 20°, the surface energy, σ ergs per sq. cm., and the sp. gr., D, at 20°/4°, for soln. with p per cent., of water :

p	24·6	34·2	50·0	70·0	80·0	100·0
D	1·635	1·530	1·361	1·192	1·111	0·9982
σ	95·0	88·0	81·7	77·4	76·0	72·75

P. W. Bridgman found that potassium nitrite exhibited a polymorphic transition at the following press., p kgrms. per sq. cm., and temp. ; and it also exhibited the change in vol., δv c.c. per gram; the effect of press. on the transition temp., $d\theta/dp$; the latent heat of the transformation, L kgrm.-metres per gram; and the change of energy, E, kgrm. m. per gram:

p	5000	6000	7000	8000	9000	9500	10,000
θ	−3·0°	14·0°	31·4°	50·8°	74·4°	89·4°	109·3°
δu	0·0312	0·0327	0·0341	0·0355	0·0369	0·0376	0·0383
$a\theta/dp$	0·0169	0·0171	0·0182	0·0212	0·2274	0·0343	0·0472
H	4·99	5·49	5·71	5·42	4·68	3·97	3·10
E	3·43	3·53	3·32	2·58	1·36	0·40	−0·73

E. Divers, and W. C. Gangloff found the m.p. of the sodium salt to be 271°; C. Matignon and G. Marchal, 276·9°; M. Oswald gave 217° for this salt; 297·5° for the potassium salt; and 97° for the hemihydrated lithium salt. According to P. C. Ray, when potassium nitrite is heated the first stage of the decomposition involves two concurrent reactions: $3KNO_2=K_2O+KNO_3+2NO$; and $4KNO_2=K_2O+2KNO_3+NO+N$. Afterwards, nitric oxide, oxygen, and nitrogen are evolved, part of the nitric oxide and oxygen being absorbed by the alkali oxide which is formed: $K_2O+2NO+O=2KNO_2$. As the temp. rises more oxygen is evolved, together with nitric oxide, and nitrogen peroxide. P. C. Ray suggested that as a result of the purely thermal decomposition, a portion of the salts breaks up into the peroxide and nitric oxide, but as the former is unstable, especially under diminished press. at the temp. at which the scission takes place, it parts with its oxygen both to the nitric oxide and also to the remaining portion of the undecomposed salt in a state of fusion, and that it is in this way that the internal oxidation and reduction are brought about. M. Oswald found that the temp. of decomposition at about 0·05 mm. press. is 185° for anhydrous lithium nitrite; 320° for sodium nitrite; and 350° for potassium nitrite. C. Matignon and G. Marchal gave $(N_{gas},O_{2gas},Na)=88{\cdot}2$ Cals.; and $HNO_{2soln.}+NaOH_{soln.}=NaNO_{2soln.}+H_2O+11{\cdot}1$ Cals.; $2NaNO_{2soln.}+H_2SO_{4soln.}=Na_2SO_{4soln.}+2HNO_{2soln.}+9{\cdot}2$ Cals.; and the heat of soln., $(NaNO_2,Aq.)=-3{\cdot}52$ Cals. C. Matignon and E. Monnet gave for the heat of oxidation $2NaNO_{2solid}+O_{2gas}=2NaNO_{3solid}+45$ Cals. According to M. Berthelot and J. Ogier, the heat of the reaction $(N_2O_{3aq.}K_2O_{aq.})=10{\cdot}6$ Cals. H. Helberg found that the mol. depression of the f.p. of sodium nitrite is normal, and does not show the irregularities recorded by M. Oswald. G. Tammann found the lowering of the vap. press. of water at 100° by the addition of 14·02, 110·03, and 229·01 grms. of potassium nitrite per 100 grms. of water to be respectively 36·9 mm., 241·1 mm., and 370·5 mm.; and with 3·02, 56·85, and 111·71 grms. of sodium nitrite per 100 grms. of water, respectively 10·1 mm.; 194·0 mm.; and 318·3 mm. J. G. Bogusky found the index of refraction, μ, of soln. of sodium nitrite at 20°, and the D-line, is $\mu=1{\cdot}33336+0{\cdot}0011559w$, where w denotes the per cent. $NaNO_2$ in soln. R. Robl observed no fluorescence with the salt in ultra-violet light. M. Schümann gave for the eq. conductivity, λ, of sodium nitrite, one mol in v litres, at 25°:

v	32	64	128	256	512	1024	∞
λ	102·0	104·4	107·2	109·6	110·8	113·0	115·5

so that $\lambda_{1024-32}=11{\cdot}0$. S. von Niementowsky and J. von Roszkowsky obtained higher values with probably a less purified sodium salt; for potassium nitrite, they gave:

v	32	64	128	256	512	1024	2048
λ	147·7	151·1	155·1	158·6	161·9	166·9	172·7

P. C. Ray and N. R. Dhar also measured the electrical conductivities of soln. of potassium and sodium nitrites, and they found for lithium nitrite, at 20°:

v	6	18	54	162	486	∞
λ	70·32	75·00	91·52	100·00	102·05	93·7

P. C. Ray and S. C. Mukherjee found the degrees of ionization of potassium nitrite of dilutions v=16·0 and 36·0 litres to be respectively 0·86 and 0·91 ; and for sodium nitrite for v=10·0 and 20·5 litres, respectively 0·87 and 0·91. F. H. Jeffrey found that the electrolysis of soln. of sodium nitrite with aluminium electrodes resulted in the formation of aluminium hydroxide, and nitric oxide, while nitric acid was found in the anolyte. The primary product at the anode is probably aluminium nitrite which is hydrolyzed to nitrous acid and aluminium hydroxide ; and the nitrous acid then forms nitric oxide and nitric acid.

J. Obermiller measured the hygroscopicity of potassium nitrite. E. Divers said that at 15°, potassium nitrite is soluble in about one-third its weight of water ; and 5 parts of sodium nitrite require 6 parts of water for dissolution ; and J. Lang added that lithium nitrite is easily soluble in water. W. C. Ball and H. H. Abram found that lithium nitrite melts below 100° in its water of crystallization ; it is dehydrated rapidly at 160° and at the same time loses traces of nitrogen oxides. It is very soluble in water, and a sat. soln. at ordinary temp. contains 90 grms. of the monohydrate per 100 c.c. of soln. It is only sparingly soluble in absolute alcohol, whereas the potassium salt is fairly soluble. M. Oswald's solubility curves are shown in Figs. 75–77. The ice-curve with potassium nitrite falls to the eutectic at —31·6° with 71·8 per cent. KNO_2 ; and the solubility represented by the amount of salt, S, dissolved by 100 parts of water, is :

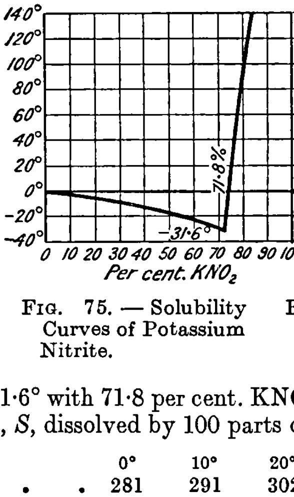

FIG. 75. — Solubility Curves of Potassium Nitrite.

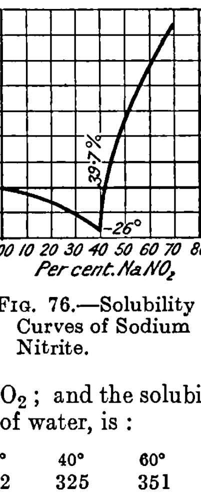

FIG. 76.—Solubility Curves of Sodium Nitrite.

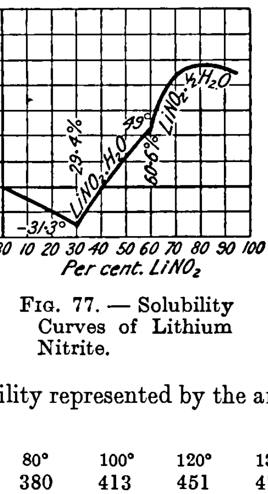

FIG. 77. — Solubility Curves of Lithium Nitrite.

	0°	10°	20°	40°	60°	80°	100°	120°	130°
S . .	281	291	302	325	351	380	413	451	473

and for θ° between —30° and 130°, $S=(600\theta+656600)/(2334-6\theta)$. The ice-curve with sodium nitrite has a eutectic at —15·5° with 39·7 per cent. of $NaNO_2$; but H. Helberg showed that the eutectic is at —26° with 38 per cent. of sodium nitrite ; and the solubility, S, is :

	0°	10°	20°	40°	60°	80°	100°	120°
S . .	73	78	84	98·5	116	136	160	198·5

The ice-curve with lithium nitrite has a eutectic at —31·3° with 29·4 per cent. of $LiNO_2$. There is a transition point at 49° and 60·6 per cent. $LiNO_2$ corresponding with the change : $LiNO_2.H_2O \rightleftharpoons \frac{1}{2}H_2O+LiNO_2.\frac{1}{2}H_2O$. The solubility, S, parts of the monohydrate in 100 parts of water, is :

	0°	10°	20°	30°	40°	50°
S	125	156	189	242	316	459

J. Lang, and W. Hampe said that in 90 per cent. alcohol, potassium nitrite forms an oily liquid ; it is insoluble in 94 per cent. alcohol ; and absolute alcohol precipitates the salt almost quantitatively from a conc. aq. soln. Sodium nitrite dissolves in warm 90 per cent. alcohol—it is scarcely soluble in 94 per cent. alcohol ; but absolute alcohol does not precipitate much salt from conc. aq. soln. C. A. L. de Bruyn found 0·31 grm. of sodium nitrite dissolves in 100 grms. of absolute ethyl alcohol at 19·5°. J. Lang said lithium nitrite is easily soluble in alcohol. E. C. Franklin and C. A. Kraus found sodium nitrite is soluble in liquid ammonia. J. Lang said the aq. soln. of potassium, sodium, and lithium nitrite are feebly alkaline; W. Hampe said neutral. H. Ley found the soln. of sodium nitrite, in water free from carbon dioxide, is alkaline to litmus, and neutral to phenolphthalein; C. Matignon and G. Marchal said that nitrous acid resembles nitric acid in its behaviour towards phenolphthalein, cochineal, litmus, *p*-nitrophenol, brazilin, and iodoeosin; but decomposes others—*e.g.* helianthin; and H. Friedenthal, and E. Salm found the neutral point of phenolphthalein corresponds with $10^{-9}N$-hydrogen ions; it follows that the conc. of the OH′-ions in the soln. will approximate $10^{-5}N$-soln. M. Oswald said that in conc. aq. soln., appreciable hydrolysis occurs at 100°: $3KNO_2+H_2O=2NO+2KOH+KNO_3$. J. Lang said that the aq. soln. of the alkali nitrites *nimmt langsam in Lösungen Sauerstoff auf*, but E. Divers has shown that these soln. can be safely evaporated on a water-bath, even at the boiling temp., without decomposition or oxidation; while P. C. Ray kept soln. evaporating spontaneously in flat dishes exposed to air between 25° and 30° for 2 months without the formation of an appreciable quantity of nitrate; and C. Russworm kept a soln. with 0·048 grm. KNO_2 per litre for a year without change. M. Oswald also detected no oxidation of the conc. soln. by oxygen at atm. press.; the aq. soln. are oxidized only in the presence of acids, and this is rather due to the oxidation of the decomposition products—nitric oxide—derived from nitrous acid itself. C. C. Palit and N. R. Dhar found that soln. of sodium nitrite are oxidized by air in the presence of ferrous hydroxide; W. P. Jorissen and C. van den Pol observed that sodium sulphite has no influence on the oxidation of soln. of sodium nitrite. W. Reinders and S. I. Vles found that pure sodium nitrite is not oxidized by oxygen in neutral or alkaline soln., but in the presence of a small quantity of nitric or other acid, it is converted into sodium nitrate. It is assumed that the formation of nitric oxide is an intermediate stage in the oxidation; the free nitrous acid is first oxidized to nitric oxide, nitrogen peroxide, and water; this is followed by the oxidation of nitric oxide to nitrogen peroxide; this reacts with water to form nitric oxide and nitric acid, which yields sodium nitrate and nitrous acid. Potassium nitrite behaves similarly. All strong acids produce the same effect, but the salts have no catalytic influence. The accelerating influence of iron and aluminium salts is due to their hydrolysis. N. R. Dhar also said that the oxidation of soln. of sodium nitrite by atm. oxygen can be induced by the simultaneous oxidation of sodium sulphite, stannous chloride, the hydroxides of manganese and cobalt, acetic acid, aldehyde, benzaldehyde, etc., by air. B. C. Banerji and N. R. Dhar found that the oxidation with iodine is sensitive to light. N. N. Mittra and N. R. Dhar observed that the oxidation of sodium sulphite by air is hastened by the simultaneous oxidation of sodium nitrite as a secondary reaction; but W. P. Jorissen and C. van den Pol found that sodium sulphite does not induce the oxidation of sodium nitrite by air or oxygen under ordinary conditions. C. Matignon and G. Marchal observed that an aq. soln. of sodium nitrite is not oxidized by prolonged contact with oxygen under a press. of 50–55 atm., even in the presence of a catalyst; but in an atm. of oxygen at 175 atm. and 395°–530° during 9 hrs., solid sodium nitrite is almost completely oxidized to nitrate—*vide supra*, nitrous acid. T. L. Bailey found that the loss of nitrite when sodium nitrite is dissolved in sulphuric acid of varying conc., and the soln. treated with a current of air, is a maximum with acid of sp. gr. 1·0–1·47. For the action of sulphurous and arsenious acids, *vide* the respective acids. H. Stamm measured the solubility of sodium nitrite in aq. ammonia. The dry nitrites are not attacked by nitric oxide, so long as the salt does not decompose. The salt is attacked by nitrogen peroxide: $NaNO_2+NO_2=NaNO_3+NO$; and $2NaNO_2+NO_2=2NaNO_3+N$. These reactions can take place when the nitrite is undergoing thermal decomposition when nitrogen peroxide is one of the products of the reaction. T. Curtius noted that ammonium chloride reacts with sodium nitrite, and when heated, nitrogen and sodium chloride are formed, presumably owing to the intermediate formation of ammonium nitrite. D. Tommasi said that if a crystal of ammonium chloride, sulphate, or nitrate be added to molten potassium nitrite, luminescence occurs. J. W. van Geuns found that a mixture of potassium nitrite and cyanide burns when ignited, but at 450° explodes violently. A. Angeli found that a mixture of sodium nitrite and thiocyanate detonates when heated—nitrohydroxylamine is stated to be an intermediate product of the reaction. According to W. Traube, sodium nitrite swells up considerably when exposed to the action of sulphur trioxide, forming a colourless, crystalline mass of **sodium nitroxyltrisulphonate,** $Na(SO_3)_3NO_2$, which is decomposed by water with the vigorous evolution of oxides of nitrogen. A. P. Lidoff observed that hyposulphurous acid reacts with a soln. of potassium nitrite, forming a hydroxylamine (*q.v.*). According to A. Gutmann, sodium thiosulphate does not act on a cold or boiling soln. of sodium nitrite; a mixture of the two is explosive. In a sealed tube at 100°, a mixture of sodium nitrite and calcium thiosulphate reacts: $2NaNO_2+2CaS_2O_3+4H_2O=2CaSO_3+Na_2SO_4+(NH_4)_2SO_4$. K. A. Hofmann and G. Buhk found that carbon monoxide is absorbed very slowly by a soln. of sodium nitrite. A soln. of sodium nitrite in the presence of an ammonium salt and copper gives off nitrous oxide. N. R. Dhar measured the solubility of ammonia and of carbon dioxide soln. of potassium nitrite. B. Suler studied the electro-reduction of potassium nitrite soln. whereby ammonia and hydroxylamine are formed.

R. H. Robinson found sodium nitrite to be unsuitable as a fertilizer, particularly in acid soils, owing to losses of nitrogen by decomposition. According to C. Marie and R. Marquis, nitrous acid is liberated from aq. soln. of the alkali nitrites by carbon dioxide, so that a strip of potassium iodide-starch paper suspended over the liquid is coloured blue. O. Baudisch found that the reduction of nitrite by potassium ferrocyanide and oxygen is sensitive to light. M. Oswald found that the presence of sodium sulphate lowers the solubility of sodium nitrite enormously—at 16°, a sat. soln. of the nitrite alone has 81·6 per cent. $NaNO_2$, but a sat. soln. of both salts together has 11·8 per cent. sodium sulphate, and 53·9 per cent. of sodium nitrite. The curves for the mutual solubility of sodium nitrite and nitrate at different temp. are shown in Fig. 78. The curve *AB* represents a soln. with two solid phases in equilibrium. There is no evidence of the formation of a double salt. E. B. Maxted found that when soln. of metallic sodium and sodium nitrite in liquid ammonia are mixed together yellow **disodium nitrite,** Na_2NO_2, is formed. The same substance is deposited on the cathode when a soln. of sodium nitrite in perfectly anhydrous liquid ammonia is subjected to electrolysis. The substance is decomposed vigorously by water with the formation of sodium nitrite, sodium hydroxide, and hydrogen. By passing a current of moist nitrogen over the disodium nitrite, the action is moderated, and the resulting soln. is found to be free from hydroxylamine and hyponitrite. According to W. Peters, when copper is warmed with a 5 per cent. aq. soln. of sodium nitrite at 60°, in the presence of carbon dioxide so as to exclude air, the gases contain nitrous and nitric oxides, and the soln. copper nitrate. The decomposition is chemical, not catalytic, and involves simultaneous oxidation and reduction. Lead, iron filings, and cobalt dissolve in the soln. without evolving gas, and, in the case of cobalt, sodium cobaltic nitrite is formed. F. E. Brown and J. E. Snyder observed no reaction with sodium nitrite and vanadium oxychloride. W. W. Lewis and co-workers discussed the use of sodium nitrite in the curing of meat.

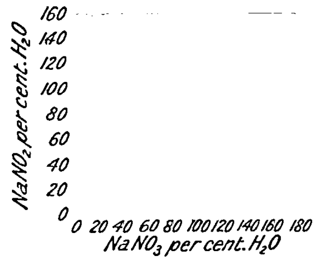

FIG. 78.—Solubility Curves of Mixed Solutions of Sodium Nitrite and Nitrate.

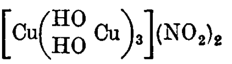
W. C. Ball and H. H. Abram prepared **rubidium nitrite,** $RbNO_2$, from soln.

of rubidium chloride and silver nitrate ; or preferably, barium nitrate and rubidium sulphate because the reaction with silver nitrite is complete only when all that salt is in soln., and it is a sparingly soluble salt. The evaporation of the soln. gives a pale yellow, deliquescent, crystalline mass. The salt retains only a little water at 100°. It is very soluble in water, and sparingly soluble in hot absolute alcohol. G. S. Jamieson prepared **cæsium nitrite,** $CsNO_2$, as a pale yellow, hygroscopic, indistinctly crystalline mass, from soln. of silver nitrite and cæsium chloride, or better, according to W. C. Ball and H. H. Abram, from barium nitrite and cæsium sulphate.

Normal **copper nitrite,** $Cu(NO_2)_2$, has not been definitely isolated in the solid state, but E. Péligot[3] claimed to have obtained it by keeping dihydrated cupric diamminonitrite for some days at 100°. J. J. Berzelius obtained a green liquid by the action of copper sulphate on lead nitrite. The soln. oxidizes in air, or when warmed, forming copper nitrate. When prepared in aq. media, H. Bassett and R. G. Durrant showed that cupric nitrate undergoes complex changes, and at ordinary temp., nitric oxide is evolved. E. Divers and T. Haga found that the dark green liquid, obtained by the action of copper on a soln. of silver nitrate or by mixing soln. of copper sulphate and potassium nitrate, contains some hydroxylamine. P. C. Ray obtained a dark green soln. by the action of nitric acid on copper in excess ; and also by the action of copper sulphate on barium nitrite, or of silver nitrite on copper chloride. L. I. de Nagy Ilosva obtained it by treating an ammoniacal soln. of copper nitrite with hydroxylamine chloride. W. Hampe said that the green soln. develops nitric oxide at ordinary temp., and P. C. Ray reported that a dil. soln. in air gradually forms the nitrate, and when conc. over sulphuric acid, under diminished press., forms nitric oxide by autoxidation. E. Divers considered that no autoxidation occurs, rather is the action produced by the oxygen of the air, and the hydrolysis of the nitrous acid. P. C. Ray and N. R. Dhar found that the aq. soln. is feebly acidic, and for dilutions with a mol of the salt in 18·12, 54·36, 162·58, and 487·74 litres, at 20°, the conductivities are respectively 58·55, 79·92, 99·46, and 111·18 ; when the calculated value at infinite dilution is 106·8 at 20°. N. W. Fischer said that when the attempt is made to conc. the soln. by evaporation, blue scales of a basic salt are formed ; W. Hampe said that if the soln. be evaporated in vacuo, and the residue washed with water, the product is **copper oxynitrite,** $CuO.Cu(NO_2)_2$, which, according to P. C. Ray, also contains a little nitrate. B. van der Meulen reported **copper hexahydroxydinitrite,** $3Cu(OH)_2.Cu(NO_2)_2$, which A. Werner represented as a hexol salt:



$$\left[Cu\left(\begin{matrix}HO\\HO\end{matrix}Cu\right)_3\right](NO_2)_2$$

by mixing eq. soln. of copper sulphate and potassium nitrite ; adding alcohol ; and evaporating the mixture at ordinary temp. The product is a mass of acicular crystals, which are stable at ordinary temp. ; readily soluble in dil. acids, and in aq. ammonia ; but sparingly soluble in water or alcohol. Boiling water decomposes the salt. H. Bassett and R. G. Durrant said that the compound does not explode by percussion. According to C. Przibylla, when a nitrite is added to a soln. of copper salt, the blue colour deepens, and a layer of conc. soln. one cm. thick is opaque. Presumably complex salts are formed. If an acid be added to the soln., nitrogen trioxide or nitric oxide is not immediately given off unless the soln. is warmed.

C. F. Schönbein said that if a soln. or mixture of cuprous or cupric oxide, or cupric carbonate in aq. ammonia, be exposed to air, some copper ammonionitrite is formed. E. Péligot reported **hydrated copper diamminohexanitrite,** $3Cu(NO_2)_2.2NH_3.H_2O$, to be formed in green crystals by the spontaneous evaporation of a soln. of **dihydrated copper diamminonitrite,** $Cu(NO_2)_2.2NH_3.2H_2O$. A soln. of this salt is said to be produced in violet needles by evaporating the soln. obtained by the action of aq. ammonia on copper while exposed to air, boiling the residue with alcohol sat. with ammonia, and cooling the filtered soln. The crystals are green at 100°, and slowly pass into cupric nitrite as indicated above. The salt explodes at a higher temp., or by percussion. It is soluble in water, with the absorption of heat, and the dil. soln. is hydrolyzed to cupric hydroxide, etc. There is a doubt about the individuality of E. Péligot's products—*vide infra*, the copper amminonitrites.

P. Pudschies obtained **copper tetramminonitrite,** $Cu(NO_2)_2.4NH_3$, by adding potassium nitrite to a soln. of copper diamminoacetate, and precipitating with alcohol and ether in the cold. H. Bassett and R. G. Durrant prepared copper tetramminonitrite by the action of air and aq. ammonia on copper filings (E. Péligot); by the extraction of the hexahydroxydinitrite with aq. ammonia; by the action of a conc. ammoniacal soln. of ammonium nitrite on cupric hydroxide; by the action of nitrous gases, from nitric acid and arsenic trioxide, on copper hydroxide suspended in aq. ammonia; and by evaporating at ordinary temp. the filtered soln. of the basic nitrite in the minimum amount of aq. ammonia, of sp. gr. 0·880. The salt forms dark blue, acicular crystals belonging to the tetragonal system. The conductivity of the aq. soln., and partition of ammonia between the salt and chloroform were measured by P. Pudschies. The electrical conductivities of a mol of the salt in 2·286 and 4·572 litres of water at 18° were respectively 68·4 and 73·0; and for a soln. in 9·144 litres, a precipitate of a basic salt was formed. H. Bassett and R. G. Durrant found that when the tetramminonitrite is exposed to moist air, while protected from dust, for about 3 months, a mixture of the diamminonitrite and the hexahydroxydinitrite is formed. Taking picric acid as 100, the sensitiveness of the tetramminodinitrite to shock is 89. The purified salt may be heated either slowly or rapidly without any explosion, but all specimens containing nitrate are apt to explode towards the end of the heating process. The explosion of the tetramminodinitrate is vigorous at 212°, and the loss of ammonia after two hrs.' heating at 200° in a continuous current of air was only 3 per cent., whereas the corresponding nitrite loses more than 15 per cent. at temp. below 100°, and this without any current of air. It appears, therefore, that ammonia is held firmly in the nitrate, but not in the nitrite, and that in mixtures the nitrite is quietly decomposed by heat, final explosion being due to subsequent action on the nitrate. H. Bassett and R. G. Durrant also prepared **copper diamminodinitrite,** $Cu(NH_3)_2(NO_2)_2$, as a purple powder by heating the finely divided tetramminodinitrite for 24 hrs. at 97°. The product readily dissolves in ammonia to form a perfectly clear blue soln., and on exposing the powder to an atm. containing dry ammonia at the ordinary temp., the violet-blue tetrammine nitrite was re-formed. If the sensitiveness of picric acid to explosion by shock is 100, that of the diamminodinitrite is 55. G. T. Morgan and F. H. Burstall prepared **copper bisethylenediaminonitrite,** $[Cuen_2](NO_2)_2$, by the action of silver nitrite on copper diaquobisethylenediamminoiodide. The dry salt is stable up to 120°; it melts with rapid decomposition at 128°. It is extremely soluble in water, but less soluble in alcohol. In aq. or alcoholic soln., the salt is not decomposed even on boiling; caustic alkalies have no effect, but dil. acid causes immediate evolution of nitrous fumes. Silver nitrate produces a quantitative separation of silver nitrite in alcoholic soln., showing that the dissolved complex nitrite is ionized in this medium. A. Fock prepared black needles of **potassium cupric nitrite,** $3KNO_2.Cu(NO_2)_2$, by evaporating in air a mixed soln. of an excess of potassium nitrite and cupric sulphate. The rhombic crystals appear green in thin layers, and have the axial ratios $a : b : c = 4992 : 1 : 0·8704$. They are stable in a desiccator, and decompose at 100°. The salt was also prepared by A. Kurtenacker.

J. L. Proust[4] first prepared **silver nitrite,** $AgNO_2$, by boiling an aq. soln. of silver nitrate with finely-divided silver for several hours; some metal was dissolved, and the evaporation and cooling of the pale yellow liquid furnished a yellow powder, which, after washing, was regarded as a sub-nitrate of silver. It was also precipitated from the yellow soln. by alcohol. H. Hess obtained the same salt by adding barium nitrite, prepared by the action of nitric oxide on baryta, to an aq. soln. of silver sulphate. He regarded it as a compound of nitric oxide with silver oxide.

The same salt was prepared by E. Péligot by adding barium nitrite to a soln. of silver nitrate. E. Mitscherlich, and V. Kohlschütter and E. Eydmann added sodium nitrite to a soln. of silver nitrate, and crystallized the precipitated silver nitrite (and oxide) from its soln. in boiling water; V. Meyer worked with potassium nitrite and silver nitrate; J. Persoz melted equal parts of silver and potassium nitrates, and crystallized the silver nitrite from hot water. E. Priwoznik treated an excess of silver with nitric acid; W. J. Russell, and A. R. Leeds passed hydrogen into a conc. soln. of silver nitrate; and E. Divers heated silver nitrate in a current of nitric oxide. The aq. soln. decomposes below 100°, and J. Lang, and N. W. Fischer said that the losses are so great when the attempt is made to purify the salt by recrystallization, that it is better instead to wash the salt with a little cold water. A. Naumann and A. Rücker crystallized the salt from a soln. of nitrous acid.

Analyses by A. Naumann and A. Rücker, J. Persoz, J. Lang, and E. Mitscherlich agree with the empirical formula $AgNO_2$. I. Kissel, J. Bewad, and P. C. Ray and P. Néogi found that when silver nitrite is treated with alkyl iodide, both ethyl nitrite and nitroethane are formed—*vide supra*, nitrous acid. It can therefore be inferred that the salt is tautomeric $Ag.ONO \rightleftharpoons Ag.NO_2$. The abnormally small ionization of silver nitrite in aq. soln. also led H. Ley and K. Schäfer to assume that only the form $Ag.O.NO$ is ionized in the normal way, while the form $Ag.NO_2$ is very little ionized. P. C. Ray and A. C. Ganguli reported that they have isolated these two forms. The one, **α-silver nitrite**, $Ag.NO_2$, is formed by double decomposition of silver nitrate and sodium nitrite in solution; the crystals which separate are washed with cold water and dried in vacuo over sulphuric acid. When the mother-liquid, left after the α-salt has separated, is allowed to stand a long time, crystals of the other salt, **β-silver nitrite**, $Ag.O.NO$, separate. The α-salt is said to decompose when melted between 220° and 250°: $2Ag.NO_2 \rightarrow 2Ag + N_2O_4$, with a side reaction: $Ag + N_2O_4 \rightarrow AgNO_3 + NO$; while the β-salt decomposes without melting, giving but little nitrogen oxide and much oxygen: $AgO.NO \rightarrow Ag + O + NO$. The scission of the β-molecule on the assumption that it is constituted $\mathrm{Ag}\rlap{\,\vdots}{-}\mathrm{O}\rlap{\,\vdots}{-}\mathrm{NO}$ is supposed to take place as indicated by the dotted lines; and of α-molecule $\mathrm{Ag}\rlap{\,\vdots}{-}\mathrm{NO}_2$. According to E. Divers, the alleged differences are not a question of a difference in constitution, but merely due to the difference in the state of subdivision of the two salts. He said: (i) Silver nitrite does not fuse but commences to decompose at 180°, and the observed fusion is due to the silver nitrate which melts below 217°. (ii) The observed difference in the two cases is due to some nitrate and residual nitric oxide in one case, and in the other case a little oxygen can be isolated. The difference in the way the salts pack in the tube and the consequent difference in the way the gases are temporarily imprisoned when the salt is heated sufficiently explain the observed results.

N. W. Fischer said that the powder is almost white, but the prismatic crystals are yellow, and this is the more pronounced the larger the crystals. Good crystals are obtained by the spontaneous evaporation of aq. soln. in darkness. J. Persoz obtained needle-like crystals which appeared colourless in the mother-liquor, but pale green when alone in air. A. Fock said that the crystals belong to the rhombic system, and have the axial ratios $a : b : c = 0{\cdot}5704 : 1 : 0{\cdot}8283$. M. Oswald gave for the sp. gr. 4·542; and P. C. Ray, 4·453. N. S. Kurnakoff and S. F. Schemtschuschny found that the press. at which the salt begins to flow is 46·6 kgrms. per sq. cm.—tin, 10·5 kgrms. per sq. cm. H. Hess said that the crystals blacken when exposed to light; J. L. Proust, that they darken in air, forming silver and silver nitrate; and N. W. Fischer that they decompose in contact with organic matter—*e.g.* paper. A. Fock said that the salt may be heated for an hour between 100° and 120° without decomposing, and J. Lang found that the air-dried salt does not lose weight at 100°, but decomposition begins at 140°–150°; on the other hand, M. Oswald found that the salt begins to break down at 60°. V. Kohlschütter and E. Eydmann said that the salt decomposes in vacuo in very much the same way as in a current of carbon dioxide. Nitrous fumes can be seen at 150° ; and at 200°, the mass begins to sinter and melt, and soon afterwards so much silver nitrate is formed that the whole mass becomes fluid. E. Péligot said that the decomposition products are silver, silver nitrate, and nitrogen peroxide ; E. Divers said that in an open vessel, the heated nitrite reacts : $3AgNO_2=N_2O_3+2Ag+AgNO_3$; and in a covered crucible : $2AgNO_2=Ag+NO+AgNO_3$; and in moist air, or in water-vapour : $AgNO_2=Ag+NO_2$. M. Oswald said that when heated quickly in vacuo, the salt decomposes : $AgNO_2=Ag+NO_2$. There are, however, some simultaneous reactions : $Ag+2NO_2=NO+AgNO_3$; and $AgNO_2+NO_2=AgNO_3+NO$. R. Abegg and H. Pick represent the decomposition of silver nitrite in aq. soln. by $2AgNO_2 \rightleftharpoons Ag+NO+AgNO_3$, or, on the ionic theory, $Ag^{\cdot}+2NO'_2 \rightleftharpoons Ag+NO+NO'_3$, and the equilibrium press., p, of the nitric oxide is 4·28 atm. at 55°, and 6·29 atm. at 65°. Equilibrium is obtained in 10–14 days. The press. of the nitric oxide is depressed by the addition of potassium nitrite such that for $0{\cdot}25N$-KNO_2, the press., p, is 3·65 atm. at 55°. For the equilibrium condition $K[Ag^{\cdot}][NO'_2]^2=p[NO'_3]$, $K=0{\cdot}000019$; the free energy of the reaction at 55° is $RT \log k=0{\cdot}34$ volt, in agreement with the e.m.f. of the cell Ag | N-Ag, N-NO'_3, N-NO'_2, NO(atm. press.) | Pt which is 0·34 volt. M. Berthelot gave for the heat of formation (Ag,N,O_2) =11·3 Cals. P. C. Ray and N. R. Dhar found the electrical conductivities for dilutions of a mol. of salt in 70·6, 211·8, and 635·4 litres are respectively 70·32, 85·73, and 110·32 at 20°, when the calculated value for infinite dilution is 115·2. A. A. Groening and H. P. Cady measured the decomposition voltages in aq. and in ammoniacal soln.

E. Mitscherlich said that 100 parts of cold water dissolve 0·83 part of silver nitrite, while N. W. Fischer gave less than half this value ; J. Lang said that it is less soluble than silver sulphate. E. Mitscherlich said the solubility increases in hot water, and J. Lang added that the soln. is then partially decomposed. A. Naumann and A. Rücker gave 3·1833 grms. per litre for the solubility of silver nitrite in water at 18°. H. J. M. Creighton and W. H. Ward gave for the solubility, S, in grams per litre :

	0°	10°	15°	20°	25°	30°	40°	50°	60°
S .	1·55	2·20	2·75	3·40	4·14	5·00	7·15	9·95	13·63

The measurements of R. Abegg and H. Pick are rather higher than these values for temp. below 20°. The results are in agreement with single determinations by H. Ley and K. Schäfer, and S. von Niementowsky and J. von Roszkowsky. R. Abegg and H. Pick found the conc. of the silver ions in a sat. soln. of silver nitrite to be 0·0146 at 25°, and the degree of ionization, 55 per cent. H. Ley and K. Schäfer's conductivity measurements gave for the degree of ionization, 59 per cent., and of the solubility product, $[Ag^{\cdot}][NO_2]$, 0·0002. The addition of silver nitrate lowers the solubility of silver nitrite in accord with the theory of the effect of like ions. The solubility of silver nitrite in aq. soln. of silver nitrate was measured by A. Naumann and A. Rücker, R. Abegg and H. Pick, and H. J. M. Creighton and W. H. Ward. The last-named workers found at 25°, with conc. expressed in mols per litre :

$AgNO_3$ . .	0	0·00258	0·00588	0·01177	0·02355	0·04710
$AgNO_2$ . .	0·0269	0·0260	0·0244	0·0224	0·0192	0·0164

The presence of potassium nitrite raises the solubility of silver nitrite ; the effect of like ions being here marked by the formation of a complex. Measurements were made by H. J. M. Creighton and W. H. Ward, who found

KNO_2 . . .	0	0·00258	0·00588	0·01177	0·02355	0·04710
$AgNO_2$ . .	0·0269	0·0259	0·0249	0·0230	0·0203	0·0181

Observations made by R. Abegg and H. Pick indicate the formation of complex univalent $Ag(NO_2)_2$-ions. M. Oswald's curves are shown in Fig. 81, and they are consonant with the formation of a salt $KAg(NO_2)_2$. The ionization constant $k_1=0{\cdot}00068$, for $Ag^{\cdot}+2NO_2 \rightleftharpoons Ag(NO_2)'_2$, or $k_1[Ag^{\cdot}][NO'_2]^2=[Ag(NO_2)'_2]$; and

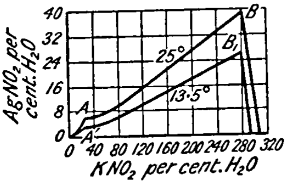


FIG. 79.—Solubility Curves of Silver and Potassium Nitrites.

$k_2=0{\cdot}052$, for $k_2[NO'_2][AgNO_2]=[Ag(NO_2)'_2]$. Calculations show that in a sat. soln. of silver nitrite, at 25°, the conc. of the $Ag(NO_2)'_2$-ions is 0·0017 mol per litre; $Ag^{\cdot}$-ions, 0·0146 mol per litre; NO'_2-ions, 0·0129 mol per litre; and non-ionized $AgNO_2$, 0·0119 mol per litre. The reduction potential of silver nitrite: $2NO'_2=NO+NO'_3$ is 0·43 volt at 25°, when the potential of the hydrogen electrode is zero. This means that when the substances taking part in the equilibrium are present in unit conc., the nitrite ion is 0·43 volt less powerful a reducing agent than hydrogen. The reducing action of the nitrite-ion is greatly increased when the conc. of the nitric oxide is small. N. R. Dhar and D. N. Bhattacharyya observed a brown film is formed on the silver electrode during the electrolysis of a soln. of silver nitrite. According to H. Pick, *oxygen* of the air rapidly oxidizes a soln. of silver nitrite, and the reaction is accelerated by the presence of finely-divided silver. The reaction begins at about 25°, and at 40°, nitric oxide is given off. J. Krutwig found that *chlorine* reacts with silver nitrite, forming nitrosyl chloride, silver chloride, and nitrogen peroxide; and W. Neelmeier, that *iodine* in different solvents, forms silver iodide and nitrogen peroxide. H. Hess showed that *hydrochloric acid* converts the nitrite into the chloride, with the evolution of gas; and E. Mitscherlich obtained silver chloride and alkali nitrites, when a soln. of alkali chloride is treated with silver nitrite. E. Divers and T. Haga showed that if suspended in water, silver nitrite reacts with *hydrogen sulphide*, forming sulphur, nitric oxide, ammonia, and hydroxylamine; and with an excess of *sulphur dioxide*, silver sulphite, sulphuric acid, and nitric oxide are formed. E. C. Franklin and C. A. Kraus found silver nitrite to be readily soluble in liquid *ammonia;* and likewise, also, J. Lang, and H. Hess, in aq. ammonia. E. Mitscherlich, A. Fock, and A. Reychler found that the soln. of silver nitrite in warm, conc. aq. ammonia deposits crystals of **silver amminonitrite,** $AgNO_2.NH_3$, on cooling. A. Reychler dried the yellow crystals with filter-paper, washed them with alcohol and ether, and then exposed them to dry air. According to A. Fock, the yellow prisms belong to the tetragonal system, and have the axial ratio $a:c=1:0{\cdot}6086$. A. Reychler said the m.p. is 70°, and the molten mass crystallizes on freezing. The salt is sparingly soluble in water, less soluble in alcohol, and almost insoluble in ether. The soln. gradually gives off ammonia, and the same gas is given off during fusion. Ethyl iodide reacts: $AgNO_2.NH_3+C_2H_5I=AgI+C_2H_5NO_2+NH_3$. A. Reychler made **silver diamminonitrite,** $AgNO_2.2NH_3$, by shaking the powdered monammine with alcohol sat. with ammonia. Ether added to the filtered soln. precipitates the white salt, which cannot be dried without losing ammonia. It is hygroscopic. The powdered monammine also absorbs ammonia with the evolution of heat and forms **silver triamminonitrite,** $AgNO_2.3NH_3$, which is very soluble in water, and gives off ammonia when exposed to air. According to C. Paal, when silver nitrite acts on hydroxylamine chloride, hydroxylamine nitrite is formed which immediately breaks up into silver hyponitrite. If an excess of silver nitrite be employed, the filtered soln. deposits crystals of **silver dinitritohyponitrite,** $Ag_2N_2O_2.2AgNO_2$. E. Divers has questioned the individuality of the alleged complex. H. Pellet found the nitrite is decomposed by *nitric acid.* E. Divers and T. Shimidzu observed no reaction with *nitrogen peroxide;* C. Paal found that *hydroxylamine chloride* furnishes hydroxylamine nitrite (*q.v.*); and A. Angeli, that *hydrazine sulphate* forms silver azide. L. Kahlenberg and J. V. Steinle represented the reaction with arsenic: $6AgNO_2+2As=As_2O_3+6Ag+3NO_2+3NO$. P. Pistschimuka found that *alkyl thiophosphates* react with silver nitrite as they do with silver nitrate. F. Bezold observed that silver nitrite is sparingly soluble in *methyl acetate;* M. Hamers, insoluble in dry *ethyl acetate,* or in ethyl acetate sat. with water at 18°; and R. Scholl and W. Steinkopf, that 100 parts of *acetonitrile* at ordinary temp. dissolve about 23 parts of silver nitrite, and at 81·6°, 40 parts, and the hot soln. on cooling deposits needle-like crystals of silver nitrite. The action of *alkyl iodides* has been discussed in connection with the constitution. N. W. Fischer found that if an aq. soln. of silver nitrite is free from the nitrate, in the absence of air, it is not reduced by *tin, antimony, bismuth,* or *nickel,* but if silver nitrate is present, reduction occurs.

G. S. Jamieson prepared **cæsium silver nitrite,** $CsNO_2.AgNO_2$, in lemon-yellow hemimorphic crystals from a hot soln. of 10 mols of cæsium nitrite and one mol of silver nitrite. The effect of potassium nitrite on the solubility of silver nitrite has been already discussed—Fig. 79. The zone of stability of the double salt is in the regions *AB,* and *A′B′*. N. W. Fischer, and J. Lang made **potassium silver nitrite,** $KNO_2.AgNO_2.\frac{1}{2}H_2O$, by crystallization from a soln. of the constituent salts with an excess of potassium nitrite, by evaporation at 30°–40°, or over conc. sulphuric acid; and W. Hampe by saturating a conc. soln. of potassium nitrite with silver nitrite at 60°–70°, and evaporating at ordinary temp. in darkness. A. Fock said that the salt is anhydrous, and that the bipyramidal crystals belong to the rhombic system, and have the axial ratios $a : b : c = 0·52751 : 1 : 1·9883$. M. Oswald also found the salt is anhydrous after drying in vacuo in the cold over phosphorus pentoxide. The sp. gr. of the solid is 2·868 at 0°/0°. N. W. Fischer said that the salt is stable in air, but decomposes when heated with its components, and at a higher temp. the silver nitrite breaks down; water extracts the alkali nitrite, leaving the silver nitrite. M. Oswald found that the salt decomposes in vacuo at 100°. J. Lang found that the salt dissolves completely in a small proportion of water, but is decomposed by a large proportion. The salt dissolves unchanged in a soln. of potassium nitrite, but not in alcohol. M. Oswald examined the effect of sodium nitrite on the solubility of silver nitrite, and obtained the results shown in Fig. 80. A complex hemihydrated **sodium silver nitrite,** $NaAg(NO_2)_2.\frac{1}{2}H_2O$, is formed from a soln. of two parts of sodium nitrite in three parts of water, and adding as much silver nitrite as the soln. will dissolve at 50°–60°. The filtered soln. gives crystals of the salt. The zone of stability of the double salt is *AB,* and *A′B′*. The sp. gr. is 3·442 at 0°/0°. The effect of lithium nitrite on the solubility of silver nitrite is shown in Fig. 81. There is no evidence of the formation of *lithium silver nitrite.*

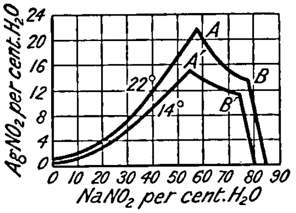

FIG. 80.—Solubility of Silver Nitrite in Solutions of Sodium Nitrite.

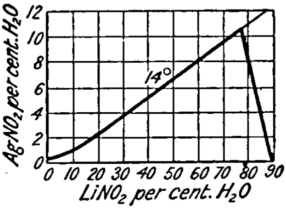

FIG. 81.—Solubility of Silver Nitrite in Solutions of Lithium Nitrite.

N. W. Fischer,[5] J. Lang, and W. Hampe prepared **calcium nitrite,** $Ca(NO_2)_2.H_2O$, by treating a boiling soln. of silver nitrite with calcium hydroxide, and removing the excess of silver by hydrogen sulphide, or the excess of calcium hydroxide by carbon dioxide. J. Lang obtained only a small proportion of calcium nitrite by heating the nitrate. P. C. Ray obtained the salt by the action of silver nitrite on a soln. of calcium chloride. F. Vogel evaporated the filtered soln. to a syrupy consistency and precipitated the salt with alcohol, washed the product a number of times with alcohol, and then dried it at 50°. N. W. Fischer obtained **strontium nitrite,** $Sr(NO_2)_2.H_2O$, by calcining the nitrate and crystallizing out the nitrate from the aq. soln. of the residue. M. Oswald also obtained tetrahydrated calcium nitrite, $Ca(NO_2)_2.4H_2O$; and the conditions of equilibrium are indicated in Fig. 82, but, added J. Lang, it is then very difficult to eliminate the undecomposed nitrate. W. Hampe used the process for the barium salt—*vide infra;* and

F. Vogel treated a soln. of silver nitrite with strontium chloride, evaporated the filtered soln. to a syrupy consistency, and added alcohol as in the case of the calcium salt. H. Hess prepared **barium nitrite,** $Ba(NO_2).H_2O$, by calcining the nitrate; digesting the mass in water; and crystallizing. He called the product *Stickstoffoxydbaryt.* J. Lang, and N. W. Fischer dissolved the calcined residue in water, crystallized out undecomposed barium nitrate, and precipitated any barium hydroxide by passage of carbon dioxide; the addition of a little alcohol precipitated crystals of barium nitrate, and afterwards flecks of the nitrite appeared. The soln. was then allowed to crystallize, and any nitrite in the residue precipitated by alcohol. Neither K. Arndt, nor P. C. Ray could recommend the process. J. Fritzche saturated a soln. of barium hydroxide with the red vapours evolved when fuming nitric acid is heated, and, after evaporating to dryness, extracted the mass with a little water to remove barium nitrate—barium nitrite remains. W. Hampe used barium carbonate suspended in water in place of barium hydroxide; and the conc. soln. remaining after barium nitrate has crystallized out, was treated with 90 per cent. alcohol; and the filtered soln. evaporated for the nitrite. K. Arndt did not recommend this mode of preparation. C. F. Rammelsberg, and P. C. Ray obtained barium nitrite by double decomposition with silver nitrite and barium chloride. K. Arndt recommended mixing the silver nitrite with sea-sand before adding it to the barium chloride soln. J. Matuschek obtained barium nitrite by the double decomposition of barium chloride and sodium nitrite, and fractional crystallization. O. N. Witt and K. Ludwig employed the following process:

> Eq. quantities of dry sodium nitrite and barium chloride are intimately mixed and added to sodium nitrite (1 eq.) dissolved in 3 times its wt. of boiling water. By using an excess of sodium nitrite, the "salting out" of part of the barium chloride before the reaction is complete is prevented. The precipitated sodium chloride is immediately removed by a hot filter, and on cooling the filtrate, well-defined crystals of barium nitrite, $Ba(NO_2)_2,H_2O$, are obtained. They are best removed by the aid of a good centrifuge. The mother-liquor, which contains the excess of sodium nitrite, may be used again. When heated, it begins to evolve oxides of nitrogen at 115°.

W. Meyerhoffer said that under the conditions here described, the salt pair, barium nitrite and sodium chloride, is stable within its interval of change, and that in the presence of water it will separate as a third salt, while barium chloride and sodium nitrite will remain in soln. To prevent this an excess of sodium nitrite is necessary. J. Matuschek showed that hydrated barium chloride and sodium nitrite interact when pounded together, and that these salts react in molecular proportion in aq. soln. at 100° if only a limited amount of water is present. The yield of barium nitrite approaches the theoretical when the amount of water added as solvent is one-third of the weight of the nitrite which would be formed if the reaction were quantitative.

M. Oswald noted the tendency of the salts to form supersaturated soln., and he obtained yellow glasses by cooling the soln. to —80°. Calcium nitrite, according to F. Vogel, forms six-sided prismatic needles which are isomorphous with the barium salt; W. Hampe described the crystals of strontium nitrate as acicular when produced by cooling the hot soln.; but octahedral, if obtained by evaporating the aq. soln. at 90°. M. Oswald found the monohydrates of barium and strontium nitrites to be isomorphous—this merits further examination. A. Eppler said the crystals belong to the cubic system. F. Vogel found barium nitrite furnishes six-sided prismatic crystals which, according to A. Fock, belong to the hexagonal system and have the axial ratio $a : c = 1 : 2{\cdot}5056$. M. Oswald gave 1·674 at 0°/0° for the tetrahydrated calcium salt; 2·408 at 0°/0° for the monohydrated strontium salt; and 3·109 at 0°/0° for the monohydrated barium salt. K. Arndt gave 1·1140 for the sp. gr. of a soln. with 150·005 grms. of barium nitrite per litre; and F. Vogel, for a soln. sat. at 0°, sp. gr. 1·40; at 20°, 1·45; at 25°, 1·50; at 30°, 1·52; and at 35°, 1·61. M. Oswald found that the aq. soln. of calcium nitrite, sat. at 16°, has a sp. gr. 1·4205 at 16°/0°, and contains 42·3 per cent. $Ca(NO_2)_2$; the soln. of the strontium salt, sat. at 19°, has a sp. gr. 1·4461 at 19°/0°, and has 39·3 per cent. $Sr(NO_2)_2$; and the soln. of barium nitrite sat. at 17°, has a sp. gr. 1·4897 at 17°/0°, and has 40 per cent. of $Ba(NO_2)_2$. The sat. soln. of strontium nitrite boils at 112·5° and 763 mm., and of barium nitrite, at 114° and 769·5 mm. The crystals of calcium nitrite are deliquescent, but, according to O. N. Witt and K. Ludwig, those of barium nitrite are not hygroscopic; and, added K. Arndt, the crystals usually contain a little less water than is required for the monohydrate, owing to effervescence. A. Fock considered the salt to be anhydrous. J. Lang and F. Vogel said that the crystals of strontium nitrite are stable in dry air, hygroscopic in moist air. P. C. Ray said that calcium nitrite, dried in a desiccator, and then on a water-bath to constant weight, is hemihydrated, $Ca(BO_2)_2.\frac{1}{2}H_2O$; J. Lang, W. Hampe, and F. Vogel said the crystals are monohydrated; M. Oswald showed that both monohydrated and tetrahydrated calcium nitrite can be formed, and that the transition temp. is 44°, Fig. 82. According to F. Vogel, calcium nitrite at 40° loses 3·1 per cent. of its water of crystallization, and at 100° all is lost. The dehydrated salt absorbs from atm. air at ordinary temp. 14·83 per cent. of water. The monohydrated strontium salt does not lose any water of crystallization, but all is given off above 100° with a slight decomposition. All the water is restored by a few days' exposure to atm. air. Similarly, the barium salt loses its 7·28 per cent. of water of crystallization below 100°, and after 20 days' exposure to atm. air, 3·10 per cent. has been restored. O. N. Witt and K. Ludwig found that the decomposition of the barium salt begins at about 115° so that the water has to be determined by the methods of organic analysis; conc. soln. boiling over 115° decompose, but dil. soln. are quite stable. M. Oswald found that the temp. at which the salts begin to decompose are 220° for calcium nitrite; 240° for strontium nitrite; and 235° for barium nitrite. According to P. C. Ray, when barium nitrite is slowly heated nitric oxide is the main product of the reaction, and a portion of the salt is converted into nitrate, $3Ba(NO_2)_2=2BaO+Ba(NO_3)_2+4NO$, with the side reaction $2Ba(NO_2)_2=BaO+Ba(NO_3)_2+NO+N$; in the second stage, the nitrate decomposes, giving off oxygen: $Ba(NO_3)_2=BaO+2NO_2+O$, and $Ba(NO_3)_2=Ba(NO_2)_2+O_2$. There are also a number of other reactions proceeding simultaneously; thus, M. Oswald found at 150°: $Ba(NO_2)_2+2NO_2=Ba(NO_3)_2+2NO+19{\cdot}6$ Cals.; and $Ba(NO_2)_2+NO_2=Ba(NO_3)_2+N+55{\cdot}2$ Cals. P. C. Ray said that calcium nitrite decomposes like the barium salt. K. Arndt gave 220° for the m.p. of barium nitrite, and M. Oswald, 217°. M. Berthelot measured the heat of formation of barium nitrite and obtained $(Ba,N_2,2O_2)=179{\cdot}6$ Cals. E. C. C. Baly and C. H. Desch measured the absorption spectrum of barium nitrite —*vide infra*, the action of nitrogen peroxide on calcium oxide.

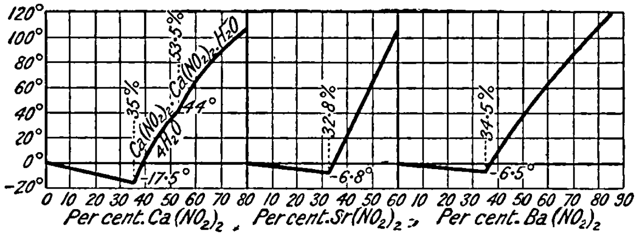

FIG. 82.—Solubility of Calcium Nitrite.

FIG. 83.—Solubility of Strontium Nitrite.

FIG. 84.—Solubility of Barium Nitrite.

F. Vogel found that 100 c.c. of an aq. soln. of calcium nitrite has 111·6 grms. of the monohydrate. M. Oswald's solubility curves are indicated in Fig. 82. The eutectic occurs at —17·5° and 35 per cent. $Ca(NO_2)_2$. The percentage solubility, *S*, is:

	−9·5°	0°	18·5°	42°	44°	54°	64°	70°	91°
S . .	36·2	28·3	43·0	51·8	53·5	55·2	58·4	60·3	71·2
Solid phase	$Ca(NO_2)_2.4H_2O$					$Ca(NO_2)_2.H_2O$			

At higher temp., the salt is much hydrolyzed. W. Hampe, and J. Lang noted that strontium nitrate is very soluble in water, and F. Vogel found that 100 c.c. of a soln. at 19·5° has 62·83 grms. of $Sr(NO_2)_2.H_2O$; while M. Oswald obtained the results indicated in Fig. 83. The eutectic at —6·8° has 32·8 per cent. $Sr(NO_2)_2$. For the solubility, *S*, of monohydrated strontium and barium nitrites, per 100 parts of water, M. Oswald gave:

S	0°	10°	20°	40°	60°	80°	100°	110°
$Sr(NO_2)_2.H_2O$	58·9	67·6	75·5	94	116	145	182	—
$Ba(NO_2)_2.H_2O$	63·5	69·5	79·5	113	170	254	461	765

J. Lang, and W. Hampe found barium nitrite to be very soluble in water, and F. Vogel measured the solubility between 0° and 35°. M. Oswald's results are indicated above and in Fig. 84. The eutectic is at —6·5°, with 34·5 per cent. $Ba(NO_2)_2$. There are no hydrates other than the monohydrates of barium and strontium nitrites. J. Lang said that the aq. soln. of barium nitrite is feebly alkaline, but W. Hampe, and K. Arndt observed the soln. has no action on litmus unless the salt has been previously evaporated to dryness with consequent decomposition. According to M. Oswald, the hydrated nitrites can be dehydrated in a vacuum over phosphoric oxide without undergoing decomposition; in conc. aq. soln. lithium nitrite and the alkaline-earth nitrites undergo hydrolysis at 100°. The solid nitrites or their sat. soln. are not oxidized by oxygen at atmospheric pressure, neither are the dry salts acted on by nitric oxide, so long as decomposition of the salt itself does not occur. Oxidation of soln. of the nitrites occurs only in the presence of acids, and is then due to oxidation of the decomposition products (nitric oxide) of nitrous acid. F. Vogel gave for the eq. conductivity, λ, aq. soln. with the conc. expressed in gram-eq. per litre, at 25°:

Conc. . .	5·0	3·0	2·5	2·0	1·0	0·1	0·05	0·01	0·005	∞
$Ca(NO_2)_2$ . .	—	—	45·5	51·2	66·4	96·0	103	116	120	124
$Sr(NO_2)_2$ . .	23·9	40·8	46·0	51·8	67·6	99·0	105	120·4	121	125
$Ba(NO_2)_2$ . .	—	40·3	45·5	51·3	66·4	99·0	105	114	115	122

P. C. Ray and N. R. Dhar also measured the electrical conductivities of soln. of the three nitrites; and P. C. Ray and S. C. Mukherjee observed that the degrees of ionization of soln. of calcium nitrite at dilutions $v=28·0$ and 19·4 litres are respectively 0·84 and 0·82; for strontium nitrite at dilutions $v=22·0$ and 21·0 litres, 0·84 in both cases; and for barium nitrite for $v=21·0$ and 31·4 litres, respectively 0·84 and 0·86.

N. W. Fischer said that calcium nitrite is insoluble in dil. alcohol, and F. Vogel, that 100 c.c. of 90 per cent. alcohol dissolve 39·0 grms. of the salt. at 20°, and 100 c.c. of absolute alcohol, 1·1 grms. W. Hampe, and J. Lang found that strontium nitrite is sparingly soluble in absolute alcohol, and F. Vogel showed that 100 c.c. of 90 per cent. alcohol, at 19·5°, dissolve 0·42 grm. of salt, and 100 c.c. of absolute alcohol, 0·04 grm. J. Lang, and W. Hampe said that barium nitrite is nearly insoluble in absolute alcohol; and F. Vogel found that 100 c.c. of alcohol and water, at 19°–21°, dissolve *S* grms. of monohydrated barium nitrite:

Alcohol .	10	20	30	40	50	60	70	80	90	100 per cent.
Ba salt .	49·30	29·30	18 41	13·33	9·11	4·84	2·66	0·98	0·00	0·00

According to E. C. Franklin and C. A. Kraus, a soln. of barium nitrite in liquid ammonia reacts with the following salts dissolved in liquid ammonia—ammonium chloride, bromide, and iodide are precipitated; ammonium chromate gives a flocculent precipitate; and ammonium borate also gives a precipitate. C. Matignon and E. Monnet observed that the oxidation of solid calcium nitrite to nitrate can be effected as in the case of sodium nitrite (*q.v.*) by heating it in oxygen under press.

J. Lang, and A. Fock prepared **potassium calcium nitrite,** $KNO_2.Ca(NO_2)_2.3H_2O$, by slowly evaporating a soln. of the component salts. J. Lang obtained **potassium strontium nitrite,** $2KNO_2.Sr(NO_2)_2$, and **potassium barium nitrite,** $2KNO_2.Ba(NO_2)_2$, in an analogous way. J. Lang also claimed to have made the monohydrate, $2KNO_2.Ba(NO_2)_2.H_2O$, in long, acicular crystals stable in air; easily soluble in water, but not in alcohol; and dehydrated at 100°—but A. Fock did not verify this result. H. Topsöe described the crystals of the calcium salt as colourless, rhombic, bipyramidal prisms with the axial ratios $a:b:c=0·642:1:0·642$; and A. Fock said that the crystals of the pseudohexagonal prisms of the barium salt are rhombic with axial ratios $a:b:c=0·5832:1:—$. A. Fock found that the crystals of the barium salt preserve their lustre when heated many hours at 120°, but at 150°, they slowly lose their lustre. J. E. Ahlen said that the calcium salt is dehydrated at 100°. W. N. Fischer reported **silver barium nitrite,** $BaAg_2(NO_2)_4.H_2O$, from a soln. of the component salts. The formula is here due to M. Oswald, who examined the three nitrites of the alkaline earths, and found only barium forms a double salt. The conditions of stability are represented by *AB*, Fig. 85. The corresponding diagrams for strontium and calcium nitrites do not show any evidence of the formation of *silver strontium nitrite*, or of a *silver calcium nitrite;* nor is any *strontium barium nitrite* formed, for the two salts give a series of mixed crystals, $(Ba,Sr)(NO_2)_2.H_2O$.

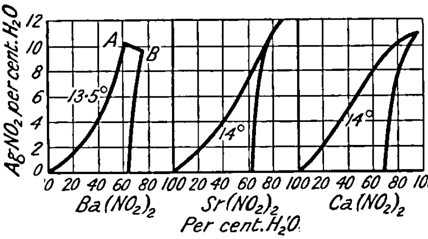

FIG. 85.—Binary System: $Ba(NO_2)_2-AgNO_2$.

FIG. 86.—Binary System: $Sr(NO_2)_2-AgNO_2$.

FIG. 87.—Binary System: $Ca(NO_2)_2-AgNO_2$.

C. Przibylla obtained a series of triple nitrites; thus, **copper calcium potassium nitrite,** $CuCaK,(NO_2)_6$, prepared by mixing a well-cooled soln. of copper chloride and sodium nitrite with a soln. of potassium chloride, calcium chloride, and sodium nitrite, is a deep green, crystalline powder, which is purified by washing with 85 per cent. alcohol and then with alcohol. **Copper calcium ammonium nitrite,** $CuCa(NH_4)_2(NO_2)_6$, prepared in a similar manner to the preceding salt but using very conc. soln., closely resembles the potassium salt, but if kept, gradually decomposes with evolution of nitrogen trioxide. **Copper barium potassium nitrite,** $CuBaK_2(NO_2)_6$, obtained by mixing a well-cooled conc. soln. of barium chloride and sodium nitrite with a soln. of copper chloride, potassium chloride, and sodium nitrite, is also a deep green, crystalline powder; it is stable when kept dry, but decomposes on recrystallization, with evolution of nitrogen trioxide and the formation of basic salts. **Copper barium ammonium nitrite,** $CuBa(NH_4)_2(NO_2)_6$, is very similar to the potassium salt, but slowly decomposes when allowed to remain at the ordinary temperature. **Copper strontium potassium nitrite,** $CuSrK_2(NO_2)_6$, is obtained in a similar manner to the preceding salts, but a large excess of strontium chloride should be employed, as otherwise a mixture of salts is obtained containing less strontium; these cannot be purified by recrystallization. The corresponding **copper strontium ammonium nitrite** is very similar to the potassium salt.

F. Vogel tried without success to make **beryllium nitrite** by the action of beryllium sulphate on barium nitrite. He found that in aq. soln. the precipitate is immediately hydrolyzed, nitrogen oxides are evolved, and only a small proportion of nitrogen remains. It might be added that many salts, unstable in aq. soln., have been made in non-aq. solvents. D. B. Q. Disjonval prepared **magnesium nitrite,** presumably $Mg(NO_2)_2$, by the action of nitrous acid on magnesium hydroxide. J. Lang, W. Hampe, and P. C. Ray obtained it by double decomposition between magnesium sulphate and sodium nitrite and magnesium sulphate, and fractional crystallization—*vide supra,* barium nitrite; and L. Spiegel, by digesting at 50°–60° a mixture of silver nitrate and magnesium chloride; removing the silver from the filtrate by hydrogen sulphide; and evaporating the filtrate first on the water-bath, and finally over sulphuric acid. P. C. Ray said that the soln. should not be evaporated on the water-bath because of its ready hydrolysis; it is best conc. under reduced press. over sulphuric acid. L. Spiegel, J. Matuschek and W. Hampe found the salt dried over sulphuric acid is dihydrated; and L. Spiegel, J. Lang, and F. Vogel prepared a trihydrated salt. The white thin plates, or prismatic columns, are deliquescent. J. Lang said that they decompose at 100°, giving off nitric oxide, and so also with the aq. soln. L. Spiegel said that the crystals cannot be dried to constant weight since a little decomposition also occurs; a marked decomposition occurs at 97°–100°, but the soln. can be boiled a long time without perceptible decomposition. F. P. Dunnington and F. W. Smither said that all but one mol of water can be driven from the salt at 97°–100°, but any further loss of water is attended by a loss of acid. According to P. C. Ray, the salt spontaneously decomposes in a sealed vessel, giving off red fumes. If heated in vacuo, the salt decomposes like barium nitrite (*q.v.*). The decomposition begins at 60°, and at 120° a basic nitrate, $MgO.Mg(NO_3)_2$, is formed which is stable at 175°. F. Vogel made analogous observations. P. C. Ray and R. R. Dhar found the electrical conductivities of soln. with a mol of the salt in 15·5, 46·5, 139·5, and 418·5 to be respectively 91·15, 108·65, 120·55, and 127·15 at 20°, and at infinite dilution, 106·9. W. Hampe found the salt to be readily soluble in alcohol. J. Lang reported **potassium magnesium nitrite** to be formed in a manner analogous to the corresponding barium salt. A. Reychler reported crystals of **magnesium silver nitrite,** $AgNO_2.19Mg(NO_2)_2.50H_2O$, to be formed from a mixed soln. of the component salts. The complex nitrite is readily soluble in water, and the soln. is rapidly decomposed by light.

According to A. Vogel and C. Reischauer,[6] **zinc nitrite,** $Zn(NO_2)_2$, is formed copiously when zinc dissolves in nitric acid, or in a soln. of zinc hydroxide in aq. ammonia, and in the latter case, crystals of the hydroxide are simultaneously formed. J. Matuschek obtained it by a process analogous to that employed for the barium salt. F. Vogel could not obtain a satisfactory result with J. Matuschek's method. The rhombic plates were **monohydrated zinc nitrite,** $Zn(NO_2)_2.H_2O$. They decompose in air, and, when dissolved in water, form nitrous acid and zinc hydroxide. W. Hampe, and J. Lang said that the conc. soln. is stable, but J. Matuschek found that it gradually forms zinc nitrate and hydroxide. According to P. C. Ray, zinc nitrite cannot be crystallized from the aq. soln., prepared by the double decomposition of a soln. of zinc sulphate and barium nitrite, for the conc. soln. decomposes—even in vacuo—with the evolution of nitric oxide and the formation of a basic nitrate. P. C. Ray and N. R. Dhar gave for the eq. conductivity of a mol of the salt in v litres of water at 20°:

v . . .	12·4	37·2	111·6	334·8	1004·4
λ . . .	59·27	80·87	104·30	116·25	117·65

The calculated value is 108·1 at infinite dilution. The aq. soln. is acidic owing to hydrolysis. By evaporating a soln. of zinc nitrite, W. Hampe obtained plates of **zinc oxynitrite,** $ZnO.Zn(NO_2)_2$. J. Lang obtained **trihydrated zinc nitrite,** $Zn(NO_2).3H_2O$, by evaporating in vacuo the filtered soln. obtained when zinc sulphate has been treated with barium nitrite. The aq. soln. is not precipitated by alcohol. The crystals decompose at 100° giving off nitric oxide. F. Ephraim and E. Bolle obtained a doubtful **zinc amminonitrite** by saturating a soln. of zinc nitrite with ammonia. J. Lang said that yellow, prismatic crystals of

potassium zinc tetranitrite, $2KNO_2.Zn(NO_2)_2.H_2O$, were produced by crystallization from a mixed soln. of the component salts. W. Hampe obtained a similar salt. A. Rosenheim and K. Oppenheim reported pale yellow, very hygroscopic crystals of **potassium zinc pentanitrite,** $3KNO_2.Zn(NO_2)_2.3H_2O$, by adding nitrous acid to a mixture of zinc hydroxide and potassium nitrite, stirred up with water. The crystals are decomposed by water.

F. Vogel prepared crystals of **cadmium nitrite,** $Cd(NO_2)_2$, by evaporating in vacuo the soln. remaining after mixing eq. proportions of barium nitrite and cadmium sulphate in aq. soln. P. C. Ray obtained cadmium nitrite in bright, pale yellow crystals, by triturating a mixture of cadmium chloride and silver nitrite, water being added from time to time, until the filtrate showed no evidence of an excess of either salt. The liquid was then evaporated in vacuo over sulphuric acid. J. Lang obtained hydrated cadmium nitrite, $Cd(NO_2)_2.H_2O$, as a yellow crystalline mass by evaporating the same soln. at as low a temp. as possible. The salt is decomposed by heat, and by water. P. C. Ray found that cadmium nitrite began to decompose at 150°, and at 230°, a brown residue of cadmium nitrate and oxide was formed. Nitric oxide is the chief gaseous product: $3Cd(NO_2)_2=2CdO+Cd(NO_3)_2+4NO$; and there is a side reaction: $Cd(NO_2)_2=CdO+N_2O_3(NO+NO_2)$. The eq. conductivity at 29° with a mol of the salt in v litres of water is:

v . . .	10	20	40	80	160	320	640	1024
λ . . .	33·7	43·9	55·1	67·1	78·3	88·3	96·1	104·6

W. Hampe obtained **cadmium oxynitrite,** $CdO.Cd(NO_2)_2$, as a white, insoluble powder by the action of water or absolute alcohol on the normal salt. According to H. Morin, when a sat. soln. of ammonium nitrate is poured upon granulated cadmium, an energetic reaction takes place with tumultuous ebullition, and the temperature rises to 110°; but there is no evolution of gas. After cooling, the liquid is filtered and allowed to evaporate over calcium chloride out of direct sunlight; it then deposits transparent rhomboidal prisms, which, when dried, do not alter on exposure to air. These crystals are decomposed by water with separation of flocculent cadmium oxide; they can, however, be crystallized from a soln. of ammonia. When heated, they melt and give off ammonia, and as soon as they are completely dry, they decompose with sudden deflagration, nitrogen oxides being given off, and a residue of anhydrous cadmium oxide left. The crystals correspond with **ammonium cadmium diamminoxytetranitrite,** $CdO.Cd(NO_2)_2.2NH_4NO_2.2NH_3.H_2O$. G. Carrara obtained a cadmium nitrite of indefinite composition about a cadmium anode during the electrolysis of a soln. of cadmium nitrate; no ammonia was detected. C. F. Schönbein said that a nitrite is formed when a cadmium rod is left in contact with a soln. of ammonium nitrite for some time. W. Hampe, and A. Fock reported crystals of **potassium cadmium trinitrite,** $KNO_2.Cd(NO_2)_2$, to be formed by evaporating a mixed soln. of the component salts. V. Kohlschütter obtained the salt by adding alcohol to an aq. soln. of the tetranitrite. The soln. first forms pale yellow cubes, or plates. The salt is not changed by recrystallization of the aq. soln. The crystals are stable in air, readily soluble in water, and sparingly soluble in alcohol. The mother-liquor remaining after the preparation of the preceding salt furnishes rhombic prisms of **potassium cadmium tetranitrite,** $2KNO_2.Cd(NO_2)_2$. J. Lang obtained the same salt by the spontaneous evaporation of a soln. of cadmium acetate with a large excess of potassium nitrite; A. Laubenheimer, by evaporating, in vacuo, over sulphuric acid, a soln. obtained by treating silver nitrite with the right proportion of cadmium and potassium chlorides; and V. Kohlschütter, from a conc. soln. of potassium nitrite and cadmium sulphate. According to A. Fock, the pale yellow crystals belong to the rhombic system and have the axial ratios $a:b:c=0·5369:1:1·9237$; H. Topsöe made some observations on this subject. P. Groth said the optic axial ratio is $2E$=c. 80°; and the indices of refraction for Na-light are $\beta=1·565$, and $\gamma=1·608$.

The crystals are readily soluble in water, but not in alcohol. The salt is not changed by boiling with water, and the soln. has a neutral reaction. According to J. Lang, the mother-liquor remaining after the separation of the tetranitrite furnishes rectangular plates of **potassium cadmium hexanitrite,** $4KNO_2.Cd(NO_2)_2$.

The early literature on mercury nitrites is somewhat confused, and difficult to follow. E. Péligot,[7] and J. H. Niemann prepared a soln. of **mercurous nitrite,** $HgNO_2$, by the action of conc. nitric acid on mercurous nitrate. E. Mitscherlich, and J. Lefort obtained a lemon-yellow basic salt by the action of mercury on a hot soln. of mercurous or mercuric nitrate ; it was taken to be mercurous nitrite. P. C. Ray supposed the lemon-yellow crystals were a basic nitrite, but later showed that they are hydroxymercurosic nitrate, $HgO(HO.HgNO_3)(HO.Hg_2.NO_3)$. C. Gerhardt correctly regarded this product as a mercurosic nitrate ; and it can be regarded as a salt of the orthonitric acid of W. N. Hartley. A. Baudrimont said that mercurous nitrite is formed by the action of nitrous acid on mercury, but C. Gerhardt could obtain only the nitrate by working at 0°. In 1860, J. Lang could say that there was no evidence that mercurous nitrite had ever been isolated—if mercurous nitrate be mixed with potassium nitrite, mercury separates and nitric oxide is evolved ; and if the potassium nitrite be in excess, potassium mercuric nitrate is formed. According to P. C. Ray, however, when mercury and dil. nitric acid are left in contact for a long time, the following salts may be formed : mercurous nitrite, $HgNO_2$; mercuric nitrite, $Hg(NO_2)_2$; mercurous nitrate, $HgNO_3.2H_2O$; and six or seven basic nitrates. Analyses show that the successive formation of these salts involves the initial production of mercurous nitrite ; after this the nitrates and basic nitrates appear. He said : Nitrite is the product of the combined action of nitrous and nitric acids 22°–33° on mercury : $2Hg+HNO_2+HNO_3=2Hg(NO_2)_2+H_2O$. Some of the nitrite is decomposed by the nitric acid, and the quantity of nitrous acid thus rapidly grows until mercurous nitrite and nitrate are accumulating in mol. proportions. Thereafter, the proportion of nitrous acid in soln. remains constant ; and it has become the catalytic agent between nitric acid and mercury which now interact : $2Hg+2HNO_3=HgNO_2+HgNO_3+H_2O$. At lower temp., the effects of diffusion and crystallization were enough to mask the equal production of nitrite and nitrate. When mercury is covered with nitric acid sp. gr. 1·11/15°, to a depth of 10 cms. at 30°–35°, the bright yellow mercurous nitrite soon begins to crystallize, generally as a crust over the mercury, but sometimes in separate large crystals. The whole may be left undisturbed for about 50 hours without the crystals showing erosion. Very little nitric oxide forms on the mercury, and even that is soon absorbed by the soln. In 24 hrs., the soln., just over the mercury, has attained a sp. gr. of 1·6–1·7, whilst at the surface its sp. gr. is hardly altered, scarcely any mercury salts being present. Mercurous nitrite is always formed when nitric acid, with 10–23 per cent. N_2O_5, acts on mercury at 22°–33° ; and an acid containing 13–14 per cent. N_2O_5, corresponding with a 1 : 4 dilution of nitric acid of sp. gr. 1·410, is the most favourable for the production of crystals of mercurous nitrite. If an acid of sp. gr. 1·135–1·140 is used in place of an acid of sp. gr. 1·11, small crystals appear in two or three days along with those of mercurous nitrate ; these soon give way to a crystalline crust, or large isolated crystals of $HgNO_3.H_2O$. The more conc. acid thus converts some nitrite into nitrate. N. R. Dhar found that the conversion of mercury into nitrite is favoured by ferric nitrite ; P. C. Ray found the converse.

P. C. Ray said that the crystals of mercurous nitrite are sulphur-yellow. The sp. gr. is 5·925, and the mol. vol. 83·04. He said that the salt develops nitric oxide at 100°, but P. C. Ray and A. C. Ghosh found that the decomposition begins at 140°, and is completed at 247°. When a thin layer of the nitrite is heated in vacuo, to 195°, P. C. Ray and J. N. Sen did not obtain a complete decomposition, and estimated that that would require a temp. of 250°. They consider that the results of the analysis of the decomposition products are in agreement with E. Divers and T. Shimidzu's observations on the thermal decomposition of silver nitrite, the primary reaction: $2HgNO_2 = 2Hg + 2NO_2$, followed by: $4NO_2 + 2Hg = 2HgNO_3 + 2NO$. Since P. C. Ray has shown that mercurous nitrite, like silver nitrite, interacts with ethyl iodide producing both ethyl nitrite and nitroethane, it is assumed that the mercurous nitrite is tautomeric having both the hydroxylic form $HgO \vdots NO$, and the imidic form $Hg \vdots NO_2$. The scission of the molecules is supposed to occur simultaneously in the regions represented by the dotted lines.

P. C. Ray said that mercurous nitrite can be kept in dry atm. *air* for years without change, but if the salt be exposed to moist air, it decomposes slowly, giving off nitric oxide. When dissolved in *water*, mercurous nitrite slowly forms mercuric nitrite and mercury, but about 22 per cent. remains undecomposed at ordinary temp., and forms, with the mercuric nitrite, mercurosic nitrite, $HgNO_2.2Hg(NO_2)_2$. If the mercurous salt be removed from the soln. by the addition of sodium chloride, a sodium mercuric nitrite is formed. On evaporating the aq. soln. of mercurous nitrite, various basic mercurosic nitrates crystallize out. Besides the anhydrous mercurous nitrite just described, P. C. Ray prepared **hemihydrated mercurous nitrite,** $HgNO_2.\frac{1}{2}H_2O$, in lemon-yellow crystals by allowing a somewhat dil. soln. of mercurous nitrite to evaporate spontaneously in a shallow dish for 2 or 3 days. This salt effloresces when kept in a desiccator over conc. sulphuric acid. T. H. Holland found that crystals are triclinic. P. C. Ray said that the action of water is similar to its effect on the anhydrous salt. E. Divers and T. Haga found that *hydrogen sulphide* reacts with mercurous nitrite suspended in water, forming sulphur, nitric oxide, ammonia, hydroxylamine, and mercuric sulphide; and with an excess of *sulphur dioxide,* mercuric sulphide, sulphuric acid, nitric oxide, and mercuric sulphide are formed. According to P. C. Ray, *sulphuric acid* slowly develops nitrous fumes in contact with mercurous nitrite, especially when heated. Mercurous nitrite changes into mercuric nitrite during the action of *dilute nitric acid* on mercury. The hydrolysis of the mercuric nitrite is the source of the basic mercurous nitrates, for the mercuric hydroxynitrite readily reacts with mercurous nitrate reforming mercurous nitrite, and mercuric hydroxynitrate, $HO.Hg.NO_3$. There is a slow escape of nitric oxide during the hydrolysis of mercuric nitrite. So long as any mercury remains, mercuric hydroxynitrate forms with it mercurous hydroxynitrate, $HO.Hg_2.NO_3$, $4HgNO_3 + 3Hg + Hg(NO_2)_2 + 2H_2O = 2NO + 4(HO.Hg_2.NO_3)$. This salt separates only in combination with the normal nitrate. In a few weeks, all the mercurous nitrite disappears, and crystals of mercurous tetrahydroxynitrate, $Hg_{10}(OH)_4(NO_3)_6$, separate out. If the temp. does not exceed 22°, for a time, these crystals are accompanied or preceded by those of mercurous hydroxytrinitrate, $Hg_4(OH)(NO_3)_3$. P. C. Ray showed that cold *concentrated nitric acid* has no immediate action on mercurous nitrite; but, after a few minutes, energetic action sets in. If the mixture is heated immediately after adding the conc. nitric acid, a violent action begins, copious red fumes are given off, and a clear soln. of mercuric salt is obtained. If, after adding conc. nitric acid, a small quantity of water is poured in, action at once commences, nitrous fumes are evolved, and the liquid becomes bluish; at the same time, a few globules of mercury separate, but disappear on warming the liquid, which contains both mercurous and mercuric salts. If, however, the salt be treated with *cold,* dil. nitric acid, the action is very slow, bubbles of gas being given off at intervals; it is only after the action has continued 3 to 4 days that the salt dissolves, and colourless crystals of a basic mercurous nitrate, $3HgNO_3.2HgOH$, or $Hg_5(OH)_2(NO_3)_3$, are deposited. When *potassium nitrite* is added to a soln. of mercurous nitrite, mercury is precipitated, and mercuric nitrite is formed. According to E. Abel, when mercury, mercuric nitrate, and $3N$-HNO_3 are shaken together, the conc. of the mercurous and mercuric salts in soln. are proportional to the conc. of the corresponding ions, and at 25°, the ratio $HgNO_3 : Hg(NO_3)_2$ is nearly constant, 239·5 : 1. This is taken to prove that the two ions have the same valency and that the reaction takes place in accord with $Hg'' + Hg = (Hg{-}Hg)^{\cdot\cdot}$, the mercurous ion consisting of two atoms. Since the reaction with an excess of potassium nitrite and mercurous nitrite is nearly quantitative, most of the mercuric ions pass into non-ionized mercuric nitrite, or into a stable complex; the measurements of H. Ley and H. Kissel, however, show that mercuric nitrite is appreciably ionized in aq. soln. The measurements of R. Abegg and H. Pick show that with mercurous nitrite the complex $Hg(NO_2)_4$-ion is formed. This corresponds with the salt $K_2Hg(NO_2)_4$—*vide infra*. The constant $k=3{\cdot}5\times10^{-13}$ for $[Hg(NO_2)''_4]=k[Hg]^{\cdot\cdot}[NO'_2]$, and therefore this complex is about five times less stable than the corresponding $HgCl''_4$-ion. P. C. Ray found that *sodium nitrite* and mercurous nitrite give a precipitate of mercury, and mercuric nitrite is formed; hot conc. soln. of mercurous nitrite and *silver nitrite* form a precipitate of silver and mercury—there is no loss of nitrogen, which remains entirely in the form of nitrite—in dil. soln. no silver was precipitated; *sodium chloride* precipitates mercurous salts as calomel when added to a soln. containing mercurous and mercuric salts; and P. C. Ray and P. Néogi, and P. Néogi and B. B. Adhicary studied the action of the alkyl iodides —*vide supra.*

J. Lang was of the opinion that normal **mercuric nitrite,** $Hg(NO_2)_2$, could not be prepared; he tried to make it by evaporating the filtered soln. resulting from the interaction of mercuric chloride and silver nitrite, but obtained only a basic salt. P. C. Ray showed that the failure is here due to the decomposition of the mercuric nitrite when evaporated on a water-bath. If conc. in vacuo over sulphuric acid, the normal salt is readily obtained in tufts of fine needles. H. Ley and H. Kissel obtained it in aq. soln. by the action of silver nitrite on an aq. soln. of mercuric chloride. P. C. Ray obtained it by the hydrolysis of mercurous nitrite as indicated above—about 22 per cent. escapes the hydrolysis. He also obtained it among the products of the action of dil. nitric acid on mercury—*vide supra.* If mol. proportions of crystals of silver nitrite and mercuric chloride are rubbed together with water in a mortar, so as to form a paste; shaken up with more water; and then evaporated in vacuo over sulphuric acid, pale, yellow, needle-like crystals of mercuric nitrite are formed. Mercuric nitrite is not stable in dry air; even in vacuo, over sulphuric acid, at ordinary temp., it gives off nitrous fumes, forming a white basic nitrate; the salt may remain for a long time in vacuo without change, but once decomposition has started, it cannot be arrested. The salt fuses with intumescence at 95°, and nitric oxide is at first evolved, and finally reddish-brown fumes appear. It was assumed that at 100°, the mercuric nitrite breaks up in two ways: $Hg(NO_2)_2=HgO+N_2O_3$; and $Hg(NO_2)_2=HgNO_3+NO$. In a general way, P. C. Ray considers that the greater the at. wt. of the element, the more pronounced the colour of the nitrites of the first and second groups in the periodic system. Mercuric nitrite is a pronounced yellow, magnesium nitrite is nearly white; barium nitrite likewise is more yellow than calcium nitrite. When exposed to air, mercuric nitrite slowly liquefies and gives off nitrous fumes; it dissolves only partially even in boiling water, the larger proportion decomposing into mercuric oxide and nitrous acid. The aq. soln. has an acid reaction. H. Ley and H. Kissel, and P. C. Ray and N. Dhar, measured the mol. conductivity, μ, of aq. soln. of normal mercuric nitrite. The latter found at 20° for soln. with a mol in v litres:

v . . .	17	153	459	1377	4131
μ . . .	5·16	10·18	14·13	34·51	83·32

P. C. Ray and S. C. Mukherjee found the degree of ionization to be 0·11 for a mol of the salt in 32 litres. P. C. Ray and N. Dhar found that if the aq. soln. be kept in a closed vessel for some time, some of the mercuric nitrite forms mercurous nitrate and a basic salt is formed; thus in 3 weeks, a soln. of sp. gr. 1·065 contained mercuric : mercurous mercury as 13·7 : 1. P. C. Ray and N. Dhar found that the conductivity measurements of aq. soln. of mercurous nitrite agree with the assumption that a complex $Hg_2(NO_2)'_5$-ion is present; this corresponds with **mercurosic nitrite,** $HgNO_2.2Hg(NO_2)_2$. For a dilution $v=187$, $\lambda=62{\cdot}33$, and when $v=561$, $\lambda=80{\cdot}10$. With dil. soln., hydrolysis occurs. If the aq. soln. be sealed up in an evacuated tube, the salt is not decomposed. When treated with alkali-lye, the solid salt forms mercuric oxide and alkali nitrite; and with sodium sulphate, the aq. soln. does not precipitate mercuric oxysulphate. P. C. Ray and S. C. Mukherjee estimated the degrees of ionization for dilutions $v=64\cdot8$ and $135\cdot2$ litres, respectively 1·82 and 1·77.

The basic mercuric nitrite obtained by J. Lang—*vide supra*—had the composition $3HgO.N_2O_3.H_2O$, and from the work of P. C. Ray, this product was probably a mixture. By evaporating an aq. soln. of mercurous nitrite, P. C. Ray reported that two **mercurosic hydroxynitrites** are formed after the soln. has deposited the triclinic prisms of hemihydrated mercurous nitrite. The next crop of crystals appears as small, orange nodules with the composition $9Hg_2O.4HgO.5N_2O_3.8H_2O$, and afterwards deep yellow clusters of needles or feathery tufts appear, their composition is given as $Hg_2O.2HgO.N_2O_3.2H_2O$. Later on, P. C. Ray showed that these salts are really mercurosic hydroxynitrates respectively, $(HgO)(HO.Hg_2.NO_3)_2$, and $(HgO)(HO.Hg.NO_3)(HO.Hg_2.NO_3)$. After these crystals have deposited, there then appear thin scaly crystals with a faint yellow tint, which, when dried over sulphuric acid, have the composition $12HgO.5N_2O_3.24H_2O$, or **mercuric hydroxynitrite**, $5Hg(NO_2)_2.7Hg(OH)_2.17H_2O$.

J. Lang, C. F. Rammelsberg, and A. Fock prepared what they regarded as **potassium mercuric tetranitrite**, $2KNO_2.Hg(NO_2)_2$, by evaporating the clear yellow soln. obtained by mixing mercuric nitrate with an excess of potassium nitrite, and drying the product in air or at 100°. P. C. Ray obtained it by grinding mercurous nitrite and potassium nitrite to a paste with the least possible quantity of water, adding more water, and evaporating the filtered soln. in vacuo over sulphuric acid. The pale yellow plates and prisms so obtained, according to A. Fock, belong to the rhombic system. They are very soluble in water, and P. C. Ray and N. Dhar found that the mol. conductivity, μ, of soln. with a mol of the salt in v litres of water, at 20°, is :

v .	17	51	153	459	1377	4131
μ . .	180·8	218·0	242·11	271·6	300·0	362·15

and a comparison of the results for the individual salts are in agreement with the assumption that the complex ion $Hg(NO_2)_4''$ is formed. P. C. Ray and S. C. Mukherjee estimated the degrees of ionization for dilutions $v=7\cdot2$ and $60\cdot4$ litres, to be respectively 1·26, and 1·58. J. Lang said that the salt is insoluble in alcohol; the aq. soln. has a neutral reaction, and can be boiled without change; aq. ammonia gives a pale yellow precipitate with the aq. soln., and the colour changes to white on washing. According to A. Rosenheim and K. Oppenheim, this salt is really hydrated **potassium mercuric pentanitrite**, $3KNO_2.Hg(NO_2)_2.H_2O$, which they prepared by treating dry mercuric nitrate with a very conc. soln. of potassium nitrite, filtering off the separated mercuric oxide, and crystallizing. V. Kohlschütter formulates the salt $[Hg(NO_2)_5H_2O]K_3$; and prepared it by allowing a mixture of dry mercuric oxalate and a very conc. soln. of potassium nitrite to stand for some time. P. C. Ray also prepared this salt; and P. C. Ray and S. C. Mukherjee estimated the degree of ionization to be 1·48 for a dilution $v=23$ litres. H. Töpsöe, A. Fock, P. Groth, and A. Sachs have described the prismatic or tabular crystals. The rhombic bipyramids have the axial ratios $a:b:c=0\cdot8671:1:0\cdot7646$, and are feebly doubly refracting; the optic axial angle $2H=92^\circ 40'$ for Li-light; $92^\circ 20'$ for Na-light; and $91^\circ 30'$ for Tl-light. V. Kohlschütter found that the crystals do not lose their combined water in vacuo over sulphuric acid; and do not lose weight when heated for an hour at 100°; they melt at about 125° without decomposition. According to A. Rosenheim and K. Oppenheim, the salt can be recrystallized from water without change; they obtained crystals of **potassium mercuric trinitrite**, $KNO_2.Hg(NO_2)_2$, by evaporating the mother-liquors obtained in the preparation of the preceding salt; and also from aq. soln. of the component salts with a small excess of potassium nitrite. The salt decomposes in aq. soln. P. C. Ray and J. N. Rakshit made sodium mercuric nitrite, without studying its composition; and P. C. Ray obtained **sodium mercuric**

heptanitrite, $3NaNO_2.2Hg(NO_2)_2$, by rubbing a mixture of mercurous nitrite and sodium nitrite in a mortar using as little water as possible; adding more water; and evaporating the filtered soln. in vacuo over sulphuric acid. The pale yellow plates and prisms are soluble in water and the aq. soln. has a mol. conductivity of 229·35, 250·0, and 266·72 for soln. with a mol in 100, 300, and 900 litres respectively. Hence P. C. Ray and N. Dhar infer that the salt ionizes, forming two $Na^{\cdot}$-ions and the complex ion $Hg(NO_2)''_4$. P. C. Ray also obtained crystals of dihydrated **sodium mercuric tetranitrite,** $2NaNO_2.Hg(NO_2)_2.2H_2O$, in a similar way to the heptanitrite, but A. Rosenheim and K. Oppenheim said that the salt is anhydrous. Hot water decomposes the salt with the separation of mercury and mercuric oxide. P. C. Ray obtained crystals of tetrahydrated **lithium mercuric hexanitrite,** $4LiNO_2.Hg(NO_2)_2.4H_2O$, by the process employed for potassium mercuric tetranitrite; and the mother-liquor gave crystals of hydrated **lithium mercuric trinitrite,** $LiNO_2.Hg(NO_2)_2.H_2O$. F. Ephraim prepared *potassium copper mercuric octochlorotetranitrite,* $K_2[Cu(NO_2)_4.H_2O]2K_2[HgCl_4.H_2O]$, in thick black prisms which may be a solid soln. or a mixture. P. C. Ray prepared **barium mercuric heptanitrite,** $2Ba(NO_2)_2.3Hg(NO_2)_2.5H_2O$, by evaporating under reduced press. over sulphuric acid, a soln. of the component salts. The dry salt is stable in a desiccator, but if not well dried, nitrous vapours may be given off. P. C. Ray and S. C. Mukherjee estimated the degree of ionization to be 3·34 for a dilution $v=126·0$ litres. P. C. Ray also made **strontium mercuric heptanitrite,** $2Sr(NO_2)_2.3Hg(NO_2)_2.5H_2O$, and **calcium mercuric heptanitrite,** $2Ca(NO_2)_2.3Hg(NO_2)_2.5H_2O$, in a similar manner. P. C. Ray and S. C. Mukkerjee estimated that for a dilution $v=42·1$ litres the degree of ionization for the calcium mercuric salt is 1·86.

P. C. Ray[8] has prepared **dimercuriammonium nitrite,** NHg_2NO_2, or, as E. C. Franklin prefers to represent it, $Hg:N.Hg.NO_2$, **mercuric mercuriimidonitrite.** According to P. C. Ray and A. C. Ghosh, when dried at 95°, it retains about half a mol of water. E. C. Franklin represented the composition of the *hemihydrate* by $HO.Hg.NH.Hg.NO_2.Hg_2N.NO_2$. K. A. Hofmann and E. C. Marburg, and E. C. Franklin prepared a *monohydrate* which the latter represents by the formula $HO.Hg.NH.HgNO_2$. P. C. Ray prepared this salt as follows: mercurous nitrite is acted on by water so as to obtain a soln. of mercuric mercurous nitrite, which is then changed to one of mercuric-sodium nitrite by careful addition of just enough sodium chloride. Another and better way of preparing mercuric-sodium nitrite soln. is to dissolve mercurous nitrite in a concentrated soln. of sodium nitrite, when half the mercury separates as metal. To the mercuric-sodium nitrite soln., filtered from the mercurous chloride dil. ammonia is gradually added until in slight excess. A cream-coloured, flocculent, but somewhat dense precipitate is produced, which is washed on a filter by aid of the suction-pump. Being slightly decomposed in the steam-oven, it has to be dried over sulphuric acid, and as it then collects into compact lumps, these are broken up and again exposed in the desiccator in order to facilitate the drying. The dry salt is pale yellow. When heated in a bulb-tube, the salt decomposes without fusing, giving off nitrous fumes, mercury, and water, and leaving a yellow residue—mostly mercuric oxide; and it gives most of its nitrogen as ammonia when heated with 20 per cent. potash-lye. P. C. Ray and A. C. Ghosh said that by analogy with the other dimercuric-ammonium salts, it might be anticipated that the nitrite would decompose: $2NHg_2NO_2=N_2+2Hg+2HgNO_2$, and that the mercurous nitrite so formed would yield its own products of decomposition. The temp. of decomposition is near 140°. Nitrous acid was found among the products of decomposition. They consider that the decomposition occurs in about four directions simultaneously: (i) $NHg_2NO_2=N_2+2HgO$; (ii) $NHg_2NO_2=N_2O+HgO+Hg$; (iii) $NHg_2NO_2=N_2+2Hg+O_2$; and (iv) $3NHg_2+3NO_2=Hg(NO_3)_2+2N_2+5Hg$. The nitrite can be converted into chloride, bromide, or nitrate.

The *nitrites of boron, aluminium, gallium, and indium* have not been reported.

F. Vogel[9] prepared **thallous nitrite,** $TlNO_2$, by mixing eq. proportions of aq. soln. of the component salts, and evaporating the filtrate on a water-bath. The yellow crystalline mass is soluble in water, but not in absolute alcohol. Crystals of the salt are precipitated from its aq. soln. by alcohol. The salt does not change in weight on heating at 140° ; but V. Thomas found that at a higher temp., it decomposes into thallous oxide and nitrogen oxide. W. C. Ball and H. H. Abram prepared thallium nitrite from a soln. of barium nitrite and thallous chloride. The evaporation of the liquid over sulphuric acid, or on a water-bath, furnishes a deep orange-red, crystalline mass. The salt readily fuses without decomposition; it is more soluble in water than the nitrate. L. Rolla and G. Belladen observed that thallous nitrite has a sp. conductivity below that of the nitrate, and undergoes normal ionization. The e.m.f. of the cell $Tl_{amalgam} \mid 0{\cdot}1N\text{-}TlNO_2$ with the normal electrode is 0·667 at 25°, and the same value is obtained if the nitrate be replaced by the nitrate. They obtained no complex salts with potassium nitrite and thallous nitrate. V. Cuttica found that the thermal behaviour of fused mixtures of thallium nitrite and nitrate excludes the formation of complexes. The two salts form an uninterrupted series of solid soln. V. Cuttica and A. Paciello observed that in aq. soln., thallous nitrite, like the alkali nitrites, is highly ionized, and the salt shows no tendency to form either complex or double nitrites; with cupric nitrate, thallous nitrite forms **thallous copper nitrite,** or *thallous cuprinitrite,* $Tl_3[Cu(NO_2)_5]$, in opaque, black, rounded crystals. This yields a pale green, aq. soln., and is decomposed by dil. acid, with formation of a blue soln. and liberation of nitrous acid. At the ordinary temp., both the solid salt and its aq. soln. are stable. In order to trace the displacement of the equilibria produced in soln. of cupri-nitrous complexes by variation of the relative conc. of the components, conductivity measurements have been made on soln. containing cupric chloride and barium nitrite in different proportions. The conductivity-composition curve shows two inflexions, due to the appearance of two complexes corresponding with the ions, $[Cu(NO_2)]$ and $[Cu(NO_2)_2]$. G. Canneri found that the treatment of a suspension of thallium sesquioxide in water with liquid nitrous anhydride, and subsequent evaporation of the soln., even in the cold under reduced press., yields, not thallic nitrite, but thallous nitrate. The latter is also obtained when soln. of thallic sulphate and barium nitrite are mixed in the cold, and the resulting liquid evaporated at low temp. That **thallic nitrite** is capable of existence in soln., although it cannot be obtained in the solid condition, is shown by the analyses and properties of the soln. The treatment of an aq. soln. of thallic nitrite with alcohol yields a precipitate of the sequioxide. In ethereal soln., thallic nitrite is far more stable, and the salt separates in the solid state on evaporation of the solvent; it could not, however, be analyzed directly. Decomposition of thallic nitrite, with formation of thallous nitrate, takes place solely in accordance with the equation $Tl(NO_2)_3 \rightarrow TlNO_3 + N_2O_3$, neither intermediate reduction products nor thallous-thallic complex compounds being formed. F. T. Frerichs and E. F. Smith obtained *didymium nitrite* in aq. soln. as a dark brown viscid liquid. G. Krüss and A. Loose attempted to prepare *yttrium and cerium nitrites* and to use the result as a means of separation of the earths. G. T. Morgan and E. Cahen obtained **cerous nitrite** contaminated with a small proportion of hydroxide by mixing eq. proportions of cold aq. soln. of cerous sulphate and barium nitrite. The pale yellow soln. was evaporated over potassium hydroxide in vacuo. The scum of basic nitrite was removed by filtration, and the yellow filtrate, when further concentrated, deposited yellow crystals. The salt is unstable, and evolves nitrous fumes at ordinary temp.; it is decomposed by warm water. The soln. yields basic nitrites when treated with alcohol. V. Cuttica and F. Gallo prepared the triple salt **ammonium copper cerous nitrite,** $15NH_4NO_2.4Cu(NO_2)_2.3Ce(NO_2)_3$, in black crystals which form a green soln. with water; **potassium copper cerous nitrite,** $12KNO_2.4Cu(NO_2)_2.Ce(NO_2)_3$, and **thallium copper cerous nitrite,** $5TlNO_2.3Cu(NO_2)_2.Ce(NO_2)_3$. H. Erdmann, and L. Pissarjewsky found that sodium and potassium nitrites precipitate thorium hydroxide from *thorium salts; titanium and zirconium salts* behave similarly.

No *tin nitrite* has been reported. J. L. Proust[10] prepared a lead nitrite by the action of metallic lead on a soln. of lead nitrate; and A. Thiel and L. Stoll showed that at 25° about 40 per cent. of the nitrate forms nitrite, and some basic nitrates as well. The reduction proceeds further at 100°, and in the presence of acetic acid. M. E. Chevreul, J. J. Berzelius, and E. Péligot prepared hydrated **lead nitrite,** $Pb(NO_2)_2.H_2O$, by passing a soln. of nitric oxide through a soln. of the basic nitrite in hot water; carbon dioxide was passed into the soln. to remove lead oxide, and the yellow filtrate was either evaporated spontaneously or under reduced press. J. Lang obtained it by double decomposition with a soln. of lead chloride and silver nitrite, and evaporating the clear soln. A. Chilesotti mixed theoretical proportions of soln. of lead chloride and lead nitrite, sat. at 25°; the soln. was cooled to —12° or —15° with vigorous stirring, and the clear filtrate evaporated to about one-sixth its bulk, and then allowed to stand in a desiccator over sulphuric acid. E. Müller and H. Barck made the normal nitrite by the action of nitric oxide on lead dioxide at ordinary temp., or on red-lead at 200°. P. Sabatier and J. B. Senderens passed nitric oxide into water in which lead dioxide was suspended. A. Thiel and L. Stoll found that by the action of lead on lead nitrate soln. at 25°, about 40 mol. per cent. of the nitrate undergoes reduction to nitrite, part of which separates together with nitrate as basic salts. This reduction is more complete at 100° or in the presence of acetic acid. Conversely, lead nitrite soln. alone, or in the presence of lead, partially changes to nitrate with the simultaneous separation of basic salts. The latter change makes the preparation of pure lead nitrite very difficult. The pure nitrite can, however, be obtained by treating solid silver nitrite with solid lead bromide in the presence of a small quantity of water. The yellow tabular or prismatic crystals are stable in air, but are easily decomposed. The salt readily dissolves in water, and the aq. soln. decomposes on evaporation. A. Chilesotti noticed that some nitrous fumes are evolved on evaporating the aq. soln. in vacuo at ordinary temp. The eq. conductivity, λ, for soln. with an eq. of salt in v litres is, at 20°:

v .	16	32	64	128	256	512	1024
λ .	59·4	72·3	85·5	98·9	111·3	122·1	129·7

The $0·1N$-soln. is less ionized than a corresponding soln. of lead nitrate, and about the same as one of lead chloride; conc. aq. soln. are worse conductors than those of lead nitrate or chloride. The conductivity increases with time, probably owing to a reaction: $3Pb(NO_2)_2+2H_2O=Pb(NO_3)_2+2Pb(OH)_2+4NO$. In the absence of air, lead nitrate and hydroxide are formed, the soln. becomes alkaline, and nitric oxide mixed with a little hydrogen is evolved. At 100°, equilibrium occurs when about 13 per cent. of the nitrite is transformed. If air be present, the decomposition goes further. According to A. Chilesotti, if a soln. of 25 grms. of lead nitrate in 1·5 litres of water is boiled for 5 hrs. along with 31 grms. of lead, an orange-yellow precipitate of **lead dioxynitrite,** $2PbO.Pb(NO_2)_2$, is produced, and F. Peters, and C. Bromeis obtained a similar product by boiling the orange-yellow basic nitritonitrate; and F. Peters, from the filtrate obtained in preparing some of the basic nitritonitrates. N. von Lorenz, and F. Peters said that the salt forms rhombic prisms which occur as masses or concentric tufts of needle-like crystals.

A number of other basic nitrites have been reported, but there is no proof of the individuality of these basic salts. P. Sabatier and J. B. Senderens made the same salt from the soln. obtained in their process of making normal lead nitrite; and R. Weinland and F. Paul, by the action of a soln. of sodium nitrite on a boiling soln. of lead oxychlorate. Thus, J. J. Berzelius, M. E. Chevreul, N. von Lorenz, E. Péligot, A. Chilesotti, and F. Peters described $4PbO.N_2O_3.H_2O$, or *lead trioxydinitrite,* $3PbO.Pb(NO_2)_2.H_2O$, or $2PbO.Pb(OH)_2.Pb(NO_2)_2$, as a red powder. F. Peters made yellowish-brown crystals of $10PbO.3N_2O_3.H_2O$, or *lead heptoxyhexanitrite,* $7PbO·3Pb(NO_2)_2.H_2O$, or $6PbO.Pb(OH)_2.3Pb(NO_2)_2$, and yellowish-green crystals of $7PbO·3Pb(NO_2)_2.3H_2O$, or $4PbO.3Pb(OH)_2.3Pb(NO_2)_2$;

A. Chilesotti, *lead dioxydinitrite*, $2PbO.Pb(NO_2)_2.H_2O$, or $PbO.Pb(OH_2.Pb(NO_2)_2$; N. von Lorenz, crystals of *lead henicosoxydocosinitrite*, $21PbO.11Pb(NO_2)_2.H_2O$, or $20PbO.Pb(OH)_2.11Pb(NO_2)_2$; and C. Bromeis, and A. Chilesotti, *lead oxydinitrite*, $PbO.Pb(NO_2)_2.H_2O$, or $Pb(OH)_2.Pb(NO_2)_2$, and the same salt with an addition 0·5 or 1 mol H_2O.

J. J. Berzelius obtained normal **lead hexanitritodinitrate,** $3Pb(NO_2)_2.Pb(NO_3)_2.4H_2O$, by adding enough sulphuric acid to a soln. of $2Pb(OH)_2.Pb(NO_2)_2.Pb(NO_3)_2$ to precipitate half the lead, or by passing carbon dioxide through the soln. so long as lead carbonate is precipitated. Lemon-yellow octahedra are obtained by evaporation in vacuo. M. E. Chevreul also prepared this salt, and observed that a crop of white needles appeared before the yellow octahedra. J. J. Berzelius, M. E. Chevreul, J. Nicklès, and A. Gomes regarded the salt as a chemical individual; E. Péligot, and A. Chilesotti, as a mixture.

A. Stromeyer observed the formation of a yellow precipitate when an acetic acid soln. of a lead salt is treated with potassium nitrite. N. W. Fischer, and W. Hampe prepared **potassium lead heptanitrite,** $K_3Pb_2(NO_2)_7.(0 \text{ to})1{\cdot}5H_2O$, by evaporating a mixed soln. of lead nitrite or acetate and potassium nitrite; needle-like crystals separate from the soln. in hot water; A. Chilesotti obtained it by mixing hot conc. soln. of 2 mols of potassium nitrite and one of lead acetate, and washing the precipitate with alcohol; and it crystallizes from a soln. of lead acetate and an excess of potassium nitrite. The orange-yellow, six-sided, monoclinic needles or prisms are stable in air. W. Hampe found them to be readily soluble in water, and less soluble in alcohol. J. Lang prepared **potassium lead tetranitrite,** $K_2Pb(NO_2)_4.H_2O$, by evaporating a soln. of lead acetate and an excess of potassium nitrite; and by the action of an excess of potassium nitrite on a soln. of lead nitrate. A. Chilesotti also prepared the salt. It furnishes orange-yellow prisms, which are readily soluble in water, but not in alcohol. The aq. soln. reacts neutral; there is a slight hydrolysis when the aq. soln. is evaporated; aq. ammonia and potassium carbonate give white precipitates with a soln. of the salt.

A. Chilesotti obtained a basic salt, **potassium lead oxypentanitrite,** $KNO_2.PbO.2Pb(NO_2)_2$, by treating a soln. of the tetranitrite with lead hydroxide, or by evaporating an aq. soln. of the tetranitrate. S. D. Hayes reported **potassium lead dinitritodinitrate,** $2KNO_3.Pb(NO_2).H_2O$, by passing nitric oxide into a supersaturated soln. of lead nitrate in potash-lye. A. N. Meldrum represented its composition $K_2Pb(NO_2)_3(NO_3).H_2O$. J. Lang, and F. Peters reported orange-yellow prisms of **potassium lead octonitritotetranitrate,** $K_6Pb_3(NO_2)_8(NO_3)_4.3H_2O$.

C. Przibylla prepared the triple salt **ammonium copper lead nitrite,** $CuPb(NH_4)_2(NO_2)_6$, by adding a soln. of copper and lead nitrites to a soln. of ammonium nitrite and sodium nitrite. The product is a black, crystalline salt having a bluish, metallic lustre; it is stable at the ordinary temp. or when gently warmed, and is very similar to the corresponding potassium salt. Like this salt, all the other triple nitrites contain $6NO_2$. A. H. van Lessen reported **potassium copper lead hexanitrite,** $K_2CuPb(NO_2)_6$, or, according to F. Ephraim, $K_2Pb[Cu(NO_2)_6]$, to be precipitated by adding acetic acid to a mixed soln. of cupric nitrate, lead acetate, and potassium nitrite. The dark green cubic crystals have a sp. gr. 3·345 at 15°.

F. von Oefele[11] found that when nitric acid acts on tellurium, using large quantities of material and a high column of liquid (not less than 50 cms.), **tellurium nitrite** was obtained as a flesh-coloured precipitate, which could be dried at 100° without decomposition. At higher temperatures it decomposes, leaving a residue of yellow tellurium dioxide. O. T. Christensen[12] prepared a series of **chromic nitritopentammines,** $[Cr(NO_2)(NH_3)_5]X_2$, or *chromic xantho-salts*. For instance, **chromic nitritopentamminochloride,** $[Cr(NO_2)(NH_3)_5]Cl_2$, was obtained as follows:

Twenty grams of chromic chloropentamminochloride are treated with 300 c.c. of water and a few drops of nitric acid, and the soln. is heated until all is dissolved. It is then left at rest, and should any unaltered chromic chloropentamminochloride separate out, it is filtered off and treated as before. To the soln. of chromic aquopentamminochloride obtained in this way 40 to 50 grms. of sodium nitrite and 25 c.c. of dil. hydrochloric acid are added, and the mixture stirred, when a yellow crystalline precipitate of chromic nitritopentamminochloride separates out; this is collected, washed with water and with alcohol, and dried at the ordinary temp. In order to purify it, the chloride is dissolved in water and filtered into a soln. of ammonium chloride; the precipitated chromic nitritopentamminochloride is collected, washed with water to remove ammonium chloride, then with alcohol, and dried at the ordinary temp.

Chromic nitritopentamminochloride is a yellow crystalline powder composed of microscopic octahedra; it is more soluble in water than chromic chloropentamminochloride, and less soluble than chromic aquopentamminochloride. According to A. Werner and A. Miolati, the mol. conductivity of soln. with a mol of the salt in v litres of water at 25°, is:

v	125	250	500	1000	2000
μ	221·0	239·3	252·0	261·0	271·6

O. T. Christensen observed that the aq. soln. of the nitritopentamminochloride in acids liberate nitrous acid from it, and hydrochloric acid converts it into chromic chloropentamminochloride. Sodium hydroxide dissolves it, forming a soln. which probably contains *chromic nitritopentamminohydroxide*, and from which chromic hydroxide separates on boiling; ammonia is also evolved. Aq. ammonia has no action on chromic nitritopentamminochloride. Cold aq. soln. of chromic nitritopentamminochloride give the following reactions: (1) With platinum chloride, a yellow crystalline precipitate consisting of needles or prismatic crystals. (2) With hydrogen fluosilicate, no precipitate, but the salt is decomposed. (3) With the double chloride of sodium and mercury, a yellowish-red crystalline precipitate. (4) No precipitates with ferro- or ferri-cyanide of potassium. (5) With potassium chromate and dichromate, beautiful yellow precipitates. (6) With sodium dithionate, a yellow crystalline precipitate, consisting of microscopic needles. Reaction is very characteristic for nitritopentamminochloride compounds. (7) With potassium and ammonium chlorides, potassium bromide, iodide, and nitrate, precipitates are obtained of the chloride, bromide, iodide, and nitrate respectively. Chromic nitritopentamminochloride furnishes a complex salt with mercuric chloride, $[Cr(NO_2)(NH_3)_5]Cl_2.2HgCl_2$, and the nitritopentammine forms a *bromide*, *iodide*, *nitrate*, a monohydrated *sulphate*, a monohydrated *dithionate*, *carbonate*, *chromate*, *dichromate*, and a *chloroplatinate*.

Normal **bismuth nitrite**, $Bi(NO_2)_3$, is unknown. L. Vanino and F. Hartl[13] prepared **bismuthyl nitrite**, $BiO(NO_2).\frac{1}{2}H_2O$, by adding sodium nitrite to an aq. soln. of mannitol bismuth nitrate. The yellowish-white precipitate decomposes above 60°, and readily dissolves in hydrochloric acid, forming a clear soln. on dilution.

W. C. Ball prepared **potassium hexanitritobismuthite**, or *potassium bismuth nitrite*, $K_3Bi(NO_2)_6.H_2O$, in orange- or golden-yellow plates, by precipitation on mixing conc. soln. of bismuth and potassium nitrites, with exclusion of air as far as practicable. The salt cannot be kept without decomposition more than a few days. W. C. Ball and H. H. Abram prepared **rubidium hexanitritobismuthite**, or *potassium bismuth nitrite*, $Rb_3Bi(NO_2)_6.2H_2O$, in a similar manner. The orange-yellow plates are less stable and less soluble than those of the potassium salt. Under similar conditions, **cæsium enneanitritodibismuthite**, or *cæsium bismuth nitrite*, $Cs_3Bi(NO_2)_6.Bi(NO_2)_3$, or $Cs_3Bi_2(NO_2)_9$, appears in place of the hexanitritobismuthite. The golden or orange hexagonal plates look like lead iodide. Under similar conditions **thallous heptanitritobismuthite**, or *thallous bismuth nitrite*, $Tl_3Bi(NO_2)_6.TlNO_2.H_2O$, is formed. The cæsium salt is the most electropositive, and it needs an extra molecule of bismuth nitrite, while the thallium salt is the most electronegative, and it needs an extra molecule of thallous nitrite.

W. C. Ball and H. H. Abram prepared a series of mixed salts of lithium nitritobismuthite. Thus, if 5 grms. of ammonium nitrate in 10 c.c. of water are added to a mixture of 16 c.c. of a 90 per cent. soln. of lithium nitrite and 4 c.c. of bismuth nitrate, cooled to 0°, a yellow crystalline precipitate of ammonium lithium hexanitritobismuthite, $(NH_4)_2LiBi(NO_2)_6.H_2O$, is formed; it decomposes when kept a few days, and it is hydrolyzed by water; yellow, octahedral crystals of potassium lithium hexanitritobismuthite, $K_2LiBi(NO_2)_6$, are produced in a similar way. The salt is quite stable, its sp. gr. is 3·21 at 15°, and it is easily hydrolyzed by water; similarly with rubidium lithium hexanitritobismuthite, $Rb_2LiBi(NO_2)_6$, which forms stable, yellow, octahedral crystals less soluble than the potassium salt; with cæsium lithium hexanitritobismuthite, $Cs_2LiBi(NO_2)_6$, in stable, yellow crystals less soluble than the rubidium salt; and with thallous lithium hexanitritobismuthite, $Tl_2LiBi(NO_2)_6$, in stable, pale brown, probably octahedral crystals sparingly soluble in water. By adding a soln. of silver nitrate to a soln. of ammonium nitrite containing bismuth nitrate, or better, by adding to an aq. soln. of sodium nitrite first bismuth nitrate and then silver nitrate, and treating the liquid with ammonium nitrate, a red crystalline precipitate of ammonium silver hexanitritobismuthite, $(NH_4)_2AgBi(NO_2)_6$, is formed. The salt is soluble in water; is hydrolyzed by water; is fairly stable at ordinary temp.; but when dry explodes feebly when rubbed in a mortar. W. C. Ball and H. H. Abram also prepared potassium silver hexanitritobismuthite, $K_2AgBi(NO_2)_6$, in orange-red, octahedral crystals less soluble than the ammonium salt; rubidium silver hexanitritobismuthite, $Rb_2AgBi(NO_2)_6$, in stable orange-yellow, probably octahedral crystals, which are sparingly soluble, and hydrolyzed by water; cæsium silver hexanitritobismuthite, $Cs_2AgBi(NO_2)_6$, in pale yellow, sparingly soluble crystals, slowly decomposed by water; blackened in light; but stable in darkness; and thallous silver hexanitritobismuthite, $Tl_2AgBi(NO_2)_6$, as a stable, red crystalline powder, very sparingly soluble in water, and slowly hydrolyzed by that menstruum. A stable yellow **ammonium sodium hexanitritobismuthite,** $Bi(NO_2)_3.2(NH_4)NO_2.NaNO_2$, or $(NH_4)_2NaBi(NO_2)_6$, crystallizing in octahedra, is obtained by dissolving bismuth nitrate in a conc. soln. of ammonium nitrate, and adding the resulting liquid to a sat. soln. of sodium nitrite at 0°, and acidified with nitrous fumes; similarly with potassium sodium hexanitritobismuthite, $K_2NaBi(NO_2)_6$, an unstable yellow, crystalline powder, which is hydrolyzed by water; rubidium sodium hexanitritobismuthite, $Rb_2NaBi(NO_2)_6$, as a yellow crystalline powder; cæsium sodium hexanitritobismuthite, $Cs_2NaBi(NO_2)_6$, and thallous sodium hexanitritobismuthite, $Tl_2NaBi(NO_2)_6$, in large, honey-yellow crystals which are fairly stable and slowly decomposed at 100°. The *monohydrate* was also prepared. W. C. Ball reported an unstable, yellow salt, probably **ammonium sodium bismuth nitratonitrite,** $Bi(NO_2)_3.2(NH_4)NO_2.(NH_4)NO_3.NaNO_3$, to be precipitated by dissolving bismuth nitrate in a soln. of sodium nitrite, and pouring the resulting orange-coloured liquor into a sat. soln. of ammonium nitrate at 0°. For complexes with nickel, *vide infra.* F. Ephraim prepared **cæsium copper lead hexanitrite,** $Cs_2Pb[Cu(NO_2)_6]$, in black, microscopic crystals, sparingly soluble in water. L. Rolla and G. Belladen obtained some complex salts from soln. of lead nitrate and thallous nitrite; and V. Cuttica and A. Paciello prepared **thallous lead nitrite,** $Tl_2Pb(NO_2)_4.H_2O$, from soln. of lead acetate and thallous nitrite, evaporated in vacuo. The orange-red crystals are more stable than lead nitrite, and the aq. soln. on heating separates lead hydroxide.

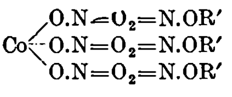
J. A. Arfvedson[14] said that **uranyl nitrite** is formed when uranyl nitrate, $UO_2(NO_3)_2.6H_2O$, is heated; at a dull red heat, uranosic oxide is formed. The work of W. O. de Coninck makes this statement somewhat doubtful.

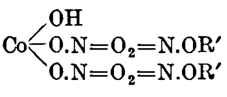
According to C. J. B. Karsten,[15] when small quantities of hydrated manganic dioxide are treated with nitric oxide in the presence of water, **manganous nitrite,** $Mn(NO_2)_2$, is formed; while with large quantities, manganous nitrate is formed. E. Mitscherlich, and J. Lang showed that when an attempt is made to concentrate the soln., hydrolysis occurs, and hydrated manganese dioxide is precipitated. Neither **ferrous nitrite** nor **ferric nitrite** has been prepared; but C. Przibylla obtained some triple salts. Thus, a bright yellow precipitate which is apparently a mixture of salts is obtained on mixing equivalent quantities of ferrous chloride, barium chloride, and potassium chloride with the necessary quantity of sodium nitrite; by varying the proportions of the metallic salts, various mixtures of salts are obtained. A compound of the formula $FeBaK_2(NO_2)_6$, **potassium barium iron nitrite,** is obtained by mixing a soln. of ferrous chloride, [12·5 c.c. (1 c.c.=0·1943 grm. Fe)], potassium chloride (13 grms.), and crystallized barium chloride (22 grms.) in 120 c.c. of water with 100 c.c. of a soln. of sodium nitrite (10 c.c.=5 grms. sodium nitrite); the precipitate is quickly separated by filtration, washed with alcohol, and dried at a gentle heat. Yellow to reddish-yellow precipitates of **potassium strontium nitrite**, and **potassium calcium nitrite** containing the three nitrites, are obtained in a similar manner to the above salts; but they contain varying proportions of each nitrite according to the relative amounts of the constituents employed. The author was unable to obtain a compound to which a simple formula could be assigned. The corresponding ammonium salts of iron nitrite can be obtained in a similar manner by employing small quantities of the constituents for each experiment; they are very similar to the potassium salts. **Iron lead potassium nitrite** is obtained on adding a soln. of ferrous and lead nitrates to a soln. of potassium nitrate and sodium nitrite as a heavy, reddish-yellow precipitate; this, after being washed by decantation with water, and then on a filter with alcohol, is an intense orange-yellow powder, insoluble in cold water and stable at the ordinary temperature.

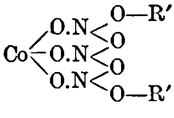
J. Lang,[16] W. Hampe, and C. F. Rammelsberg obtained a dark brown or a dark red soln. by mixing a soln. of barium nitrite and cobalt sulphate; it is thought that *cobaltous nitrite* is present; when the soln. is evaporated, some nitric oxide is given off. W. Hampe considered the red solid product is **cobaltosic nitrite.** W. R. E. Hodgkinson and N. E. B. Bellairs said that aq. ammonia exposed to air dissolves metallic cobalt, forming a nitrite; and C. Matignon and G. Desplantes observed that the metal is oxidized under these conditions. C. Duval obtained cobalt nitrite by the action of sodium or potassium nitrite, in the presence of ammonium acetate, on cobalt acetate, using ammonia, alcohol, or acetone as solvents. It is yellow and slightly soluble in water. During the evaporation of the reddish-brown soln. of cobaltous nitrite, some small dark brown crystals which formed were considered by J. Lang to be *cobaltic nitrite,* and by W. Hampe, basic cobaltic nitrite. According to A. Rosenheim and I. Koppel, when nitrous acid is added to a suspension of cobalt carbonate in water, a brown soln. is formed from which, on evaporation at ordinary temp., dark brown crystals of cobaltous nitrite are obtained along with crystals of **cobaltosic oxyhexanitritodinitrite,** $2CoO.2Co(NO_2)_3.Co(NO_3)_2.14H_2O$. There is therefore no satisfactory evidence that moderately pure cobaltous or cobaltic nitrite has been isolated. L. le Boucher treated a soln. of cobalt nitrate in pyridine and water with sodium nitrite at 0°; in an atm. of hydrogen, a light red **cobaltous tripyridinonitrite,** $Co(NO_2)_2.3C_5H_5N$, was obtained. By crystallization from pyridine, dark red crystals of **cobaltous hexapyridinonitrite,** $Co(NO_2)_2.6C_5H_5N$, were obtained. Both compounds were hydrolyzed by water. The latter compound was readily oxidized in air, mixed crystals of the nitrate being formed.

O. L. Erdmann reported **potassium cobaltous tetranitrite,** $K_2Co(NO_2)_4$, or $6KOH.3Co_3(NO_2)_2$, to be separated as a yellow crystalline powder when soln. of cobaltous chloride and an excess of potassium nitrite are mixed. No oxygen is absorbed from the air during its formation, and O. L. Erdmann, and S. P. Sadtler used an atm. of carbon dioxide. The salt was also prepared by A. Stromeyer, and C. D. Braun. The salt is insoluble in cold water, but soluble in hot water, forming a red soln. It forms a violet soln. if potassium acetate is present, containing cobaltous salts. The salt decomposes when heated. C. D. Braun said that cobaltic hydroxide is precipitated when the soln. is boiled with potash-lye. O. L. Erdmann said that the cobalt is not contained in the salts as a base in the ordinary sense of the word. C. D. Braun supposed that the cobalt is present as sesquioxide. C. W. Blomstrand has discussed the constitution of the salt. For **potassium cobalt diamminotetranitrite,** $K[Co(NH_3)_2(NO_2)_4]$, *vide infra.* S. P. Sadtler obtained black or dark green cubic crystals of $KCo(NO_2)_2.\frac{1}{2}H_2O$, **potassium cobaltous dinitrite,** by mixing a dil. soln. of potassium nitrite and a hot soln. of cobaltous chloride; and the mother-liquid furnishes a yellow flocculent precipitate of **potassium cobaltous trinitrite,** $K_2Co(NO_2)_2.H_2O$. The same salt was made by mixing hot conc. soln. of potassium nitrite and cobaltous chloride. A. Rosenheim and I. Koppel made **potassium cobaltic oxyoctonitrite,** $Na_4Co_2(NO_2)_8O$, by the method indicated below for the sodium salt.

According to G. C. Williamson and P. Berckman, *aureolin*, or *cobalt yellow*—a double nitrite of cobalt and potassium—was first used as a pigment about 1800, and possibly a little earlier. N. W. Fischer made **potassium cobaltic nitrite,** $K_3Co(NO_2)_6.1\frac{1}{2}H_2O$, as a yellow powder, by mixing an acidified soln. of cobaltous chloride with potassium nitrite. E. St. Evre, and A. Stromeyer prepared the salt in a somewhat similar way; and the former also treated with an excess of potassium nitrite the blue precipitate obtained by adding potassium hydroxide to cobaltous nitrate; the same salt was obtained by treating the precipitate and mother-liquor with nitric oxide. A. Rosenheim and I. Koppel made the salt by suspending freshly precipitated cobaltous chloride in a small proportion of water, adding the calculated quantity of potassium hydroxide, carbonate, or nitrite, and then mixing the mass with nitrous acid until the cobalt carbonate is all dissolved. The analyses of the salt—by O. L. Erdmann, C. D. Braun, S. P. Sadtler, M. Cunningham and F. M. Perkin, A. Stromeyer, and E. St. Evre—are not very concordant. C. W. Blomstrand, and A. Rosenheim and I. Koppel discussed the constitution of the salt. While A. Werner represented the constitution of the three series of complex cobaltic nitrites by $[Co(NO_2)_6]M'_3$; $[Co(NO_2)_4X]_3M'$; and $[Co(NO_2)_3X_3]$, A. Rosenheim and I. Koppel represented them graphically as derivatives of orthonitrous acid, $N(OH)_3$:







The yellow crystals consist of four-sided prisms. C. D. Braun found that the salt, dried at 40°–60°, does not change in weight at 100°, but at 200° it loses about 23·73 per cent. in weight. According to E. St. Evre, when the salt is heated in a sealed tube, it becomes orange-yellow, and melts, giving off water, nitrogen peroxide, and nitrous acid, and leaves behind a mixture of cobalt sesquioxide and potassium nitrite. If heated in dry carbon dioxide, nitric oxide and nitrogen are also formed; in hydrogen, acid vapours, and ammonia are produced; the residue, with water, yields cobalt, and an alkaline liquid containing some cobalt. The salt potassium cobaltic hexanitrite is sparingly soluble in cold water; T. Rosenbladt said that at 17°, 1000 parts of cold water dissolve 0·893 part of salt. The salt is decomposed by hot water with the exclusion of air, forming nitric oxide; if air be present, nitric fumes are evolved and the liquid becomes alkaline and rose-red, forming ordinary cobaltous and potassium nitrites. A. Rosenheim and I. Koppel said that when boiled with water, the salt dissolves with the evolution of nitric acid, and the evaporation of the soln. furnishes a mixture of red and yellowish-brown crystals which cannot be separated. E. St. Evre said that the salt is not soluble in alcohol or ether, and only a trace dissolves in carbon disulphide. M. Pierrat found that with soln. containing the following percentage amounts of alcohol, the solubilities, in grams per litre, were:

Alcohol . .	94·7	42·4	27·3	15·9	8·7	0 per cent.
Solubility . .	0·026	0·033	0·036	0·056	0·09	0·21

A. Stromeyer found it to be insoluble in cold or hot of fairly concentrated soln.

of potassium sulphate, chloride, nitrate, or acetate; but in a soln. of sodium or ammonium chloride it is more soluble than it is in water. E. St. Evre found that chlorine does not decompose the salt in the cold, nor does cold hydrochloric or nitric acid dissolve the salt, but when heated the salt is decomposed with the evolution of red vapours. Hydrogen sulphide attacks the salt suspended in water, very slowly; but ammonium sulphide very quickly forms a black sulphide. According to C. D. Braun, a boiling soln. of sodium hydrophosphate decomposes the salt with the separation of a blue precipitate, and the filtrate contains nitric acid. A boiling conc. soln. of sodium pyrophosphate furnishes a clear brownish olive-green liquid which becomes paler when boiled; when the cold liquid is treated with potassium cyanide, and a little acetic acid, potassium cobaltinitrocyanide, $K_4Co_2Cy_9(NO_2).3H_2O$, is formed. According to A. Stromeyer, potassium hydroxide acts on the salt with difficulty, and, added C. D. Braun, and R. Wegscheider, if a conc. soln. is employed, the salt becomes greenish-yellow. A. Stromeyer showed that hot soda-lye, or hot baryta-water, decomposes the salt, forming brown cobaltic hydroxide if air be absent. C. D. Braun found that hot lime-water acts similarly. If the salt be boiled with water and silver carbonate, cobaltic hydroxide is precipitated and the liquid on evaporation yields colourless needles which S. P. Sadtler considered to be silver nitrite. Further, a boiling soln. of ferrous sulphate results in the separation of ferric hydroxide and the formation of nitrous acid. The salt is not decomposed by potassium cyanide, but, added A. Rosenheim and I. Koppel, a conc. soln. of potassium cyanide heated on a water-bath decomposes much of the salt with the evolution of nitrogen and nitrous oxide, forming a brown soln. which contains potassium cobalticyanide. For the cobaltic amminonitrite, *vide infra.*

A. Rosenheim and I. Koppel prepared yellow **rubidium cobaltic hexanitrite,** $Rb_3Co(NO_2)_6$, by the method for the potassium salt. T. Rosenbladt obtained it by boiling a soln. of equal parts of cobaltous nitrate and sodium acetate in 15 parts of water, adding 20 per cent. acetic acid, and stirring up the mixture with a conc. soln. of sodium nitrite. T. Rosenbladt said that 1000 parts of water at 17° dissolve 0·0505 part of the salt. Hence, H. Erdmann said that it is the least soluble of all the rubidium salts. T. Rosenbladt, and H. Erdmann also prepared yellow **cæsium cobaltic hexanitrite,** $Cs_3Co(NO_2)_6$. According to the former, 1000 parts of water at 17° dissolve 0·0497 part of the salt. According to A. Stromeyer, sodium nitrite gives no precipitate with a soln. of cobaltous chloride and sodium acetate. C. D. Braun obtained no complex salt by treating soln. of cobaltous salts with sodium hydroxide and nitrite.

A. Rosenheim and I. Koppel found that if an excess of a conc. soln. of sodium nitrite be added to a boiling soln. of cobaltous chloride and acetic acid, some nitric oxide is evolved, and a yellow salt, $Na_2Co(NO_2)_5.\frac{1}{2}H_2O$, sodium cobaltic pentanitrite, is precipitated. S. P. Sadtler washed the salt with a soln. of sodium acetate, and then with alcohol. A. Rosenheim and I. Koppel also prepared a basic salt, $Na_4Co_2(NO_2)_8O$, **sodium cobaltic oxyoctonitrite,** by allowing the brown mother-liquors obtained in the preparation of the hexanitrite to evaporate over sulphuric acid; a reddish-brown, crystalline powder is obtained, which is not, however, the pure salt; when dissolved in water, it is not precipitated by alcohol; with nitrous acid, it yields the preceding salt; with potassium chloride, it does not give a precipitate, and when the mixture is allowed to evaporate over sulphuric acid, the corresponding potassium salt is obtained as a brown, microcrystalline powder. S. P. Sadtler, and M. Cunningham and F. M. Perkin prepared **sodium cobaltic hexanitrite,** $Na_3Co(NO_2)_6$, and A. Rosenheim and I. Koppel obtained it by the method employed for the potassium salt, but in this case, the salt is precipitated by adding alcohol to the black, filtered soln. The yellow precipitate was washed by suction with alcohol, and ether, and dried in air. A little of the oxyoctonitrite is present as impurity. The salt dissolves in water, forming a yellowish-brown soln. which gives off nitric oxide when heated. R. Wegscheider said that sodium cobaltic hexanitrite can be prepared readily by adding to a hot conc. soln. of sodium nitrite a soln. of a cobaltous salt, free from nickel, acidifying with acetic acid, and boiling for a few minutes. The soln. gives a yellow precipitate of potassium cobaltinitrite with potassium salts, is not precipitated by dil. sodium hydroxide soln. in the cold (indicating the absence of Co'' and $Co^{\cdot\cdot\cdot\cdot}$ ions), but yields a precipitate of cobaltic hydroxide on boiling, which shows that the complex salt contains tervalent cobalt and is decomposed by boiling alkalies. Alkaline soln. are not stable in the cold. The general reactions resemble those of the potassium salt, excepting the greater solubility of the sodium salt. N. Schiloff and B. Nekrassoff studied the adsorption of the salt by activated charcoal. R. H. Adie and T. B. Wood described **sodium dipotassium cobaltic nitrite,** $K_2NaCo(NO_2)_6.H_2O$, obtained as a yellow precipitate by adding the sodium salt to a one per cent. soln. of potassium chloride acidified with acetic acid. It does not lose its water of crystallization at 130°. Its solubility in water is rather less than one part in 20,000 parts. This salt was also obtained by W. A. Drushel, L. T. Bowser, and O. M. Shedd. W. C. Bray said that the precipitation is delicate enough to detect sixty parts of potassium per million. F. E. Brown and J. E. Snyder found that a crystal of this salt swells and blackens when boiled with vanadium oxytrichloride. L. L. Burgess and O. Kamm showed that the corresponding **disodium potassium cobaltic nitrite,** $NaK_2Co(NO_2)_6$, can also be made. **Lithium cobaltic hexanitrite,** $Li_3Co(NO_2)_6$, and **ammonium cobaltic hexanitrite,** $(NH_4)_3Co(NO_2)_6.1\frac{1}{2}H_2O$, were prepared by O. W. Gibbs and T. A. Genth, O. L. Erdmann, S. P. Sadtler, W. C. Ball and H. H. Abram, and A. Rosenheim and I. Koppel.

A. Rosenheim and I. Koppel obtained a green compound, thought to be **copper cobaltic nitrite,** by the action of sodium cobaltic nitrite on a cupric salt. M. Cunningham and F. M. Perkin prepared **silver cobaltic hexanitrite,** $Ag_3Co(NO_2)_6$, as an orange-yellow salt, fairly soluble in water, by adding a soln. of silver nitrate to a conc. soln. of sodium cobaltic nitrite. L. L. Burgess and O. Kamm also obtained the intermediate salts **potassium disilver cobaltic hexanitrite,** $Ag_2KCo(NO_2)_6$, and **dipotassium silver cobaltic hexanitrite,** $K_2AgCo(NO_2)_6$. They also obtained **rubidium silver cobaltic hexanitrites, cæsium silver cobaltic hexanitrites, thallium silver cobaltic hexanitrites,** and **ammonium silver cobaltic hexanitrites.** A. Rosenheim and I. Koppel also reported **silver cobaltic oxyhexanitrite,** $2Ag_2O.Co_2O_3.3N_2O_3.3H_2O$, to be formed when silver nitrate is treated with a soln. of the potassium salt. It is sparingly soluble in water, and is decomposed by boiling water with the formation of silver nitrite. A. Rosenheim and I. Koppel prepared **barium cobaltic dodecanitrite,** $Ba_3Co_2(NO_2)_{12}.14H_2O$, from a soln. of sodium cobaltic hexanitrite and barium chloride; or by the action of nitrous acid on cobalt carbonate and barium nitrite suspended in water. The deep brown soln. is filtered before all the cobalt carbonate is dissolved, and then treated with more nitrous acid. The conc. soln. gives a yellow or brownish-yellow microcrystalline powder; the crystals are six-sided plates. The salt is less stable than the corresponding alkali salts. It is almost insoluble in cold water, and is decomposed by hot water. The corresponding **strontium cobaltic dodecanitrite,** and **calcium cobaltic dodecanitrite** were not analyzed. The mother-liquor from barium cobaltic dodecanitrite, containing a slight excess of cobalt carbonate when evaporated over sulphuric acid, furnishes a crop of crystals of the dodecanitrite and afterwards dark red crystals of **barium cobaltic oxyoctonitrite,** $Ba_2Co_2O(NO_2)_8$, which dissolve in warm water without decomposition. Corresponding **strontium cobaltic oxyoctonitrite,** $Sr_2Co_2O(NO_2)_8$, and **calcium cobaltic oxyoctonitrite** were also prepared. **Magnesium cobaltic hexanitrite,** $Mg_3[Co(NO_2)_6]_2$, has also been made. Dark red crystals of **zinc cobaltic oxytrinitrite,** $ZnCoO(NO_2)_3$, were also prepared. S. C. Ogburn prepared **cadmium cobaltic dodecanitrite,** $Cd_3[Co(NO_2)_6]_2$, by double decomposition with sodium cobaltic nitrite and a sat. soln. of cadmium sulphate. The product was isolated from the mother-liquor by fractional crystallization. It is canary-yellow in colour, and stable both in soln. and in the solid form. It is slightly hygroscopic; insoluble in cold water, but readily soluble in boiling water; and slightly soluble in alcohol or ether. He also prepared three bismuth salts: **bismuthyl cobaltic tetranitrite,** $(BiO)_3Co(NO_2)_4$; **bismuthyl cobaltic pentanitrite,** $(BiO)_3Co(NO_2)_5$, and **bismuthyl cobaltic hexanitrite,** $(BiO)_3Co(NO_2)_6$. The first-named salt is the most stable. The colours range from yellow to orange; they are sparingly soluble in alcohol, and insoluble in ether. They are rapidly decomposed in soln. or in the solid state. They are produced by the action of sodium cobaltic nitrite on a sat. soln. of bismuth nitrate, and were obtained from the mother-liquor by rapid filtration at various stages of the precipitations. A. Rosenheim and I. Koppel prepared a **mercurous cobaltic hexanitrite,** $Hg_3Co(NO_2)_6$, by the action of a soln. of a mercurous salt on one of sodium cobaltic nitrite, and L. L. Burgess and O. Kamm said that it is the least soluble of all these complex cobaltic nitrites. S. M. Jörgensen, T. Rosenbladt, and M. Cunningham and F. M. Perkin prepared **thallium cobaltic hexanitrite,** $Tl_3Co(NO_3)_6$, as a scarlet-red salt by mixing soln. of thallous carbonate and of sodium cobaltic nitrite. T. Rosenbladt said that 1000 parts of water at 17° dissolve 0·0420 part of the salt. A. Rosenheim and I. Koppel obtained cubic crystals of **lead cobaltic dodecanitrite,** $Pb_3Co_2(NO_2)_{12}.12H_2O$, by a process like that used for the analogous barium salt. The product is stable when dry; it is almost insoluble in water; but decomposed, when suspended in water, by the passage of hydrogen sulphide. M. Cunningham and F. M. Perkin prepared the salt, but with $11H_2O$ not $12H_2O$. The complex amines—$Pb[Co(NH_3)_2(NO_2)_4]_2$, and $[Co_2(N_2O_2)(NH_3)_{10}]NO_3.\frac{1}{2}Pb(NO_3)_2$—are described below. A. Stromeyer reported **potassium lead cobaltic nitrite,** $3K_2O.3PbO.2Co_2O_3.10N_2O_3.4H_2O$, obtained by the action of a mol of nitrous acid on a mol of cobalt sulphate and three mols of lead acetate, sulphate, or nitrate. The soln. is then treated with acetic or nitric acid, and the soln. slowly deposits crystals of the triple salt. A. Rosenheim and I. Koppel could not verify this. They obtained **cobaltous cobaltic oxynitritonitrate,** $2CoO.Co_2O_3.3N_2O_3+Co(NO_3)_2.14H_2O$, in small black crystals, by treating cobalt carbonate suspended in water with nitrous acid, and allowing the brown soln. to evaporate at ordinary temp.

O. L. Erdmann prepared some triple nitrites of bivalent cobalt. Thus, **potassium calcium cobalt nitrite,** $2KNO_2.Ca(NO_2)_2.Co(NO_2)_2$; **potassium strontium cobalt nitrite,** $2KNO_2.Sr(NO_2)_2.Co(NO_2)_2$; and **potassium barium cobalt nitrite,** $2KNO_2.Sr(NO_2)_2.Co(NO_2)_2$. V. Cuttica and M. Paoletti said that these compounds form dirty yellow powders stable in air and may be regarded as salts of one and the same complex quadrivalent ion, $Co(NO_2)_6$. The latter is, however, not stable in presence of water, in contact with which the salts yield an insoluble golden-yellow compound, $K_2Co(NO_2)_4$, the stable cobaltonitrous ion being hence $[Co(NO_2)_4]''''$. The high value of the active mass of the ion $[NO_2]'$ present in the conditions of the reaction in which the triple salt originates tends to displace the equilibrium $[Co(NO_2)_4]''+2NO_2' \rightleftharpoons [Co(NO_2)_6]''''$ towards the right, a displacement in the same sense, that is, towards the formation of undissociated mols. of the triple nitrite, being determined also in the equilibrium

$$[Co(NO_2)_6]^{Zn}_{K_6}$$

They prepared **barium thallium cobalt nitrite,** $Co(NO_2)_2.2Ba(NO_2)_2.TlNO_2$; **sodium barium cobalt nitrite,** $Co(NO_2)_2.2Ba(NO_2)_2.NaNO_2$, as a dirty green powder; **potassium zinc cobalt nitrite,** $2Co(NO_2)_2.Zn(NO_2)_2.6KNO_2$, as a dirty yellow powder; **potassium cadmium cobalt nitrite,** $2Co(NO_2)_2.Cd(NO_2)_2.6KNO_2$, as a pale chestnut-brown powder; and **potassium mercuric cobalt nitrite,** $Co(NO_2)_2.Hg(NO_2)_2.6KNO_2$, as a deep chestnut-brown powder. V. Cuttica and F. Gallo prepared potassium cerous cobalt nitrite, $2Co(NO_2)_2.Ce(NO_2)_3.5KNO_2$, as a green powder decomposed by water; rubidium cerous cobalt nitrite, $2Co(NO_2)_2.Ce(NO_2)_3.5RbNO_2$, is green, and thallous cerous cobalt nitrite,

$2Co(NO_2)_2.Ce(NO_2)_3.5ThNO_2$, is deep brown. The compounds are decomposed by water and by cold dil. acids. They can be represented by the general formula:

$$[Co(NO_2)_6]_2{}^{Ce}_{K_5}$$

where Ce represents Ce, La, Pr, Nd, or Y atoms, and K represents K, Rb, or Tl atoms. V. Cuttica prepared **potassium lead cobalt nitrite,** $Co(NO_2)_2.Pb(NO_2)_2.2KNO_3$; **rubidium lead cobalt nitrite,** $Co(NO_2)_2.Pb(NO_2)_2.2RbNO_2$; **ammonium lead cobalt nitrite,** $Co(NO_2)_2.Pb(NO_2)_2.2NH_4NO_2$; and **thallium lead cobalt nitrite,** $Co(NO_2)_2.Pb(NO_2)_2.2TlNO_2$, as dark green, microcrystalline powders by mixing a neutral soln. of a cobaltous salt, a conc. soln. of a lead salt, and then a large excess of the alkali nitrate soln. The formation of the potassium lead cobaltous salt enables one part of potassium in 10,000 parts of soln. to be detected. S. M. Jörgensen prepared **cobaltic hexamminohexanitrite,** $[Co(NH_3)_6][Co(NO_2)_6]$, as a yellow powder by mixing soln. of cobaltic hexamminochloride, and sodium cobaltic nitrite. It is almost insoluble in water; and when treated with thallium sulphate gives scarlet-red *thallous cobaltic hexanitrite,* $[Co(NO_2)_6]Tl_3$. P. Jacobson prepared **cobaltic hexamminotrinitrite,** $[Co(NH_3)_6](NO_2)_3$, by the action of solid sodium nitrite on cobaltic hexamminotrichloride. This salt was also prepared by C. Duval. E. Birk, and W. Biltz studied the mol. vol.

S. M. Jörgensen made **cobaltic hexamminodiamminotetratrinitritocobaltiate,** $[Co(NH_3)_6]$-$[Co(NH_3)_2(NO_2)_4]_3$; **cobaltic nitratopentammine hexanitritocobaltiate,** $[Co(NH_3)_5(NO_3)]$-$[Co(NO_2)_6].2H_2O$; and **cobaltic nitratopentammine tetranitritodiamminocobaltiate,** $[Co(NH_3)_5$-$NO_3][Co(NH_3)_2(NO_2)_4]_2$; and A. Werner and H. Müller, **cobaltic isothiocyanatopentammine nitrite,** $[Co(NH_3)_5(SCN)](NO_2)_2$. C. Duval prepared **cobaltic aquopentamminonitrite,** $[Co(NH_3)_5(H_2O)](NO_2)_3$. For **cobaltic hydronitritoimidoctammine nitrate,** $\{Co_2(NH)(NH_3)_8$-$(HNO_2)\}(NO_3)_4.H_2O$, also the sulphate, and chloride, *vide supra,* amides; likewise also for **cobaltic hydronitritoimidohexamminotetrachloride,** $\{Co_2(NH)(NH_3)_6(HNO_2)\}Cl_4.H_2O$.

A series of cobaltic **nitritopentammines** were discovered by O. W. Gibbs in 1852, and investigated by O. W. Gibbs and F. A. Genth, in 1856. They applied the term *xantho-salts,* and they supposed the group $(\frac{1}{2}N_2O_3.\frac{1}{2}H_2O)$ was present. In 1864, C. D. Braun showed that the nitrite radicle is present. O. W. Gibbs made a further study of the series in 1875; and in 1899, S. M. Jörgensen showed that a series of isomeric salts can be produced, and he called the isomers, isoxantho-salts. He showed that in the xantho-salts, the NO_2-group is probably present as $—NO_2$, and in the isoxantho-salts, as $—O.NO$.

C. Duval prepared **cobaltic nitritopentamminonitrite, sulphatopentamminonitrite, carbonatopentamminonitrite, and oxalatopentamminonitrite.** J. Meyer and H. Moldenhauer prepared **cobaltic nitritopentamminoselenate,** $[Co(NO_2)(NH_3)_5]SeO_4$. By boiling cobaltic aquopentammine sulphate with barium nitrite, O. W. Gibbs obtained **cobaltic nitritopentamminodinitrite,** $[Co(NH_3)_5NO_2](NO_2)_2.2H_2O$; if cobaltic chloropentamminochloride is treated with silver nitrite, **cobaltic silver nitritopentamminodinitrite,** $[Co(NH_3)_5NO_2](NO_2)_2.AgNO_2$, is formed. S. M. Jörgensen, O. W. Gibbs, and S. P. Sadtler made **cobaltic nitritopentamminohexanitritocobaltiate,** $[Co(NH_3)_5NO_2]_3[Co(NO_2)_6]_2$, by the action of sodium hexamminocobaltiate, on the nitritopentamminochloride; and **cobaltic nitritopentammine tetranitritodiamminocobaltiate,** $[Co(NH_3)_5NO_2][Co(NH_3)_2(NO_2)_4]_2$, was also prepared. O. W. Gibbs and F. A. Genth made **cobaltic nitritopentamminosulphate,** $[Co(NH_3)_5NO_2]SO_4$, by the action of nitrous fumes on an ammoniacal soln. of cobalt sulphate. Its properties were also investigated by S. M. Jörgensen, and C. D. Braun. **Cobaltic nitritopentamminohydrosulphate,** $[Co(NH_3)_5NO_2]SO_4.H_2SO_4$, was also examined by S. M. Jörgensen. W. Gibbs and F. A. Genth, and S. M. Jörgensen prepared **cobaltic nitritopentamminodichloride,** $[Co(NH_3)_5NO_2]Cl_2$. It is obtained by the action of the sulphate of the series on barium nitrite. The properties were studied by F. M. Jäger, A. Werner and C. H. Herty, A. Werner and A. Miolati, and E. Petersen. N. Schiloff and B. Nckrassoff studied the adsorption of the complex salt by activated charcoal. The isomer, **cobaltic isonitritopentamminodichloride,** $[Co(NH_3)_5O.NO]Cl_2$, was also prepared by S. M. Jörgensen by warming cobaltic chloropentamminodichloride with water and ammonia; the filtered liquid is cooled and neutralized with dil. hydrochloric acid; a soln. of sodium nitrite and hydrochloric acid is next added, and the red isomeride is precipitated; it is converted into the normal salt by dissolving it in water containing a few drops of ammonia, and precipitating with conc. hydrochloric acid. The iso-salt is about 4 times as soluble in cold water as the normal salt. Complex salts of the normal chloride with *mercuric chloride*, *auric chloride*, and *platinic chloride* were examined by O. W. Gibbs, O. W. Gibbs and F. A. Genth, and S. M. Jörgensen. O. W. Gibbs, O. W. Gibbs and F. A. Genth, C. D. Braun, S. M. Jörgensen, and E. Petersen examined **cobaltic nitritopentamminodinitrate**, $[Co(NH_3)_5NO_2](NO_3)_2$; O. W. Gibbs, **cobaltic nitritopentammine nitratochloroaurate**, $[Co(NH_3)_5NO_2]NO_3(AuCl_4)$, and likewise **cobaltic nitritopentammine nitratochloroplatinate**, $[Co(NH_3)_5NO_2]_2(NO_3)_2(PtCl_6)$; O. W. Gibbs, and F. M. Jäger, **cobaltic nitritopentammine chloronitrate**, $[Co(NH_3)_5NO_2](NO_3)Cl$; O. W. Gibbs, and A. Werner and A. Miolati, **cobaltic nitritopentammine dibromide**, $[Co(NH_3)_5NO_2]Br_2$; O. W. Gibbs, **cobaltic nitritopentammine bromonitrate**, $[Co(NH_3)_5NO_2](NO_3)Br$; C. D. Braun, **cobaltic nitritopentammine diiodide**, $[Co(NH_3)_5NO_2]I_2$; O. W. Gibbs, **cobaltic nitritopentammine sulphatoiodide**, $[Co(NH_3)_5NO_2]_2(SO_4)I_2.2H_2O$; and **cobaltic nitritopentammine sulphatoperiodide**, $[Co(NH_3)_5NO_2](SO_4)I_2$; S. M. Jörgensen made **cobaltic nitritopentammine fluosilicate**, $[Co(NH_3)_5NO_2]SiF_6$; O. W. Gibbs, **cobaltic nitritopentammine chromate**, $[Co(NH_3)_5NO_2]CrO_4.H_2O$; and **cobaltic nitritopentammine dichromate**, $[Co(NH_3)_5NO_2]Cr_2O_7.H_2O$. W. Flügel prepared **cobaltic nitritopentamminoamidosulphonate**, $[Co(NH_3)_5(NO_2)](NH_2SO_3)_2$, as well as the **imidosulphonate, hydroxynitritomonosulphonate, hydroxynitritodisulphonate, iso-hydroxynitritodisulphonate**, and **nitritotrisulphonate**. O. W. Gibbs, O. W. Gibbs and F. A. Genth, and C. D. Braun prepared the *ferrocyanide ;* and O. W. Gibbs and F. A. Genth, C. D. Braun, and S. M. Jörgensen, the *oxalate*. P. R. Ray prepared **cobaltic nitritopentamminothiosulphate**, $[Co(NH_3)_5(NO_2)]S_2O_3$, by passing air into an ammoniacal soln. of cobalt hydroxide, ammonium thiosulphate, and sodium nitrite.

In 1894, S. M. Jörgensen discovered the **nitritoaquotetrammines** ; and a few years later, A. Werner and R. Klein prepared some members of the series. These salts are like the nitritopentammines with one ammonia mol. replaced by a mol. of water ; they can therefore be regarded as aquoxantho-salts.

S. M. Jörgensen examined **cobaltic nitritoaquotetrammine tetranitritodiamminocobaltiate**, $[Co(NH_3)_4(H_2O)(NO_2)][Co(NH_3)_2(NO_2)_4]_2$; **cobaltic nitritoaquotetramminonitrite**, $[Co(NH_3)_4(H_2O)(NO_2)][Co(NH_3)_2(NO_2)_4]_2$; **cobaltic nitritoaquotetramminosulphate**, $[Co(NH_3)_4(H_2O)(NO_2)]SO_4$; S. M. Jörgensen, and A. Werner and C. H. Herty, **cobaltic nitritoaquotetramminodichloride**, $[Co(NH_3)_4(H_2O)(NO_2)]Cl_2$; S. M. Jörgensen, a basic chloride, and a chloroaurate; S. M. Jörgensen, **cobaltic nitritoaquotetramminodibromide**, $[Co(NH_3)_4(H_2O)(NO_2)]Br_2$; A. Werner and R. Klein, **cobaltic nitritoaquotetramminodiiodide**, $[Co(NH_3)_4(H_2O)(NO_2)]I_2$; A. Werner and R. Klein, **cobaltic nitritoaquotetramminocarbonate**, $[Co(NH_3)_4(H_2O)(NO_2)]CO_3$; J. Meyer and H. Moldenhauer prepared **cobaltic cis-dinitritotetramminoselenate**, $[Co(NO_2)_2(NH_3)_4]_2SeO_4$, as well as **cobaltic trans-dinitritotetramminoselenate** respectively from flavo- and croceo-cobaltic chloride and silver selenate; J. Meyer and K. Gröhler, **cobaltic aquonitritotetramminohydrosulphate**, $[(NH_3)_4Co(H_2O)(NO_2)](HSO_4)_2$; **cobaltic aquonitritotetramminohydroselenate**, $[(NH_3)_4Co(H_2O)(NO_2)](HSeO_4)_2$; and **cobaltic aquonitritotetramminoselenate**, $[(NH_3)_4Co(H_2O)(NO_2)]SeO_4$. S. M. Jörgensen, and A. Werner and R. Klein also made an *oxalate* and a *tartrate*.

In 1875, O. W. Gibbs made a series of **dinitritotetrammines** under the name *croceo-salts ;* and S. M. Jörgensen, in 1894, made a series of isomeric dinitritotetrammines which he called *flavo-salts*. A. Werner showed that the two series of salts are probably structurally alike, and are probably analogous to the cis- and trans- forms of nitrous acid. The solubilities of several of these salts were by J. N. Brönsted and A. Petersen, by V. K. la Mer and C. F. Mason, and by F. Ephraim.

S. M. Jörgensen, and A. Werner and A. Miolati examined **cobaltic trans-dinitritotetramminonitrite**, $[Co(NH_3)_4(NO_2)_2]NO_2$; **cobaltic cis- and trans-dinitritotetrammine hexanitritocobaltiate**, $[Co(NH_3)_4(NO_2)_2][Co(NO_2)_6]$—the former is dihydrated, the latter anhydrous ; **cobaltic cis- and trans-dinitritotetrammine tetranitritodiamminocobaltiate**, $[Co(NH_3)_4(NO_2)_2]Co(NH_3)_2(NO_2)_4]$; S. M. Jörgensen, A. Werner and A. Miolati, A. Werner and C. H. Herty, and E. Petersen, **cobaltic cis- and trans-dinitritotetramminonitrate**, $[Co(NH_3)_4(NO_2)_2]NO_3$; a *cis-hydronitrate* and a *cis-potassium nitrate* were also prepared ; S. M. Jörgensen, and A. Werner and A. Miolati, **cobaltic cis- and trans-dinitritotetramminosulphate**, $[Co(NH_3)_4(NO_2)]_2SO_4$; S. M. Jörgensen, and A. Werner prepared the cis-salt; and O. W. Gibbs, A. Werner, S. M. Jörgensen, F. M. Jäger, A. Werner and A. Miolati, and A. Werner and C. H. Herty, the trans-salt of **cobaltic dinitritotetramminochloride**, $[Co(NH_3)_4(NO_2)_2]Cl$. N. Schiloff and B. Nekrassoff studied the adsorption of the salt by activated charcoal. S. M. Jörgensen made the *cis-chloroaurate*, the *cis-chloroplatinite*, and the *cis-chloroplatinate*, while O. W. Gibbs made the *trans-chloroaurate*, and *trans-chloroplatinate*. O. W. Gibbs made **cobaltic trans-dinitritotetramminobromide**, $[Co(NH_3)_4(NO_2)_2]Br$; and **cobaltic trans-dinitritotetramminoperiodide**, $[Co(NH_3)_4(NO_2)_2]I_3$. F. Ephraim and P. Mosimann studied the *polyiodides* of the cis-and trans-salts, and also **bismuth cobaltic dinitritotetramminoiodide**, $[Co(NH_3)_4(NO_2)_2]I.BiI_3$. The **perchlorate**, and **selenate** were also prepared. S. M. Jörgensen prepared the cis-salts, and O. W. Gibbs the trans-salts of **cobaltic dinitritotetramminochromate**, $[Co(NH_3)_4(NO_2)_2]_2CrO_4$, and **cobaltic dinitritotetramminodichromate**, $Co(NH_3)_4(NO_2)_2]_2Cr_2O_7$. W. Flügel prepared *cis-* and *trans*-salts of **cobaltic dinitritotetramminonitrilotrisulphonate**, $[Co(NH_3)_4(NO_2)_2]_3N(SO_3)_3$, and also the *cis-* and *trans*-**iso-nitritodisulphonates**, and **amidosulphonates**.

A. Werner and co-workers prepared a series of **dinitritodiethylenediamines** in what are probably two stereoisomeric forms. The cis-series corresponds with the flavo-salts, and the trans-series with the croceo-salts. In the formulæ, for the sake of brevity, en, or En, is written in place of ethylenediammine. A. Werner also made the trans-salts with pyridine in place of ethylenediammine.

A. Werner and E. Humphrey prepared **cobaltic cis- and trans-dinitritodiethylenediamino nitrite**, $[Coen_2(NO_2)_2]NO_2$; A. Werner and E. Humphrey, **cobaltic cis- and trans-dinitritodiethylenediamine nitrate**, $[Coen_2(NO_2)_2]NO_3$; A. Werner and E. Humphrey, **cobaltic cis-dinitritodiethylenediamine sulphate**, $[Coen_2(NO_2)_2]_2SO_4$; A. Werner and E. Humphrey, and L. Gerb, **cobaltic cis- and trans-dinitritodiethylenediamine chloride**, $[Coen_2(NO_2)_2]Cl$, as well as a *cis-chloroaurate*, and *cis- and trans-chloroplatinites*, and *cis- and trans-chloroplatinates*; A. Werner and E. Humphrey, and F. M. Jäger, **cobaltic cis- and trans-dinitritodiethylenediamine bromide**, $[Coen_2(NO_2)_2]Br$; and **cobaltic cis- and trans-dinitritodiethylenediamine iodide**, $[Coen_2(NO_2)_2]I$. A. Werner and L. Gerb also made **cobaltic cis- and trans-nitritonitratodiethylenediamine nitrate**, $[Coen_2(NO_2)(NO_3)]NO_3$. A. Werner also made **cobaltic cis- and trans-dinitritodiethylenediamine dithionate**, $[Coen_2(NO_2)_2]_2S_2O_6$.

In 1901, A. Werner prepared **chloronitritodiethylenediamines** in stereoisomeric forms. The cis-series corresponds with the flavo-salts, and the trans-series with the croceo-salts.

A. Werner, and A. Werner and L. Gerb described **cobaltic cis-nitritochlorodiethylenediamine nitrite**, $[Coen_2Cl(NO_2)]NO_2$; **cobaltic cis- and trans-nitritochlorodiethylenediamine nitrate**, $[Coen_2Cl(NO_2)]NO_3$—the crystals of the trans-salts were also examined by F. M. Jäger; and A. Werner prepared an *acid cis-nitrate*. A. Werner and L. Gerb prepared **cobaltic cis-nitritochlorodiethylenediamine hydrosulphate**, $Coen_2Cl(NO_2)HSO_4$; A. Werner and L. Gerb, **cobaltic cis- and trans-nitritochlorodiethylenediamine chloride**, $[Coen_2Cl(NO_2)]Cl$; likewise also the two *bromides*, the two *iodides*, and the two *thiocyanates*. C. Duval prepared **cobaltic cis- and trans-dinitrotetramminonitrite, trans-dichlorotetramminonitrite, cis- and trans-dichlorotetramminonitrite, cis- and trans-diiodotetramminonitrite, chloronitrotetramminonitrite, diaquotetramminonitrite, and chloroaquotetramminonitrite.**

S. M. Jörgensen prepared **cobaltic hydroxynitritotetramminochloride**, $[Co(NH_3)_4(NO_2)(OH)]Cl.H_2O$. A. Werner showed that the original idea that the salt was a basic chloride, $[Co(NH_3)_2(H_2O)(NO_2)]Cl(OH)$, was wrong. A. Werner prepared a *hydrochloride*, a *bromide*, a *hydrobromide*, a *hydroiodide*, and a *nitrate*. A. Werner prepared **cobaltic nitritohydrocarbonatotetramminonitrate**, $[Co(NH_3)_4(NO_2)(HCO_3)]NO_3.H_2O$, by passing carbon dioxide into a soln. of cobaltic hydroxynitritotetramminonitrate. The dark yellow crystals are almost insoluble in water. A. Werner and R. Klein prepared a series of **cobaltic nitritothiocyanatotetrammines**—*e.g.* $[Co(NH_3)_4(NO_2)(SCN)]Cl$, in addition to the chloride, the bromide, iodide, periodide, nitrate, and thiocyanate, as well as complexes with mercuric chloride, and silver nitrate. A. Werner and L. Gerb made **cobaltic nitritothiocyanatodiethylenediamines**—*e.g.* **cobaltic nitritothiocyanatodiethyldiamminochloride**, $[Coen_2(NO_2)(SCN)]Cl$, as well as the bromide, iodide, and nitrate. S. M. Jörgensen, and K. A. Hofmann and S. Reinsch prepared **cobaltic nitritosulphitotetrammine**, $[Co(NH_3)_4(NO_2)(SO_3)]$.

In 1866, O. L. Erdmann discovered the first of a series of **trinitritotriammines**, and the other members of the series were studied by O. W. Gibbs in 1875, and S. M. Jörgensen in 1894. The first member, **cobaltic trinitritotriammine**, or cobaltic triamminonitrite, $[Co(NH_3)_3(NO_2)_3]$, was obtained by O. L. Erdmann, P. R. Rey, and by W. Gibbs. S. M. Jörgensen prepared it by the following process: cobalt carbonate (10 grms.), dissolved in hydrochloric acid (50 c.c.), was treated with varying quantities of sodium nitrite and 20 per cent. ammonia and the mixture oxidized in various ways; the dark brown liquor obtained was filtered from the insoluble matter, and evaporated to dryness in a draught. The residue was dissolved in 50–70 c.c. of cold water, whereby a second residue was obtained, and a dark brown soln. which, when treated with dil. nitric acid, yielded the xanthonitrate. The insoluble residues were washed with cold water until free from chlorine, whereby the croceo- and xantho-chlorides were removed, and the residue free from chlorine was extracted with hot water containing some acetic acid, when the triamine nitrite was dissolved. This was separated from the croceo-diamine nitrite and other sparingly soluble impurities by fractional crystallization from very dil. acetic acid; the bulk of the croceo-diammine nitrite was obtained in the last extraction of the residues.

A. Werner thought that the compound existed in two isomeric forms, but S. M. Jörgensen showed that the alleged isomers are the results of difficulties in the habits of the crystals of one compound—if crystallized from dil. acetic acid at 66°, rhombic plates are formed; and at 85°, hot aq. or conc. acetic acid soln. give yellowish-brown needles. H. Jäger gave for the axial ratios of the rhombic bisphenoids, $a:b:c=0{\cdot}8682:1:0{\cdot}6020$. The sp. gr. is 2·020 at 17°. The salt is sparingly soluble in cold water, readily soluble in hot water. The aq. soln. does not give the usual reactions for the nitrites. W. Biltz, and E. Birk studied the mol. vol. The electrical conductivity was measured by A. Werner and co-workers, and E. Petersen. These compounds have not the general characters of ordinary salts. N. Schiloff and B. Nekrassoff studied the adsorption of the salt by activated charcoal.

There are a number of other members of the series. Thus, A. Werner and A. Grün prepared **cobaltic trinitritoethylenediaminammine**, $[Co(NH_3)en(NO_2)_3]$; S. M. Jörgensen, **cobaltic sulphatobisdinitritobistriammine**, $[(NH_3)_3(NO_2)_2Co(SO_4)Co(NO_2)_2(NH_3)_3]$; S. M. Jörgensen, and A. Werner, **cobaltic dinitritochlorotriammine**, $[Co(NH_3)_3Cl(NO_2)_2]$, which was examined by A. Werner and A. Miolati, and E. Petersen; S. M. Jörgensen, **cobaltic dinitritobromotriammine**, $[Co(NH_3)_3Br(NO_2)_2]$; A. Werner, **cobaltic nitritoxalatotriammine**, $[Co(NH_3)_3(C_2O_4)(NO_2)]$; and L. A. Tschugaeff, **cobaltic nitritodimethylglyoximammine**, $[Co(NH_3)(NO_2)(D_2H_2)]$, where D_2H_2 stands for dimethylglyoxime.

O. L. Erdmann prepared **tetranitritodiamminocobaltiates** in 1866, and these products are sometimes called Erdmann's salts—usually the ammonium salt. They were studied by O. W. Gibbs, who proved that the cobalt forms part of the negative radicle. A. Werner represented these salts by the general formula $M[Co(NH_3)_2(NO_3)_4]$, and considered them to be *ein wichtiges Uebergangsgleid*, between the neutral trinitritotriammines, $[Co(NH_3)_3(NO_2)_3]$, and the hexanitritocobaltiates, $M_3Co(NO_2)_6$. These salts were also studied by S. M. Jörgensen, and A. Werner and fellow-workers. J. N. Brönsted and A. Petersen measured the solubilities of some of these salts; and S. Berkman and H. Zocher, their magnetic susceptibilities. O. L. Erdmann, and O. W. Gibbs made **ammonium tetranitritodiamminocobaltiate**, $NH_4[Co(NH_3)(NO_2)_4]$, by the spontaneous evaporation of mixed soln. of neutral cobaltous chloride, and ammonium nitrite.

S. M. Jörgensen mixed a soln. of 90 grms. of crystallized cobaltous chloride at 250 c.c. of water with a soln. containing 100 grms. of ammonium chloride, 135 grms. crystal sodium nitrite, and 750 c.c. of water along with 25 c.c. of 20 per cent. aq. ammonia. The mixture was treated for 1½ hrs. with a rapid current of air. The filtered liquid was allowed to stand 14 days exposed to air. The liquid was decanted from the crystals, the latter were washed by suction—once with iced-water, and once with a soln. of the pure salt. The mother-liquor mixed with the wash-water deposits another crop of crystals after standing some time exposed to air.

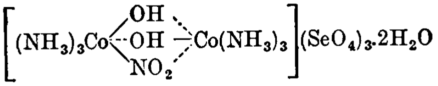
The brown rhombic prisms were shown by F. M. Jäger to have the axial ratios $a:b:c=0{\cdot}8837:1:0{\cdot}5226$; and a sp. gr. 1·933 at 15°. The salt develops ammonia when treated with potassium hydroxide. This salt can be used as a starting point for the preparation of some other ammines. According to S. M. Jörgensen, with ammonia, it forms the cobaltic dinitritotetrammine tetranitritodiamminocobaltiate. O. L. Erdmann prepared **potassium tetranitritodiamminocobaltiate**, $K[Co(NH_3)_2(NO_2)]$, by adding potassium nitrite to a soln. of cobaltous and ammonium chlorides. The salt was also prepared by O. W. Gibbs, S. M. Jörgensen, and A. Werner. According to F. M. Jäger, the brown crystals belong to the rhombic system and have the axial ratios $a : b : c = 0\cdot8783 : 1 : 0\cdot5192$, and a sp. gr. 2·076 at 15°. The soln. in water is dark yellow, and it gives no precipitate with potassium hydroxide or ammonium carbonate. With ammonia the potassium salt reacts like the ammonium salt. R. Kremann studied the transport numbers; and A. Werner and A. Miolati, the electrical conductivity. Sodium tetranitritodiamminocobaltiate, $Na[Co(NH_3)_2(NO_2)_4]$, was also prepared. N. Schiloff and B. Nekrassoff studied the adsorption of the salt by activated charcoal.

S. M. Jörgensen obtained the closely similar salts, **rubidium tetranitritodiamminocobaltiate**, $Rb[Co(NH_3)_2(NO_2)_4]$; and **cæsium tetranitritodiamminocobaltiate**, $Cs[Co(NH_3)_2(NO_2)_4]$. O. L. Erdmann, O. W. Gibbs, and S. M. Jörgensen prepared **silver tetranitritodiamminocobaltiate**, $Ag[Co(NH_3)_2(NO_2)_4]$, as an orange-yellow precipitate by treating the potassium salt with silver nitrate. The salt can be recrystallized in needles or plates from its aq. soln. O. W. Gibbs prepared **mercurous tetranitritodiamminocobaltiate**, $Hg[Co(NH_3)_2(NO_2)_4]$, in orange-yellow crystals, presumably with the composition just indicated; similar remarks apply to the prismatic crystals of **thallous tetranitritodiamminocobaltiate**, $Tl[Co(NH_3)_2(NO_2)_4]$, and the orange-brown plates of **lead tetranitritodiamminocobaltiate**, $Pb[Co(NH_3)_2NO_2)_4]_2$, prepared by O. W. Gibbs. A. Werner and A. Gubser prepared **chromium dichlorotetraquatetranitritodiamminocobaltiate**, $Cr(H_2O)_4Cl_2[Co(NH_3)_2(NO_2)_4].2H_2O$, in yellowish-green plates, by the action of chromium chlorohydroxide on potassium tetranitritodiamminocobaltiate. The corresponding **chromium dibromotetraquotetranitritodiamminocobaltiate** was made in dark green crystals, in a corresponding way. A. Werner and D. Kalkmann also prepared **chromium hexacarbamide tetranitritodiamminocobaltiate**, $Cr(CON_2H_4)_6[Co(NH_3)_2(NO_2)_4]_3.H_2O$; and **chromium chlorohexacarbamide tetranitritodiamminocobaltiate**, $Cr(CON_2H_4)_6Cl[Co(NH_3)_2(NO_2)_4].3H_2O$. O. W. Gibbs, and S. M. Jörgensen prepared **cobaltihexammine tetranitritodiamminocobaltiate**, $[Co(NH_3)_6][Co(NH_3)_3(NO_2)_4]$; **cobaltinitritopentammine tetranitritodiamminocobaltiate**, $[Co(NH_3)_5NO_2]Co(NH_3)_2(NO_2)_4]$; S. M. Jörgensen, **cobaltinitritoaquotetrammine tetranitritodiamminocobaltiate**, $[Co(NH_3)_4(H_2O)(NO_2)][Co(NH_3)_2(NO_2)_4]$; S. M. Jörgensen, **cobalticis- and trans-dinitritotetrammine tetranitritodiamminocobaltiate**, $[Co(NH_3)_4(NO_2)_2][Co(NH_3)_2(NO_2)_4]$, the electrical conductivity was measured by A. Werner and A. Miolati; S. M. Jörgensen, and O. W. Gibbs, **cobaltinitratopentammine tetranitritodiamminocobaltiate**, $[Co(NH_3)_5NO_3][Co(NH_3)_2(NO_2)_4]$; and A. Werner, **cobaltidichloroaquotriammine tetranitritodiamminocobaltiate**, $[Co(NH_3)_3(H_2O)Cl_2][Co(NH_3)_2(NO_2)_4]$; K. A. Hofmann and K. Buchner prepared **toluidine tetranitritodi-p-toluidinocobaltiate**, $CH_3.C_6H_4.NH_2.H[Co(CH_3.C_6H_4.NH_2)_2(NO_2)_2]$, and also **sodium tetranitratodinitrosohydrazinocobaltiate**, $Na[Co(NO_2)_4(NO.NH)_2]$. F. Ephraim and F. Moser prepared **copper tetranitrohexamminocobaltiate**, $[Cu(NH_3)_4][(NO_2)_4Co(NH_3)_2]_2$; **zinc tetranitritoheptamminocobaltiate**, $[Zn(NH_3)_4][(NO_2)_4Co(NH_3)_2]_2$; **nickel tetranitritohexamminocobaltiate**, $[Ni(NH_3)_4][(NO_2)_4Co(NH_3)_2]_2$; **copper oxalatodinitritohexamminocobaltiate**, $[Cu(NH_3)_4][(C_2O_4)(NO_2)_2Co(NH_3)_2]_2$; **zinc oxalatodinitritohexamminocobaltiate**, $[Zn(NH_3)_4][(C_2O_4)(NO_2)_2Co(NH_3)_2]_2$; **cadmium oxalatodinitritohexamminocobaltiate**, $[Cd(NH_3)_4][(C_2O_4)(NO_2)_2Co(NH_3)_2]_2$; and **nickel oxalatodinitritodecamminocobaltiate**, $[Ni(NH_3)_8][(C_2O_4)(NO_2)_2Co(NH_3)_2]_2$.

S. M. Jörgensen prepared a salt of the **dinitritodichlorodiamminocobaltiates** where the acidic radicle is univalent. The complex obtained was **cobaltinitritochlorotetrammine dinitritodichlorodiamminocobaltiate**, $[Co(NH_3)_4(NO_2)Cl][Co(NH_3)_2(NO_2)_2Cl_2]$. S. M. Jörgensen also prepared a series of **dinitrito-oxalatodiamminocobaltiates** represented by the *ammonium* salt, $NH_4[Co(NH_3)_2(NO_2)_2(C_2O_4)]$. The *potassium, sodium, barium, magnesium, silver, cobalt, cobalt silver, cobalthexammine*, and *cobaltidinitritotetrammine dinitritoxalatodiamminocobaltiates* were also prepared. L. A. Tschugaeff prepared a series of **dinitritodimethylglyoximinocobaltiates**, and **dinitritodimethylglyoximinocobaltic acid**, $H[Co(NO_2)_2Di_2H_2].H_2O$. The *ammonium, ethylammonium, diisobutylammonium, potassium, rubidium, cæsium*, and *sodium salts* were made. S. M. Jörgensen also made **ammonium oxalatobisdinitritobisdiamminocobaltiate**, $NH_4[(NH_3)_2(NO_2)_2Co.C_2H_4.Co(NO_2)_2(NH_3)_2]$. J. J. Meyer and co-workers prepared **dicobaltic tetranitrito-μ-selenatohexammine**, $[(NH_3)_3(NO_2)_2Co.O.SeO_2.O.Co(NO_2)_2(NH_3)_3].2H_2O$; **dicobaltic μ-amidonitritooctamminoselenate**:

$$\left[(NH_3)_4Co\!<\!\begin{smallmatrix}NO_2\\NH_3\end{smallmatrix}\!>\!CO(NH_3)_4\right](SeO_4)_2.2H_2O$$

and **dicobaltic μ-nitritodihydroxyhexamminoselenate:**



$$\left[(NH_3)_3Co\begin{matrix}OH\\OH\\NO_2\end{matrix}Co(NH_3)_3\right](SeO_4)_3.2H_2O$$

J. Lang found that the filtrate obtained from mixed soln. of barium nitrite and nickel sulphate can be evaporated without decomposition if the temp. be not raised. W. Hampe said that the soln. deposits a basic salt, *nickel oxynitrite*, $Ni_2O(NO_2)_2$. The reddish-yellow crystals of **nickelous nitrite,** $Ni(NO_2)_2$, are stable in air and at 100°. C. Duval obtained the salt as in the corresponding case of cobalt nitrite (*q.v.*). The salt forms a green soln. with water which gives no precipitate with alcohol. The aq. soln. decomposes at 80°–90°, and if then mixed with alcohol, dil. potash-lye decomposes the dry salt. When treated with ammonia, it forms a blue soln. P. C. Ray and N. R. Dhar found the electrical conductivities of soln. with a mol of the salt in 18·17, 54·51, 163·53, and 490·59 litres to be respectively 57·32, 78·52, 95·35, and 114·12 at 20°, when the calculated value at infinite dilution is 94. The aq. soln. is feebly acid to litmus. According to O. L. Erdmann, mixed soln. of ammonium nitrite and nickel acetate give an unstable green liquid, which remains clear when mixed with much alcohol, but on standing for a long time gives red crystals, which form more quickly in ammoniacal soln., or if absolute alcohol in excess be added. The product is considered to be **nickel tetramminodinitrite,** $Ni(NO_2)_2.4NH_3$. L. Soret and F. Robineau prepared a similar salt. Aq. ammonia of sp. gr. 0·924 (3 kilos.) and sodium nitrite (1 kilo.) are added to the nickel sulphate (1 kilo.) dissolved in boiling distilled water (1 litre); the mixture is placed aside for 4–5 days, and the resulting crop of crystals, after washing, is recrystallized from a hot ammoniacal soln. The small red crystals were considered by O. L. Erdmann to belong to the monoclinic system; they form a green soln. with cold water, and on warming, the soln. becomes turbid, forming a green precipitate. The salt decomposes in moist air giving off ammonia, and becoming green. The salt is insoluble in alcohol, and is recrystallized by adding alcohol to the ammoniacal soln. The salt begins to decompose at 100°, giving off ammonia and becoming green; at a higher temp., nickel oxide alone remains.

N. W. Fischer prepared **potassium nickel hexanitrite,** $K_4Ni(NO_2)_4$, in brownish-red octahedral crystals from a mixed soln. of nickel and potassium nitrites. J. Lang, O. L. Erdmann, and W. Hampe employed an analogous process. J. Lang said that the dry salt decomposes before it melts, giving off acid and nitric oxide vapours. The salt forms a green aq. soln. It is stable in air, and can be obtained unchanged by evaporating the aq. soln. J. Lang said that the aq. soln. has a slight alkaline reaction, and only a small green precipitate is produced with a long boiling; W. Hampe said the aq. soln. decomposed before boiling begins. The salt is insoluble in absolute alcohol, but traces are dissolved by 90 per cent. alcohol. The salt forms a basic nitrate when boiled with alcohol. Hydrogen sulphide forms nickel sulphide when passed into the aq. soln. J. Lang did not produce crystals of **sodium nickel nitrite** from a mixed soln. of sodium and nickel nitrites. J. Lang obtained **barium nickel tetranitrite,** $Ba_2Ni(NO_2)_4$, by allowing a mixed soln. of barium nitrite and nickel acetate to stand for some hours. The pale red crystalline powder is more soluble in water than the potassium salt. O. L. Erdmann said that the salt gradually decomposes, forming nitric oxide, nitrogen peroxide, and a greenish mass. J. Lang observed no loss in weight at 100°. C. Przibylla tried the triple salts: *ammonium barium nickel nitrite*, as well as *ammonium strontium nickel nitrite*, and *ammonium calcium nickel nitrite*, but found the products are mixtures, not chemical individuals. J. Lang reported **potassium barium nickel nitrite,** $K_2BaNi(NO_2)_6$, to be formed by concentrating a mixed soln. of nickel acetate and potassium barium nitrite; and also by the action of barium acetate on potassium nickel nitrite; O. L. Erdmann obtained it by the action of an excess of potassium nitrite on a mixed soln. of barium and nickel chlorides. The brownish-yellow powder was stated by J. Lang to consist of microscopic tetragonal plates; O. L. Erdmann said that the salt separates from the hot soln. in microscopic cubes and octahedra. The salt is sparingly soluble in cold water, readily soluble, without apparent decomposition, in hot water. The aq. soln., however, decomposes when boiled, forming nitric oxide, and a basic nitrate. The salt is insoluble in alcohol. F. Ephraim prepared **cæsium barium nickel nitrite,** $Cs_2Ba[Ni(NO_2)_6]$, as an orange-brown powder very sparingly soluble in water. O. L. Erdmann, J. Persoz, and C. Przibylla prepared **potassium strontium nickel nitrite,** $K_2SrNi(NO_2)_6$, as in the case of the barium salt. O. L. Erdmann said the reddish-yellow salt consists of microscopic cubes, and loses no weight at 140°. C. Künzel, and O. L. Erdmann made **potassium calcium nickel nitrite,** $K_2CaNi(NO_2)_6$, from a mixed soln. of a nickel salt, calcium chloride, and potassium nitrite in excess. O. L. Erdmann obtained it from a mixture of calcium chloride and potassium nickel nitrite. The yellow salt consists of microscopic octahedra belonging to the cubic system. The salt is sparingly soluble in cold water, but readily soluble in hot water. The salt is decomposed when heated with water. It is insoluble in alcohol, and this reagent precipitates the salt from its aq. soln. There is no loss in wt. at 130°–140°. It melts with decomposition at a higher temp. giving off nitric oxide and nitrogen peroxide. V. Cuttica and G. Carobbi could not prepare *potassium magnesium nickel nitrite,* but they obtained a number of other triple nitrites. The salt $Ni(NO_2)_2.4KNO_2$ is regarded as being constituted $[Ni(NO_2)_6]K_4$, and it ionizes in water: $[Ni(NO_2)_6]K_4 \rightleftharpoons Ni(NO_2)_6'''' + 4K^{\cdot}$; and $[Ni(NO_2)_6]'''' \rightleftharpoons Ni(NO_2)_2 + 4NO'_2$ also occurs. They prepared **potassium zinc nickel nitrite,** $2[Ni(NO_2)_6]K_4.Zn(NO_2)_2$, as a flesh-red crystalline mass; V. Cuttica prepared pale yellow **potassium nickel cadmium nitrite,** $4KNO_2.2Cd(NO_2)_2.Ni(NO_2)_2$; and flesh-coloured **ammonium nickel cadmium nitrite,** $2NH_6NO_2.Cd(NO_2)_2.Ni(NO_2)_2$; V. Cuttica and G. Carobbi made **potassium mercuric nickel nitrite,** $[Ni(NO_2)_6]K_2Hg$, dark green crystals forming a green aq. soln. in which the salt produces seven ions per mol. V. Cuttica and A. Paciello prepared **thallous nickel nitrite,** or *thallous nickelonitrite,* $Tl_4[Ni(NO_2)_6]$, in stable flesh-red crystals which yield stable, green aq. soln. V. Cuttica prepared **potassium cerous nickel nitrite,** $5Ni(NO_2)_2.3Ce(NO_2)_3.13KNO_2$, as a flesh-red powder. V. Cuttica made brick-red **thallium nickel cadmium nitrite,** $4TlNO_2.2Cd(NO_2)_2.Ni(NO_2)_2$; V. Cuttica and G. Carobbi obtained **thallium mercuric nickel nitrite,** in orange-red crystals, $3Ni(NO_2)_2.Hg(NO_2)_2.6TlNO_2$, or $2Ni(NO_2)_2.Hg(NO_2)_2.8TlNO_2$, according to the conditions; and V. Cuttica and F. Gallo, **thallium cerous nickel nitrite,** $6Ni(NO_2)_2.2Ce(NO_2)_3.7TlNO_2$, as a pale chestnut-brown powder; V. Cuttica and G. Carobbi made impure **thallium uranyl nickel nitrite,** as a chestnut-brown powder. C. Przibylla prepared a brown crystalline powder of *barium thallous nickel nitrite,* which was probably a mixture. He prepared brownish-yellow **potassium lead nickel nitrite,** $K_2PbNi(NO_2)_6$, by mixing dil. soln. of the component nitrates with an excess of sodium nitrite; **ammonium lead nickel nitrite,** $(NH_4)_2PbNi(NO_2)_6$, was obtained in an impure state; and **thallous lead nickel nitrite** formed a brown powder consisting of particles almost cubical in shape. The index of refraction was high. V. Cuttica and G. Carobbi prepared **potassium cobalt nickel nitrite,** $2K_4[Co(NO_2)_6].[Co(NO_2)_6]K_2Ni$, as a greenish-yellow powder; and **thallium cobalt nickel nitrite,** $[Co(NO_2)_6]Tl_2Ni.4TlNO_2$, as a dark red powder.

W. C. Ball and H. H. Abram added 10 c.c. of bismuth nitrate soln. to 40 c.c. of a 50 per cent. soln. of sodium nitrite, and then a soln. of 5 grms. of ammonium nitrate and 2 grms. of nickel nitrate in 20 c.c. of water—all cooled to 0°—in a few minutes a yellowish-brown, microcrystalline powder of **ammonium nickel nitritobismuthite** was formed. The composition of different specimens varied considerably, and the salt slowly decomposes; it is quickly hydrolyzed by water. In an analogous manner, **potassium nickel nitritobismuthite,** $K_4NiBi_2(NO_3)_{12}.6H_2O$. was formed as an unstable, yellowish-brown, microcrystalline powder; similarly with **rubidium nickel nitritobismuthite,** $Rb_7Ni\{Bi(NO_2)_6\}_3.4H_2O$; **cæsium nickel nitritobismuthite,** $Cs_7Ni\{Bi(NO_2)_6\}_3.6H_2O$; and **thallous nickel nitritobismuthite,** $Tl_4Ni\{Bi(NO_2)_6\}_2$.

O. W. Gibbs[17] prepared **potassium ruthenium hexanitrite,** $K_3Ru(NO_2)_6$, from a soln. of the component salts. It is easily soluble in water, alcohol, and ether ; and with ammonium sulphide it gives a red soln. C. E. Claus said that the salt is sparingly soluble in water, and readily soluble in a soln. of potassium nitrite. A. Joly and co-workers prepared orange-red **potassium ruthenium pentanitrite,** $K_2Ru(NO_2)_5$, from a neutral soln. of potassium nitrite and ruthenium chloride in the calculated proportions. Yellow **potassium ruthenium oxydodecanitrite,** $K_8Ru_2O(NO_2)_{12}$, was also obtained from an alkaline soln. in the presence of an excess of alkali nitrite. This salt is sparingly soluble in water, and it separates with water of crystallization, but becomes anhydrous at 100°. It explodes in vacuo at 360°–440°, forming nitrogen and nitric oxide, and a residue, which, when leached with water, contains KRu_3O_8. L. Brizard found that crystals of **potassium ruthenium dihydroheptanitrite,** $K_3Ru_2H_2(NO_2)_7.4H_2O$, are formed when a dil. and slightly warm soln. of the complex chloride, $Ru_2H_2(NO)Cl_3.3KCl.2HCl$, slightly acidified with hydrochloric acid, is mixed with successive small quantities of potassium nitrite until liberation of nitrogen oxides ceases. The colour of the soln. changes from red to orange-yellow, and, after conc., it deposits crystals of the complex nitrite. This salt is very soluble in water, but almost insoluble in a concentrated soln. of potassium chloride. It becomes anhydrous at 100°, but does not begin to decompose much below 360° ; at this temp., however, decomposition is rapid. When heated with hydrochloric acid, it is rapidly reconverted into the double chloride from which it was formed. A. Joly and E. Leidié found that when a soln. of sodium nitrite is gradually added to a soln. of ruthenium chloride at 60°–80° until the liquid is neutral, an orange-red soln. is obtained, which, on cooling, deposits the **sodium ruthenium pentanitrite,** $Na_2Ru(NO_2)_5.2H_2O$, in orange-yellow, dichroic, monoclinic prisms, very soluble in water, from which they can be repeatedly recrystallized without decomposing. When heated with dil. hydrochloric acid, the salt yields the nitrosochloride, $Ru(NO)Cl_3,2NaCl$; when mixed with potassium hydroxide and sat. with chlorine, it gives off vapours of ruthenium peroxide. From 5 to 6 kilos. of this salt were obtained from 60 kilos. of iridium residues, rich in ruthenium, and hence sodium nitrite is of great service in the extraction of the metal from substances in which it is present in small quantity. The sodium salt at 360° or 440° yields the compound Na_2O,Ru_4O_9, which cannot be a mere mixture of the alkali oxide and the ruthenium oxide, since the latter would decompose at 440°. At a dull red heat, the nitrite yields the oxide RuO_2, which retains only a trace of alkali after being washed with boiling water. If the temp. is so high that the alkali nitrite fuses, the greater part of the ruthenium is converted into the ruthenate Na_2RuO_4.

C. E. Claus prepared **potassium rhodium hexanitrite,** $K_3Rh(NO_2)_6$, as an orange-yellow powder by boiling a soln. of rhodium chloride with an excess of potassium nitrite. The salt is sparingly soluble in water, and readily soluble in hot hydrochloric acid, or in an excess of potassium nitrite soln. The soln. in potassium nitrite is coloured dark red by ammonium sulphide. O. W. Gibbs prepared a complex salt of **potassium rhodium chloronitrite.** C. E. Claus prepared **sodium rhodium hexanitrite,** $Na_3Rh(NO_2)_6$, in a manner analogous to that employed for the potassium salt. It is a white powder consisting of microscopic octahedra. The salt is sparingly soluble in boiling water, and is slowly decomposed by hot conc. hydrochloric acid, and, according to J. Lang, it is rapidly decomposed by aqua regia. J. Lang obtained **barium rhodium dodecanitrite,** $Ba_3Rh_2(NO_2)_{12}$, from barium rhodium chloride and silver nitrite. The white powder consists of microscopic cubes and octahedra.

W. Manchot and A. Waldmüller found that when nitric oxide acts on a soln. of palladous nitrate the primary nitrosyl complex which is formed produces

palladous nitrite, $Pd(NO_2)_2$. J. Lang prepared **palladous diamminonitrite,** $Pd(NO_2)_2(NH_3)_2$, by evaporating the filtered soln. obtained by adding silver nitrite to a soln. of palladous diamminonitrite. An isomeric form is obtained from palladous oxide, potassium nitrite, and ammonia. There is also the complex salt $Pd(NH_3)_2(NO_2)_2Pd(NO_2)_2$, or $Pd(NH_3)(NO_2)_2$, **palladium amminonitrite,** produced when a hot soln. of palladous diamminochloride is treated with potassium palladous nitrite, and either cooled or evaporated so as to obtain yellow prismatic crystals. N. W. Fischer, and J. Lang prepared **potassium palladous tetranitrite,** $K_2Pd(NO_2)_4$, by treating soln. of palladous chloride or nitrate with an excess of potassium nitrite. A white powder separates from dil. soln., while conc. soln. furnish yellow prisms. The aq. soln. yields the **dihydrated potassium palladous tetranitrite,** $K_2Pd(NO_2)_4.2H_2O$, in plates which lose all their water in vacuo over potassium hydroxide. When heated, the salt decomposes. A yellow, crystalline precipitate of **silver palladous tetranitrite,** $Ag_2Pd(NO_2)_4$, is obtained by adding silver nitrate to a soln. of the potassium salt. It crystallizes from hot water in dark yellow prisms. A. Rosenheim and H. Itzig prepared trihydrated **potassium palladous iodonitrite,** $K_2PdI_2(NO_2)_2.3H_2O$, by saturating a conc. soln. of potassium nitrite with palladous iodide and allowing the mixture to crystallize over sulphuric acid. The salt crystallizes in purplish-red, prismatic needles, effloresces on exposure to the air, and decomposes when dissolved in water or treated with dil. acids, with precipitation of palladous iodide. **Potassium palladous oxalatonitrite,** $K_2Pd(NO_2)_2C_2O_3$, was also obtained by warming the preceding salt with a molecular proportion of oxalic acid, and it crystallizes in beautiful, yellow needles sparingly soluble in cold, but easily soluble in hot water. Yellow rhombic crystals of **potassium palladic hexanitrite,** $K_2Pd(NO_2)_6$, were prepared by E. Pozzi-Escot and H. C. Couquet by treating a soln. of palladic chloride with potassium nitrite and then with an excess of alkali hydroxide or aq. ammonia at a low temp. O. W. Gibbs prepared **hydrohexanitritoiridic acid,** $H_3Ir(NO_2)_6$, in pale yellow needles readily soluble in water. **Potassium iridic hexanitrite,** $K_3Ir(NO_2)_6.H_2O$, was obtained by the action of an excess of potassium nitrite or iridium chloride. The pale greenish-yellow crystals are easily soluble in water; the compound forms a complex salt with potassium iridium chloride, **potassium iridic chloronitrite,** $K_3Ir(NO_2)_6.K_3IrCl_6$. **Sodium iridic hexanitrite,** $Na_3Ir(NO_2)_6.H_2O$; the complex $Na_3Ir(NO_2)_6.Na_3IrCl_6$; **sodium iridic chloronitrite,** $Na_2IrCl(NO_2)_4.H_2O$; and **barium iridic chloronitrite,** $Ba_3Ir_2(NO_2)_2.Ba_3Ir_2Cl_{12}$, also have been prepared.

J. Lang,[18] and L. F. Nilson prepared **hydrotetranitritoplatinous acid,** $H_2Pt(NO_2)_4$, or *platinous hydronitrite,* $Pt(NO_2)_2.2HNO_2$, or $(HO.NO : NO.O)_2Pt$, by treating the barium salt with the calculated quantity of sulphuric acid, and evaporating the filtered soln. in vacuo, over sulphuric acid and sodium hydroxide. The salts are described below. The red microscopic prisms readily form hydroctonitritotriplatinous acid (*vide infra*). The crystals of hydrotetranitritoplatinous acid form a yellow aq. soln. with a feeble acidic reaction; the alcoholic soln. is colourless. The aq. soln. gives no precipitate with potassium chloride. The salts of this acid readily crystallize from conc. soln. They are very soluble in water. Most of them are stable at 100°, but part or all the water of crystallization is lost at that temp. There is the **potassium tetranitritoplatinite,** $2KNO_2.Pt(NO_2)_2$, or $[(NO_2)_2Pt(NO_2)_2]K_2$, and **potassium oxalatodinitritoplatinite,** $K_2C_2O_4.Pt(NO_2)_2$, or $K_2[(C_2O_4)Pt(NO_2)_2]$. L. F. Nilson obtained **platinous oxydihydrotetranitritoplatinite,** $PtO.H_2Pt(NO_2)_4$, represented by a series of salts—silver, beryllium, aluminium, indium, chromium, and iron (*vide infra*). **Hydroctonitritotriplatinous acid,** $H_4Pt_3O(NO_2)_8.2H_2O$, separated as a brown or green powder during the evaporation of the mother-liquor from the above acid. It gives off water but not nitrogen at 100°. It readily dissolves in water, forming a yellow acid-liquor which drives carbon dioxide from the carbonates. By saturating the acid with potassium carbonate, L. F. Nilson obtained **potassium oxyoctonitritotriplatinite,** $K_4Pt_3O(NO_2)_8.2H_2O$, in yellow plates, which are stable in air; and lose only their water of crystallization at 100°. The salt can be recrystallized from its aq. soln.

The sexibasic acid, **oxyhydrohexanitritoplatinous acid,** $H_6Pt_3O(NO_2)_6$, is represented by the **potassium oxyhexanitritoplatinite,** $K_2H_4Pt_3O(NO_2)_6.3H_2O$. M. Vèzes prepared it in small quantities by treating potassium tetranitritoplatinite with a halogen. The hot conc. soln. of potassium tetranitritoplatinite is titrated with an eq. amount of sulphuric acid, and the green soln. is heated; nitrous fumes are evolved, and, on cooling, dark red needles separate. The salt loses water slowly in cold dry air, rapidly at 100°. It dissolves sparingly in cold water, and readily in hot water; it is insoluble in alcohol. The aq. soln. is stable and reacts acid to litmus.

J. Lang prepared **platinous tetramminodinitrite,** $[Pt(NH_3)_4](NO_2)_2.2H_2O$, by the action of soln. of platinous tetramminodichloride and silver nitrite, and evaporating the filtrate at a low temp. The four-sided prisms effloresce in air, and are dehydrated over conc. sulphuric acid. At 145°, they lose 2 mols of ammonia, forming cis-platinous diamminodinitrite, $[Pt(NH_3)_2(NO_2)_2]$; and at 250°, there is a feeble detonation. The salt is easily soluble in hot and cold water; and insoluble in 90 per cent. alcohol. The aq. soln. does not decompose when boiled. If warmed with potassium tetrachloroplatinite, not in excess, some $Pt(NH_3)_2(NO_2)_2$, or $[Pt(NH_3)_4]Pt(NO_2)_4$, is formed—**platinous tetramminotetranitritoplatinite**; this compound is also produced by the action of platinous tetramminodichloride on potassium tetranitritoplatinite. L. A. Tschugaeff and W. Chlopin obtained it by the action of platinous tetramminodichloride on the complex salt, $[Pt(C_2H_5.S.C_2H_4.S.C_2H_5)_2]Pt(NO_2)_4$. The yellow six-sided needles can be heated below 250° in dry air without change, but at that temp. they blacken, forming $[Pt(NH_3)_2(NO_2)_2]Pt(NO_2)_2$. The salt is sparingly soluble in cold water, and easily soluble in hot water. Aq. ammonia dissolves it more easily than does water; and after boiling the ammoniacal soln., the cis- and trans-forms of platinous diamminodinitrite are produced. Cold dil. acids have no action; but the salt is decomposed by conc. sulphuric acid; conc. hydrochloric acid acts slowly in the cold, rapidly when heated. L. A. Tschugaeff and S. S. Kiltuinowich prepared **platinous nitritotriamminonitrite,** $[(NH_3)_3Pt(NO_2)](NO_2)$. The tetramminotetranitritoplatinite occurs in the isomeric forms:

$$\left[\begin{matrix}NH_3\\NH_3\end{matrix}\;Pt\;\begin{matrix}NO_2\\NO_2\end{matrix}\right] \qquad\qquad \left[\begin{matrix}NO_2\\NH_3\end{matrix}\;Pt\;\begin{matrix}NH_3\\NO_2\end{matrix}\right]$$

J. Lang heated platinum tetramminodinitrite to 140°–150°, and obtained **platinous trans-diamminodinitrite,** $[Pt(NH_3)_2(NO_2)_2]$; and he also made it by digesting the diiodide with silver nitrite. P. T. Cleve passed the red nitrous fumes from starch and nitric acid into a soln. of the trans-dinitrate; and also boiled the trans-dichloride with potassium nitrite in order to prepare this compound. L. Ramberg purified the product by recrystallization from a hot soln. of sodium nitrite. M. Vèzes made it by the action of ammonia on a soln. of potassium oxalatodinitritoplatinite, and K. A. Hofmann and K. Buchner, by the action of conc. aq. ammonia on $[Pt(C_7H_9N)(NO_2)_3]H.C_7H_9N$. The white crystalline powder contains small four-sided prisms. It is not changed at 100°, but detonates feebly at about 240°. It is sparingly soluble in cold water, and a little more soluble in hot water; L. Ramberg said that 0·63 grm. of the salt is dissolved per litre at 25°. It is insoluble in alcohol. It is more soluble in aq. ammonia than in water without forming the tetramminodinitrite. The salt is decomposed by hot nitric acid, and the soln. gives colourless crystals of the diamminodinitritodinitrate; sulphurous acid is oxidized to sulphuric acid; conc. sulphuric acid decomposes the salt; hydrochloric acid attacks it in the cold; bromine forms an addition product, $Pt(NH_3)_2(NO_2)_2Br_2$. If platinous tetramminotetranitritoplatinite be heated to 230°–240°, **platinous diamminotetranitritoplatinite,** $[Pt(NH_3)_2(NO_2)_2]Pt(NO_2)_2$, is formed. J. Lang obtained the same product by heating silver tetranitritoplatinite with platinous trans-diamminodichloride, extracting with water, and drying over sulphuric acid. The golden yellow scales are not changed at 100°, but they are decomposed at 250°–260°. The salt dissolves sparingly in cold water, readily in hot water. Aq. ammonia dissolves it more readily than does water, and the soln. deposits the cis- and trans-diamminodinitrite on cooling. Cold acids slowly decompose the salt.

P. T. Cleve prepared **platinous cis-diamminodinitrite,** $[Pt(NH_3)_2(NO_2)_2]$, by the method employed for the trans-salt, using the cis-salts as the initial products. L. Ramberg purified this salt by the same method as that previously employed. The same salt was made by J. Lang as indicated above; and L. Ramberg made it in colourless needles by the action of ammonia on platinous bisethylthiolacetodinitrate. P. T. Cleve said that the boiling soln. deposits pale yellow prisms. The salt detonates when heated, and is sparingly soluble in cold water; L. Ramberg said that a litre of water dissolves 0·88 grm. of the salt at 25°. According to P. T. Cleve, the salt is decomposed by nitric acid, and sulphur dioxide. Aqua regia produces ammonium chloroplatinate; bromine and chlorine furnish cis- and trans-$[Pt(NH_3)_2(NO_2)_2X_2]$; dil. hydrochloric acid scarcely attacks it in the cold, but when heated, the salt is decomposed.

I. I. Tschernyaeff treated platinous oxalatodinitrite with hydroxylamine and obtained **platinous cis-dinitritohydroxylamine,** $[Pt(NH_3O)_2(NO_2)_2]$, which, with ammonia forms **platinous nitritodihydroxylaminoammine,** $[Pt(NH_3O)(NH_2O)(NH_3)(NO_2)]$, or

$$\left[\begin{matrix}NH_3O\\NH_3\end{matrix}\ Pt<\begin{matrix}NH_2O\\NO_2\end{matrix}\right]$$

This compound is not attacked by cold acids, but with hot hydrochloric acid, it forms **platinous nitritochlorohydroxylammine,** $Pt[(NH_3O)N(H_3)(NO_2)Cl]$, which, with water, hydrolyzes to form **platinous hydroxynitritohydroxylaminoammine,** $[Pt(NH_3O)(NH_3)(NO_2)(OH)]$, and forms a monohydrate with alkali-lye, which, with hydrochloric acid, reforms the chloronitrite. Both the hydrate, and the nitritodihydroxylaminoammine with pyridine form **platinous nitritopyridinohydroxylaminoammine,** $[Pt(NH_2O)(Py)(NH_3)(NO_2)]$, which is decomposed by acids. Similarly **platinous trans-dinitritohydroxylamine,** $[Pt(NH_3O)(NH_2O)(NO_2)_2]$, or

$$\left[\begin{matrix}NO_2\\NH_3O\end{matrix}\ Pt<\begin{matrix}NH_2O\\NO_2\end{matrix}\right]$$

is obtained in yellowish needles, less soluble in water than the *cis*-compound, and which, with ammonia, forms $[Pt(NH_3O)_2(NH_3)(NO_2)]$, and, with dil. hydrochloric acid, furnishes **platinous nitritodihydroxylaminoamminochloride,** $[Pt(NH_3O)_2(NH_3)(NO_2)]Cl$; it is re-formed by treating this compound with alkali-lye, and with hydrochloric acid and potassium chloroplatinate dark red crystals of the **chloroplatinite,** $[Pt(NH_3O)_2(NH_3)(NO_2)]_2PtCl_4$, are formed. These compounds illustrate how the substitution of an atom of hydrogen in hydroxylamine increases the acid properties of the latter by the proximity of the NO_2-group; just as in picric acid, the activity of the (OH)-group is augmented by the NO_2-groups.

I. I. Tschernyaeff found that platinous trans-dinitrodiammine with hydroxylamine hydrochloride gives off nitrogen, and forms **platinous trans-chloronitritodiammine,** $[Pt(NH_3)_2Cl(NO_2)]$; and with more hydroxylamine there is formed **platinous trans-nitritohydroxylaminodiamminonitrite,** $[Pt(NH_3)_2(NH_3O)(NO_2)]NO_2$, which gives a red **chloroplatinite**; and similarly with **platinous cis-nitritohydroxylaminodiamminonitrite,** $[Pt(NH_3)_2(NH_3O)(NO_2)]NO_2$, which also forms a dark red chloroplatinite.

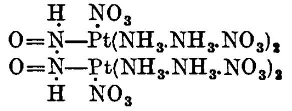
I. I. Tschernyaeff found that an excess of hydroxylamine reacts with platinous trans-pyridinoamminodinitrite to form **platinous trans-nitritohydroxylaminopyridinoamminonitrite,** $[Pt(NH_3O)(Py)(NH_3)(NO_2)]NO_2$, which gives a rose-coloured **chloroplatinite** in rhombic plates. Platinous trans-pyridinoamminodinitrite and ammonia furnish **platinous cis-**

nitritopyridinodiamminonitrite, $[Pt(NH_3)_2(Py)(NO_2)]NO_2$, which gives a yellow **chloroplatinite.** Sodium nitrite acts on platinous trans-hydroxylaminopyridinodichloride, $[Pt(NH_3O)(Py)Cl_2)$, to form **platinous trans-dinitritohydroxylaminopyridine,** $[Pt(NH_3O)(Py)\cdot(NO_2)_2]$; and on platinous trans-hydroxylaminoamminodichloride, $[Pt(NH_3O)(NH_3)Cl_2]$, to form **platinous trans-chloronitritohydroxylaminoammine,** $[Pt(NH_3O(NH_3)Cl(NO_2)]$. The trans-chloronitrites with hydroxylamine hydrochloride yield the trans-dinitrites; and a number of pyridine compounds were prepared, which with alkali-lye form the trans-hydroxynitrites. Thus, the trans-chloronitrite yields needles of **platinous trans-nitritopyridinodiamminochloride,** $[Pt(NH_3)_2Py(NO_2)]Cl$, which forms rose-coloured plates of the **chloroplatinite.** When platinous chloronitritopyridinoammine, $[Pt(NH_3)(Py)Cl(NO_2)]$, is treated with hydroxylamine, it forms colourless needles of **platinous nitritohydroxylaminopyridinoamminochloride,** $[Pt(NH_3O)(NH_3)(Py)(NO_2)]Cl$: when platinous nitritochloropyridinohydroxylamine, $[Pt(NH_3O)(Py)Cl(NO_2)]$, is treated with ammonia, it forms a yellow gelatinous mass which, with hydrochloric acid and potassium chloroplatinite forms bright yellow chloroplatinite, of **platinous nitritohydroxylaminopyridinoammine,** $[Pt(NH_3O)(NH_3)\text{-}(Py)(NO_2)]_2PtCl_4$. If platinous nitritochlorohydroxylaminoammine is treated with pyridine and potassium chloroplatinite, rose-coloured prisms of the chloroplatinite of **platinous nitritohydroxylaminopyridinoammine,** $[Pt(NH_3O)NH_3)(Py)(NO_2)]_2PtCl_4.2H_2O$ are formed.

I. I. Tschernyaeff showed that if platinous trans-dinitritodiammine is treated with hydrazine sulphate it forms **diplatinous dinitritodihydrazinodiamminosulphate,** $[(NH_3)(NO_2)Pt(N_2H_4)_2Pt(NH_3)(NO_2)]SO_4$; and with platinous trans-dinitritohydroxylaminoammine, **diplatinous dinitritodihydroxylaminodihydrazinosulphate,** $(NH_3O)(NO_2)Pt(N_2H_4)_2Pt(NH_3)(NO_2)]SO_4$, is formed. Platinous cis- and trans-dinitrodiammines with ethylenediamine respectively form **platinous dinitroethylenediamine,** $[Pt(en)(NO_2)_2]$, and **platinous nitritoamminodiethylenediaminohydroxide,** $[Pt(en)_2(NH_3)(NO_2)]OH$; while platinous trans-nitritochlorodiammine gives **platinous dinitritoethylenediaminotetramminochloride,** $[(NH_3)_2(NO_2)Pt(en)Pt(NO_2)(NH_3)_2]Cl_2$, which forms a bright yellow **chloroplatinite**; and when it is boiled with ethylenediamine and treated with potassium chloroplatinite, it yields the chloroplatinite of **platinous nitritoamminodiethylenediamine.** If platinous nitritochloro-hydroxylaminoammine is treated with ethylenediamine, it furnishes the chloroplatinite of **diplatinous dinitritodihydroxylaminoethylenediaminodiammine,** $[(NH_3O)(NH_3)(NO_2)Pt(en)Pt(NO_2)(NH_3)(NH_3O)].PtCl_4$.

E. Koefoed prepared a series of salts with *dimethylamine* in place of ammonia, $[Pt\{(CH_3)_2NH\}_2(NO_2)_2]$; S. G. Hedin, *pyridine*, cis- and trans-$[Pt(C_5H_5N)_2(NO_2)_2]$; L. Tschugaeff and W. Chlopin, C. W. Blomstrand, and C. Enebuske, *dimethyl sulphide*, trans-$[Pt\{(CH_3)_2S\}_2(NO_2)_2]$; C. W. Blomstrand, and M. Weibull, *diethyl sulphide*, trans-$[Pt\{(C_2H_5)_2S\}_2(NO_2)_2]$; C. Rudelius, and C. W. Blomstrand, *dipropyl sulphide*, cis- and trans-$[Pt\{(C_3H_7)_2S\}_2(NO_2)_2]$; C. Rudelius, and M. Weibull, *diisopropyl sulphide*, trans-$[Pt\{(C_3H_7)_2S\}_2(NO_2)_2]$; H. Löndahl, and M. Weibull, *dibutyl sulphide*, cis- and trans-$[Pt\{(C_4H_9)_2S\}_2(NO_2)_2]$; H. Löndahl, and C. W. Blomstrand, *dibenzylsulphide*, $[Pt\{(C_6H_5.CH_2)_2S\}_2(NO_2)_2]$; H. Löndahl, *diethylene sulphide*, $[Pt(C_2H_4)_2S_2(NO_2)_2]$; L. Tschugaeff and W. Chlopin, *dimethylethylenedithioether*, $[Pt(CH_3.S.C_2H_4.S.CH_3)_2(NO_2)_2]$, *diethylethylenedithioether*, $[Pt(C_2H_5.S.C_2H_4.S.C_2H_5)_2(NO_2)_2]$; *dipropylethylenedithioether*, $[Pt(C_3H_7.S.C_2H_4.S.C_3H_7)_2(NO_2)_2]$, *dibutylethylenedithioether*, $[Pt(C_4H_9.S.C_2H_4.S.C_4H_9)_2\cdot(NO_2)_2]$, *diethylpropylenedithioether*, $[Pt(C_2H_5.S.C_3H_6.S.C_2H_5)_2(NO_2)_2]$, *diethylhydroxypropylenedithioether*, $[Pt(C_2H_5.S.CH(OH).CH_2.S.C_2H_5)_2(NO_2)_2]$; and the salt $[Pt\{(C_2H_5)_2S\}\{(C_3H_7)_2S\}(NO_2)_2]$; S. Tyden, *thioglycollic acid*, $[Pt\{S(CH_2.COOH)_2\}_2(NO_2)_2]$, *sodium thioglycollate*, $[Pt\{S(CH_2.COONa)_2\}_2(NO_2)_2]$, and $[Pt\{S(CH_2.COOH)_2\}\cdot(HOOC.CH_2S.CH_2COOH)(NO_2)]$; J. Petrén, *diethylselenide*, $[Pt\{(C_2H_5)_2Se\}_2(NO_2)_2]$; and $[Pt\{(C_2H_5)_2S\}\{(C_2H_5)_2Se\}(NO_2)_2]$; K. A. Hofmann and K. Buchner, *toluidine*, $[Pt(C_7H_9N)(NO_2)_3]H.C_7H_9N$.

O. Carlgren and P. T. Cleve prepared **platinum dihydroxytetrammine nitrite,** $[Pt(NH_3)_4(OH)_2](NO_2)_2$, in acicular crystals by the action of silver nitrite on the chloride. P. T. Cleve, and W. Odling prepared **platinum dinitritotetrammine nitrate,** $[Pt(NH_3)_4(NO_2)_2](NO_3)_2$, by passing the red vapours from starch and nitric acid into an aq. soln. of platinous tetramminosulphate; E. A. Hadow, and B. Gerdes, by passing these vapours into a soln. of platinous tetramminonitrate acidified with nitric acid; E. Koefoed, by the action of sodium nitrite on the same soln. According to P. T. Cleve, B. Gerdes, and E. A. Hadow, the deep blue powder consists of microscopic octahedra or dodecahedra. E. A. Hadow said that the salt can be dried at 100° without decomposition ; and P. T. Cleve observed no change at 120°, but at 140° it becomes yellow and then brown. At 143°, the salt decomposes ; and at 170°, E. Koefoed found that it suddenly explodes. It dissolves in water with decomposition, and when the aq. soln. is crystallized, $[Pt(NH_3)_4(OH)(NO_3)](NO_3)_2$ is formed. It dissolves in soda-lye with decomposition. E. A. Hadow represented the constitution :



$$\begin{array}{l} \;\;\;\mathrm{H}\;\;\;\mathrm{NO_3} \\ \mathrm{O{=}\dot{N}{-}\dot{P}t(NH_3.NH_3.NO_3)_2} \\ \mathrm{O{=}\dot{N}{-}\dot{P}t(NH_3.NH_3.NO_3)_2} \\ \;\;\;\mathrm{H}\;\;\;\mathrm{NO_3} \end{array}$$

P. T. Cleve made *platinum nitritoiodo-tetrammine nitrate*, $[Pt(NH_3)_4(NO_2)I](NO_3)_2$; *platinum nitritotrichlorodiammine*, $[Pt(NH_3)_2Cl_3(NO_2)]$; *platinum cisdinitritodinitratodiammine*, $[Pt(NH_3)_2(NO_2)_2(NO_3)_2]$; P. T. Cleve, and C. W. Blomstrand, *platinum cis- and trans-dinitritodichlorodiammine*, $[Pt(NH_3)_2Cl_2(NO_2)_2]$; and *platinum cis- and trans-dinitritodibromodiammine*, $[Pt(NH_3)_2Br_2(NO_2)_2]$; C. W. Blomstrand, *platinum cis-dinitritosulphatodiammine*, $[Pt(NH_3)_2(NO_2)_2(SO_4)]$; P. T. Cleve, *platinum dinitritohydroxychlorodiammine*, $[Pt(NH_3)_2(NO_2)_2(OH)Cl]$; and *platinum dinitritonitratochlorodiammine*, $[Pt(NH_3)_2(NO_2)_2(NO_3)Cl]$. J. Petrén, *platinum dinitritodichlorobisdimethylselenide*, $[Pt\{(CH_3)_2Se\}_2(NO_2)_2Cl_2]$; *platinum dinitritodibromobisdimethylselenide*, $[Pt\{(CH_3)_2Se\}_2(NO_2)_2Br_2]$; and *platinum dinitritodiiodobisdimethylselenide*, $[Pt\{(CH_3)_2Se\}_2(NO_2)_2I_2]$; J. Pretrén also prepared *platinum dinitritodibromotetraethylsulphoselenide*, $[Pt\{(C_2H_5)_2Se\{(C_2H_5)_2S\}(NO_2)_2Br_2]$, as well as *platinum dinitritodiiodotetraethylsulphoselenide*. E. Koefoed prepared a complex *platinum nitritonitrosylchlorodiammine hydrochloride*, $Pt(NH_3)_2(NO_2)(NO)Cl.HCl.\frac{3}{4}H_2O$.

L. F. Nilson prepared **dihydrated ammonium tetranitritoplatinite**, $(NH_4)_2Pt(NO_2)_4.2H_2O$, by rubbing together eq. proportions of ammonium chloride and silver tetranitritoplatinite with as little water as possible, and evaporating the soln. in vacuo. The colourless or pale yellow six-sided plates are stable in air. According to H. Töpsöe, the rhombic crystals have the axial ratios $a:b:c=0.4910:1:0.9094$. L. F. Nilson said that the crystals become anhydrous **ammonium tetranitritoplatinite**, $(NH_4)_2Pt(NO_2)_4$, in vacuo over sulphuric acid. If heated over a free flame, the salt explodes. It is sparingly soluble in water. J. Lang reported a *monohydrate* to be formed during the evap. of the aq. soln., but L. F. Nilson could not find it. J. Lang prepared **potassium nitritoplatinite**, or *potassium platinous tetranitrite*, $K_2Pt(NO_2)_4$, by crystallization from a mixture of potassium chloroplatinite and potassium nitrite in the molar proportions 1 : 4. M. Vèzes obtained it from a soln. of platinum in aqua regia and potassium nitrite ; and also from potassium oxalatoplatinite and potassium nitrite. The colourless four- or six-sided monoclinic prisms have, according to H. Töpsöe, the axial ratios $a:b:c=0.6068:1:0.7186$, and $\beta=96°\ 12\frac{1}{2}'$. According to J. Lang, 100 parts of water at 15° dissolve 3·7 parts of the salt, and the solubility is greater in warm water. The soln. has a neutral reaction, and the aq. soln. deposits crystals of the salt undecomposed. J. Lang, L. F. Nilson, M. Vèzes, and H. G. Söderbaum obtained colourless rhombohedra of **dihydrated potassium tetranitritoplatinite**, $K_2Pt(NO_2)_4.2H_2O$, by the slow evaporation of the aq. soln. H. Dufet found the triclinic pinacoids have the axial ratios $a:b:c=0.7282:1:0.7112$, $\alpha=79°\ 50'$, $\beta=108°\ 48'$, and $\gamma=94°\ 50.5'$. The crystals lose nearly all their water in 24 hrs. C. W. Blomstrand observed that chlorine and bromine react with potassium tetranitritoplatinite, forming chloro- or bromo-nitrites ; but iodine has scarcely any action. M. Vèzes prepared a series of chloronitrites, bromonitrites, or iodonitrites, by the action of the halogen or halide acid. J. Lang found that potash-lye decomposes the salt ; alkali carbonates have no action on the salt ; hydrogen sulphide, and ammonium sulphide darken the heated salt ; sulphuric acid or hydrochloric acid makes the soln. dark green ; when the soln. is heated, red fumes are given off ; stannous chloride gives a yellow precipitate and a dark red soln. ; mercurous nitrate gives a white precipitate ; ferrous sulphate, a yellowish-brown precipitate in about 24 hrs. ; urea gives, when heated, a yellow soln. with the evolution of a little gas; urea nitrate acts similarly, and later gives a yellow precipitate which detonates when heated. A. Miolati found that the dry salt with liquid nitrogen peroxide forms a green solid, **potassium dinitroxyltetranitritoplatinite,** $K_2Pt(NO_2)_4.N_2O_4$, which is stable over calcium chloride; but is decomposed over sulphuric acid. It is decomposed at 150°; it is decomposed by aq. ammonia, forming platinous diamminodinitrite; and it forms a complex salt with pyridine, $Pt(C_2H_5N)_2(NO_2)_2$.

L. F. Nilson prepared **rubidium tetranitritoplatinite,** $Rb_2Pt(NO_2)_4$, from the soln. obtained by mixing the silver salt with rubidium chloride. The spontaneous evaporation of the soln. furnishes colourless prisms of **dihydrated rubidium tetranitritoplatinite,** $Rb_2Pt(NO_2)_4.2H_2O$; at 100°, this salt becomes anhydrous. H. Töpsöe found the monoclinic prisms of the anhydrous salt have the axial ratios $a:b:c=0{\cdot}6142:1:0{\cdot}7103$, and $\beta=95°\ 01'$; and they are isomorphous with the potassium salt; the axial ratios of the monoclinic prisms of the dihydrate are $a:b:c=2{\cdot}0109:1:1{\cdot}7935$, and $\beta=91°\ 40'$, and they are isomorphous with the ammonium salt. H. A. Miers emphasized that rubidium does not here occupy an intermediate position crystallographically between potassium and cæsium. L. F. Nilson added that the hydrate is stable in air at ordinary temp., but in a dry atm. efflorescence occurs. The water is lost at 100°. Both salts are soluble in cold water, more so in hot water. L. F. Nilson likewise prepared colourless or pale yellow crystals of **cæsium tetranitritoplatinite,** $Cs_2Pt(NO_2)_4$. The properties are like those of the rubidium salt. H. Töpsöe gave $a:b:c=1{\cdot}6122:1:0{\cdot}6291$, and $\beta=99°\ 50'$ for the axial ratios of the monoclinic prisms. L. F. Nilson prepared colourless prisms of trihydrated **lithium tetranitritoplatinite,** $Li_2Pt(NO_2)_4.3H_2O$, as in the case of the rubidium salt. The water is expelled at 100°; the crystals are hygroscopic, and easily soluble in water. H. Töpsöe found the axial ratios of the rhombic bipyramids to be $a:b:c=0{\cdot}9576:1:0{\cdot}7504$. J. Lang made **sodium tetranitritoplatinite,** $Na_2Pt(NO_2)_4$, by evaporating the soln. obtained by mixing sodium nitrite and sodium tetrachloroplatinite; M. Vèzes, by mixing soln. of hydrochloroplatinic acid and an excess of sodium nitrite; and L. F. Nilson, from mixed soln. of sodium chloride and silver tetranitritoplatinite. The slow evaporation of the soln. furnishes pale yellow, rhombic or monoclinic prisms, which H. Töpsöe found to have the axial ratios $a:b:c=1{\cdot}4442:1:0{\cdot}6637$. The crystals separating from the aq. soln. are probably hydrated, but they readily effloresce. All the water is expelled at 100°. J. Lang said that the salt is very soluble in cold or hot water, and the soln. has a neutral reaction. Chlorine or hydrochloric acid decomposes the soln.

L. F. Nilson treated a conc. soln. of barium tetranitritoplatinite with one of copper sulphate, and obtained acicular, yellow crystals of **copper oxytetranitritoplatinite,** $CuO.3CuPt(NO_2)_4.18H_2O$, which decompose at 100°, and in aq. soln. The mother-liquor from the basic salt furnishes green needles of trihydrated **copper tetranitritoplatinite,** $CuPt(NO_2)_4.3H_2O$, which are decomposed at 100°. The salt is very soluble in water. J. Lang made silver tetranitritoplatinite, $Ag_2Pt(NO_2)_4$, mixing potassium tetranitritoplatinite and silver nitrate in hot conc. soln. and cooling; and E. Priwoznik, by digesting an excess of a silver platinum alloy with nitric acid. The salt can be purified by recrystallization from hot water, and dried at 100°. The yellowish-green, or bronze-yellow, needle-like crystals were found by H. Töpsöe to be monoclinic prisms, with the axial ratios $a:b:c=0{\cdot}9660:1:0{\cdot}5091$, and $\beta=98°\ 0{\cdot}5'$; F. von Foullon gave $a:b:c=0{\cdot}9686:1:0{\cdot}5127$, and $\beta=78°\ 18\frac{1}{2}'$, where 78° is probably a slip of the pen for 98°. The crystals are stable in air. J. Lang said that they blacken when exposed to light, and decompose without detonation when heated; E. Priwoznik observed that nitrogen peroxide is first evolved and then oxygen. The salt is scarcely soluble in cold water, but is readily dissolved by hot water; F. L. Nilson found that small quantities of a basic salt—$Ag_2Pt_2O(NO_2)_2$, silver oxydinitritodiplatinite—are formed when the normal salt is crystallized. The crystals of the basic salt are green or greenish-yellow, four-sided prisms. J. Lang found that ammonia transforms the tetranitrito-platinite into a white substance easily soluble in water, and forming prisms when the aq. soln. is crystallized. Green silver chloride is formed by treating the aq. soln. with hydrochloric acid—the green colour is due to absorbed nitrogen peroxide.

L. F. Nilson prepared **calcium tetranitritoplatinite,** $CaPt(NO_2)_4.5H_2O$, in yellow four-sided prisms by the action of conc. soln. of calcium chloride on the silver salt. The crystals are stable in moist air, but effloresce over sulphuric acid; they lose all their water at 100°; and are very soluble in water. L. F. Nilson prepared **strontium tetranitritoplatinite,** $SrPt(NO_2)_4.3H_2O$, by the action of a soln. of strontium chloride on the silver salt. The colourless or pale yellow, six-sided plates were shown by H. Töpsöe to be triclinic pinacoids—pseudomonoclinic—with axial ratios $a:b:c=0{\cdot}5598:1{\cdot}5712$, or $\alpha=93°\ 6'$, $\beta=90°\ 0'$, and $\gamma=90°\ 0'$. L. F. Nilson added that the crystals are stable in air, and lose two-thirds the total water at 100°; they blacken at dull redness; and are sparingly soluble in cold water, but readily soluble in hot water. J. Lang, and L. F. Nilson made **barium tetranitritoplatinite,** $BaPt(NO_2)_4.3H_2O$, by the action of soln. of barium chloride on the silver salt. The colourless plates or prisms were found by H. Töpsöe to be triclinic pinacoids—pseudomonoclinic—with axial ratios $a:b:c=0{\cdot}5722:1:1{\cdot}7172$, and $\alpha=92°\ 12'$, $\beta=90°\ 0'$, and $\gamma=90°\ 0'$. J. Lang, and L. F. Nilson found the crystals to be quite stable in air; and after drying in air, to lose nothing in weight in vacuo over potassium hydroxide. The crystals are sparingly soluble in cold water, but readily soluble in hot water. They are also more soluble in cold water than the potassium salt.

L. F. Nilson prepared a basic salt—**beryllium oxytetranitritodiplatinite,** $BePt_2O(NO_2)_4.9H_2O$—from conc. soln. of beryllium sulphate and barium tetranitritoplatinite, after evaporation first on a water-bath and then over conc. sulphuric acid or in vacuo. The small red pyramidal crystals lose six mols of water at 100°; they are sparingly soluble in cold water, forming a yellow soln. which develops nitrous fumes on a water-bath. L. F. Nilson obtained **magnesium tetranitritoplatinite,** $MgPt(NO_2)_4.5H_2O$, by the action of magnesium sulphate on the barium salt. The colourless six-sided prisms are monoclinic, and H. Töpsöe found for the axial ratios $a:b:c=0{\cdot}6101:1:0{\cdot}4101$, and $\beta=98°\ 35{\cdot}5'$. L. F. Nilson found the crystals to be stable at 100°, and to decompose at dull redness. L. F. Nilson obtained colourless or pale yellow crystals of **zinc tetranitritoplatinite,** $ZnPt(NO_2)_4.8H_2O$, from zinc sulphate and the barium salt. They are fairly stable in air, but decompose at 100°. They are readily soluble in water. H. Töpsöe said that the triclinic pinacoids are isomorphous with the nickel and manganese salts. L. F. Nilson made yellow crystals of **cadmium tetranitritoplatinite,** $CdPt(NO_2)_4.3H_2O$, from cadmium sulphate and the barium salt. They are stable in moist air; effloresce in dry air, and lose all their water of crystallization without decomposition at 100°. H. Töpsöe said the monoclinic prisms have the axial ratios $a:b:c=1{\cdot}0627:1:1{\cdot}5850$, and $\beta=98°\ 25{\cdot}5'$. L. F. Nilson, and J. Lang obtained a basic salt—**mercurous oxytetranitritoplatinite,** $Hg_2O.Hg_2Pt(NO_2)_4.H_2O$—by the action of a feebly acid soln. of mercurous nitrate on a soln. of potassium tetranitritoplatinite. The pale yellow precipitate consists of microscopic prisms; they lose a mol of water at 60°; and blacken at 100°. L. F. Nilson said that if boiling soln. of mercuric chloride and silver tetranitritoplatinite are mixed, silver chloride is precipitated, and the filtrate when evaporated gives a yellow amorphous substance and pale yellow crystals which could not be separated—one may be normal or basic *mercuric tetranitritoplatinite.*

L. F. Nilson evaporated over sulphuric acid the liquid obtained by the action of barium tetranitritoplatinite on aluminium sulphate. The colourless cubic crystals of **aluminium dodecanitritotriplatinate,** $Al_2Pt_3(NO_2)_{12}.14H_2O$, so obtained are fairly stable, but decompose at 100°; if the aq. soln. be evaporated on a water-bath orange-red needles are produced with the composition $AlPt_2(OH)_3(NO_2)_4.4H_2O$, **aluminium trihydroxytetranitritodiplatinite.** They lose water at 100°; and are slightly soluble in cold water; easily soluble in water; and soluble in alcohol. By treating soln. of the silver salt with indium trichloride, and evaporating the filtrate, L. F. Nilson obtained red, needle-like crystals of a basic salt—**indium trihydroxytetranitritoplatinite,** $InPt_2(OH)_3(NO_2)_4.4H_2O$—sparingly soluble in cold water. L. F. Nilson also prepared lemon-yellow, four-sided prisms of **yttrium dodecanitritotriplatinite,** $Y_2[4NO_2.Pt]_3.9H_2O$, and $Y_2[4NO_2.Pt]_3.21H_2O$; orange-yellow, four-sided prisms of **erbium dodecanitritotriplatinite,** $Er_2[4NO_2.Pt]_3.9H_2O$, and $Er_2[4NO_2.Pt]_3.21H_2O$; yellow, four-sided plates or rhombohedra of **cerous dodecanitritotriplatinite,** $Ce_2[4NO_2.Pt]_3.18H_2O$; yellow, four-sided plates of rhombohedra of **lanthanum dodecanitritotriplatinite,** $La_2[4NO_2.Pt]_3.18H_2O$; and yellow, four-sided plates or rhombohedra **didymium dodecanitritotriplatinite,** $Di_2[4NO_2.Pt]_3.18H_2O$, from the barium salt and the sulphate of the rare earth. Colourless four- or six-sided needles or prisms of **thallous tetranitritoplatinite,** $Tl_2Pt(NO_2)_4$, were also made by the action of thallous sulphate on the barium salt. The crystals are stable in moist and dry air, and at 100°; they are soluble in cold water, more so in hot water. H. Töpsöe gave for the axial ratios of the monoclinic prisms $a:b:c=1·2309:1:0·9034$, and $\beta=105° 30'$. L. F. Nilson prepared **lead tetranitritoplatinite,** $PbPt(NO_2)_4.3H_2O$, from the filtrate by treating soln. of lead chloride and silver tetranitritoplatinite. The six-sided prisms are stable in air; lose their water at 100°; and are sparingly soluble in water. H. Töpsöe gave for the monoclinic prisms—pseudohexagonal—the axial ratios $a:b:c=0·5471:1:1·3055$, and $\alpha=92° 18'$.

L. F. Nilson prepared crystals of **chromium trihydroxytetranitritodiplatinite,** $CrPt_2(OH)_3(NO_2)_4.11H_2O$, from the soln. obtained by treating soln. of chromic sulphate with barium tetranitritoplatinite. The small red crystals resemble the basic beryllium salt. They lose nine mols of water at 100°; and are soluble in water. He also obtained **manganese tetranitritoplatinite,** $MnPt(NO_2)_4.8H_2O$, from manganese sulphate and the barium salt. The crystals are fairly stable in air, but gradually form brown manganese oxide; they decompose at 100°. H. Töpsöe gave for the axial ratios of the triclinic pinacoids, $a:b:c=0·7025:1:—$, and $\alpha=84° 31'$, $\beta=107° 52'$, and $\gamma=98° 43'$. By evaporating in vacuo over sulphuric acid the filtrate from a mixed soln. of ferrous sulphate and the barium salt, L. F. Nilson obtained a basic salt—**ferrous trioxydodecanitritohexaplatinite,** $Fe_2Pt_6O_3(NO_2)_{12}.30H_2O$; and similarly by evaporating the filtrate from a mixture of ferric chloride and silver tetranitritoplatinite. The crystals resemble those of the basic salts of beryllium and chromium. They lose 24 mols of water at 100°, and are soluble in water. He also prepared **cobaltous tetranitritoplatinite,** $CoPt(NO_2)_4.8H_2O$, by evaporating the filtrate from a soln. of cobalt sulphate and the barium salt. The red, four-sided prisms are isomorphous with those of the manganese salt. The crystals are stable in air; decompose at 100°; and dissolve readily in water. H. Töpsöe found the axial ratios of the triclinic pinacoids to be $a:b:c=0·6998:1:0·88$, and $\alpha=84° 57'$, $\beta=108° 5'$, and $\gamma=97° 0'$. The corresponding **nickel tetranitritoplatinite,** $NiPt(NO_2)_4.8H_2O$, was obtained by L. F. Nilson, in a manner similar to that used for the cobalt salt. The properties are similar, and H. Töpsöe found the crystals to be isomorphous.

A. Miolati obtained **potassium hydrochlorotetranitritoplatinite,** $K_2Pt(NO_2)_4.HCl$, by treating powdered potassium tetranitritoplatinite with cold, conc. hydrochloric acid. The product is soluble in water, and on evaporation crystals of **potassium chlorotrinitritoplatinite,** $K_2Pt(NO_2)_3.2H_2O$, are formed. M. Vèzes made the latter salt by heating a soln. of a mol of potassium tetranitritoplatinite, and a mol of hydrogen chloride in dil. soln. The pale yellow plates are stable in air; lose water at 100°; and melt at a higher temp., giving off nitrous fumes. 100 parts of cold water dissolve 33·3 parts of salt; and hot water, 50 parts. The yellow soln. is stable even at 100°. A soln. of potassium nitrite reforms the tetranitritoplatinite, and an excess of chlorine forms chloroplatinate; a little chlorine-water forms trichlorotrinitritoplatinate; and a little hydrogen chloride forms

potassium dichlorodinitritoplatinite, $K_2Pt(NO_2)_2Cl_2$. The latter salt was also made by M. Vèzes by cooling a mixed conc. soln. of potassium tetrachloroplatinite and tetranitritoplatinite; and by boiling equi-molar parts of potassium oxalatodinitritoplatinite, and copper chloride. The yellow needles were shown by H. Dufet to be monoclinic prisms with axial ratios $a:b:c=0\cdot5538:1:0\cdot3074$, and $\beta=103^\circ 51'$. The crystals are stable in air; they lose no weight at 100°; they melt and decompose at dull redness; 100 parts of cold water dissolve 33·3 parts of salt, and hot water, 50 parts. The aq. soln. is very stable. An excess of chlorine or hydrochloric acid converts it into chloroplatinate, and an excess of potassium nitrite into nitritoplatinite. A. Miolati was unable to prepare potassium dichlorodinitritoplatinite, $K_2PtCl_2(NO_2)_2$.

M. Vèzes prepared **potassium bromotrinitritoplatinite,** $K_2Pt(NO_2)_3Br.2H_2O$, as in the case of the corresponding chloro-salt. The crystals are isomorphous with the same compound. The properties are also analogous. M. Vèzes made **potassium dibromodinitritoplatinite,** $K_2Pt(NO_2)_2Br_2.H_2O$, by the methods employed for the corresponding chloro-salt. The pale yellow plates are triclinic pinacoids which H. Dufet found to have the axial ratios $a:b:c=0\cdot9920:1:1\cdot3170$, and $\alpha=90^\circ 58'$, $\beta=91^\circ 42\cdot5'$, and $\gamma=91^\circ 7'$. The properties of the salt resemble those of the corresponding chloro-salt. L. F. Nilson prepared **potassium diiododinitritoplatinite,** $K_2Pt(NO_2)_2I_2.2H_2O$, by the action of a mol of potassium tetranitritoplatinite on 2 gram-atoms of iodine in alcoholic soln. at 30°–40°; and M. Vèzes, by the action of eq. proportions of lead iodide and potassium oxalatodinitritoplatinite. The conc. of the soln. furnishes reddish-yellow prisms which H. Dufet classed as tetragonal bipyramids with the axial ratio $a:c=1:0\cdot5891$; the refractive indices for Na-light are $\omega=1\cdot7909$, and $\epsilon=1\cdot6527$; the optical character is negative. The dichroic crystals are pale greenish-yellow viewed parallel to the c-axis; and orange, perpendicular to that axis. L. F. Nilson found that the crystals are stable in air; they lose their water at 100°; they are very soluble in water; the aq. soln. darkens at 100°; the salt is very soluble in alcohol. L. F. Nilson made **rubidium diiododinitritoplatinite,** $Rb_2Pt(NO_2)_2I_2.2H_2O$, from a soln. of rubidium sulphate and barium diiodonitritoplatinite. The lemon-yellow plates were considered by P. Groth to be triclinic pinacoids, and to have the axial ratios $a:b:c=0\cdot9418:1:0\cdot5873$, and $\alpha=84^\circ 41'$, $\beta=98^\circ 20'$, and $\gamma=87^\circ 24'$. H. A. Miers emphasized that rubidium is not always intermediate between potassium and cæsium crystallographically, as here. G. Negri considers these observations are not accurate. The salt is stable in air; it loses its water at 100°; and is readily dissolved by water. L. F. Nilson prepared the corresponding **cæsium diiododinitritoplatinite,** $CsPt(NO_2)I_2{\cdot}2H_2O$, in a similar manner. The properties are also similar. The lemon-yellow, monoclinic, prismatic crystals were found by P. Groth to have the axial ratio $a:b:c=0\cdot9425:0\cdot6502$, and $\beta=98^\circ 20'$. L. F. Nilson prepared yellow crystals of **lithium diiododinitritoplatinite,** $Li_2Pt(NO_2)_2I_2.6H_2O$, in a similar manner. They deliquesce in air; lose 5 mols of water at 100°, and decompose; they are very soluble in water. L. F. Nilson also made **sodium diiododinitritoplatinite,** $Na_2Pt(NO_2)_2I_2.4H_2O$, in a similar way. The lemon-yellow crystals are stable in air; lose all their water at 100°; and are very soluble in water. P. Groth found the axial ratios of the triclinic pinacoids to be $a:b:c=0\cdot9049:1:0\cdot7126$, and $\alpha=102^\circ 9'$, $\beta=111^\circ 23\cdot5'$, and $\gamma=80^\circ 31\cdot5'$. They are feebly dichroic. The corresponding **cupric diiododinitritoplatinite,** or a basic derivative, was obtained by L. F. Nilson by the action of cupric sulphate on the barium salt. Green, four-sided, prismatic crystals were mixed with a black substance. L. F. Nilson prepared **silver diiododinitritoplatinite,** $Ag_2Pt(NO_2)_2I_2$, by the action of silver nitrate on an alkali diiododinitritoplatinite. The lemon-yellow powder is amorphous and it is decomposed by water: $2Ag_2Pt(NO_2)_2I_2+H_2O=4AgI+PtO.H_2Pt(NO_2)_4$. The salt decomposes at 100°, and it is very sparingly soluble in water. L. F. Nilson prepared **calcium diiododinitritoplatinite,** $CaPt(NO_2)I_2.6H_2O$, by the action of alcoholic iodine on calcium tetranitritoplatinite. The yellowish-red monoclinic prisms were found by P. Groth to have the axial ratios $a:b:c=1{\cdot}238:1:1{\cdot}794$, and $\beta=124°\ 14'$. The crystals are stable in air; give off 5 mols of water at 100° with decomposition; and are very soluble in water. L. F. Nilson also made **strontium diiododinitritoplatinite**, $SrPt(NO_2)_2I_2.8H_2O$, in a similar way. The amber-yellow plates are stable in air, but they become matte; they lose 6 mols of water at 100°; and are very soluble in water. P. Groth found the monoclinic prisms have the axial ratios $a:b:c=0{\cdot}9175:1:1{\cdot}8101$, and $\beta=119°\ 3'$; the optic axial angle $2E=80°–90°$. L. F. Nilson also made **barium diiododinitritoplatinite**, $BaPt(NO_2)_2I_2.4H_2O$, by the method used for the calcium salt. The amber-yellow crystals are stable in air; give off a mol of water at 100°; and are very soluble in water. P. Groth gave $a:b:c=0{\cdot}8456:1:0{\cdot}5435$, and $\beta=112°\ 4\frac{1}{2}'$ for the axial ratios of the monoclinic prisms; and $2E=c.\ 75°$ for the optic axial angle.

L. F. Nilson made **beryllium diiododinitritoplatinite**, $BePt(NO_2)_2I_2.6H_2O$, from beryllium sulphate and the barium salt—the original represents beryllia-like alumina. The yellow four-sided plates smell of iodine; they are decomposed at 100°; and are readily soluble in water. He also made **magnesium diiododinitritoplatinite**, $MgPt(NO_2)_2I_2.8H_2O$, in a similar manner. The yellow tabular crystals are stable in moist air, but effloresce in dry air; they lose water and decompose at 100°; and are readily dissolved by water. The aq. soln. is partially decomposed on a water-bath. P. Groth gave $a:b:c=0{\cdot}4890:1:0{\cdot}3724$, and $\beta=99°\ 29'$ for the axial ratios of the monoclinic prisms. L. F. Nilson prepared **zinc diiododinitritoplatinite**, $ZnPt(NO_2)_2I_2.8H_2O$, in the form of greenish-yellow, small, four-sided columns. The properties are like those of the magnesium salt. Yellow prismatic crystals of **cadmium diiododinitritoplatinite**, $CdPt(NO_2)_2I_2.2H_2O$, were made in a similar way. They are stable in air and at 100°, and are very soluble in water. He also obtained a dark brown, imperfectly crystallized mass of **mercurous oxydiiododinitritoplatinite**, $Hg_2O.2Hg_2Pt(NO_2)_2I_2.9H_2O$, by the action of mercurous nitrate on the barium salt. He could not procure **mercuric diiododinitritoplatinite** by the action of mercuric chloride on the barium salt.

L. F. Nilson made **aluminium hexaiodohexanitritotriplatinite**, $Al_2Pt_3(NO_2)_6I_6.27H_2O$, by the action of aluminium sulphate on the barium salt, and evaporating the soln. at ordinary temp. The yellow needles have properties like those of the beryllium salt. Thallous sulphate and the sodium salt give small yellow crystals of **thallous diiododinitritoplatinite**, $Tl_2Pt(NO_2)_2I_2$, which are stable in air and at 100°. The following salts were also made from the barium salt and the corresponding sulphate: yellowish-green crystals of **yttrium hexaiodohexanitritotriplatinite**, $Y_2Pt_3(NO_2)_6I_6.27H_2O$; **erbium hexaiodohexanitritotriplatinite**, $Er_2Pt_3I_6(NO_2)_6.18H_2O$; **cerous hexaiodohexanitritotriplatinite**, $Ce_2Pt_3I_6(NO_2)_6.18H_2O$; **lanthanum hexaiodohexanitritotriplatinite**, $La_2Pt_3I_6(NO_2)_6.24H_2O$; and **didymium hexaiodohexanitritotriplatinite**, $Di_2Pt_3I_6(NO_2)_6.24H_2O$. Lead nitrite and the barium salt furnish **lead dihydroxydiiododinitritoplatinite**, $Pb(OH)_2.PbPt(NO_2)I_2$, in yellow microscopic crystals, stable in air and at 100°; and soluble in water. Manganese sulphate and the barium salt furnish yellow six-sided plates of **manganese diiododinitritoplatinite**, $MnPt(NO_2)_2I_2.8H_2O$; they are very slowly decomposed in air; easily decomposed at 100°; soluble in water without decomposition; and the aq. soln. can be conc. on a water-bath with very little decomposition. With ferrous sulphate and the barium salt, **ferrous diiododinitritoplatinite**, $FePt(NO_2)_2I_2.8H_2O$, is obtained in small, yellow, four-sided prisms, which are decomposed only very slowly in air, but quickly at 100°. With ferric sulphate and the barium salt, yellowish-green needles of **ferric hexaiodohexanitritotriplatinite**, $Fe_2Pt_3(NO_2)_6I_6.6H_2O$, are formed. They smell of iodine; decompose at 100°; and are soluble in water. L. F. Nilson prepared **cobalt diiododinitritoplatinite**, $CoPt(NO_2)_2I_2.8H_2O$, in an analogous manner. It forms yellow plates which slowly decompose in air, and decompose rapidly at 100°. Green plates of **nickel diiododinitritoplatinite**, $NiPt(NO_2)_2I_2.8H_2O$, were similarly prepared. This salt is very like the cobalt salt. C. W. Blomstrand, A. Miolati and I. Bellucci, and M. Vèzes passed chlorine into an aq. soln. of potassium tetranitritoplatinite, and obtained pale yellow prisms of **potassium dichlorotetranitritoplatinate,** $K_2PtCl_2(NO_2)_4$. The monoclinic prismatic crystals were found by H. Dufet to have the axial ratios $a:b:c=1{\cdot}021:1:1{\cdot}322$, and $\beta=102°\ 16'$. M. Vèzes found that the crystals are not changed in air; they lose no water at 100°; and melt with decomposition at dull redness. 100 parts of cold water dissolve 2·5 parts of salt; and boiling water, 5·0 parts. The yellow aq. soln. is fairly stable, but when kept at 100° for a long time, nitrous fumes are slowly evolved. The aq. soln. gives needles of potassium dichlorodinitritoplatinite, $K_2PtCl_2(NO_2)_2$. An excess of chlorine or hydrochloric acid converts the dichlorotetranitritoplatinite into the chloroplatinate. It is decomposed when boiled with a soln. of potassium nitrite, and the normal salt, $K_2Pt(NO_2)_4$, is formed. The salt is soluble in a soln. of potassium chloride, or nitrite. M. Vèzes made **potassium trichlorotrinitritoplatinate,** $K_2Pt(NO_2)_3Cl_3$, by the action of two gram-atoms of chlorine, and a mol of monochlorotrinitritoplatinite; and **potassium pentachloronitritoplatinate,** $K_2Pt(NO_2)Cl_5.H_2O$, by the action of a large excess of hydrochloric acid on a warm conc. soln. of potassium tetranitritoplatinite. M. Vèzes first represented this as a nitroso-salt, $K_2Pt(NO)Cl_5$. C. W. Blomstrand prepared **potassium dibromotetranitritoplatinate,** $K_2Pt(NO_2)_4Br_2$, by the action of bromine on the tetranitritoplatinite; crystals are readily obtained by cooling the hot sat. soln. M. Vèzes, and A. Miolati and I. Bellucci employed a somewhat similar process. The yellow, monoclinic, prismatic crystals were found by H. Dufet to have the axial ratios $a:b:c=1{\cdot}0108:1:1{\cdot}3927$, and $\beta=100°\ 31'$. The salt is not changed in air, or at 100°; it melts and decomposes at dull redness; 100 parts of cold water dissolve 2·5 parts of salt, and boiling water, 50 parts of salt. The yellow soln. is stable, but with prolonged boiling, nitrous fumes are given off. The salt is dissolved. A soln. of potassium nitrite, and crystals of the tetranitritoplatinite are formed; and excess of bromine or hydrobromic acid forms the chloroplatinate. The salt is slightly soluble in a soln. of potassium bromide; and insoluble in alcohol. A boiling soln. in aq. alcohol forms aldehyde, and the dibromodinitritoplatinite. M. Vèzes prepared **potassium tribromotrinitritoplatinate,** $K_2Pt(NO_2)_3Br_3$, from 3 gram-atoms of bromine, as bromine water, and a mol of potassium tetranitritoplatinite in hot, conc. soln. The red prisms were shown by H. Dufet to be rhombic bipyramids with axial ratios $a:b:c=0{\cdot}7344:1:0{\cdot}6524$. The general properties are like those of the corresponding chloro-salt. This salt was first represented as a nitroso-salt, $K_2Pt(NO)(NO_2)_2Br_3$. When the proportion of bromine was increased to 4 gram-atoms, M. Vèzes obtained **potassium tetrabromodinitritoplatinate,** $K_2PtBr_4(NO_2)_2$, in long, red prisms. Their general properties resemble those of the corresponding chloro-salt. M. Vèzes could not make *potassium pentabromonitritoplatinate.* M. Vèzes made **potassium tetraiododinitritoplatinate,** $K_2Pt(NO_2)_2I_4$, by the action of an alcoholic soln. of iodine on the diiododinitritoplatinite at 80°. The conc. soln. on cooling deposits black crystals with a greenish lustre. H. Dufet represented them as rhombic bipyramids with axial ratios $a:b:c=0{\cdot}7874:1:0{\cdot}6430$. M. Vèzes found the crystals are stable in air, and at 100°; they decompose at a dull red-heat; they are sparingly soluble in cold water, but are readily dissolved by hot water; and when the aq. soln. is boiled, the diiododinitritoplatinite is formed. He also made **potassium pentaiodonitritoplatinate,** $K_2Pt(NO_2)I_5$, which he regarded at first as a nitroso-salt, $K_2Pt(NO)I_5$. It was obtained by adding an alcoholic soln. of iodine to a conc. soln. of the diiododinitritoplatinite, and concentrating the soln. at a suitable temp. The black crystals behave very much like those of the preceding salt. A. Miolati and I. Bellucci prepared **silver dibromotetranitritoplatinate,** $Ag_2PtBr_2(NO_2)_4$, by the action of a conc. soln. of silver nitrate on powdered potassium dibromotetranitritoplatinate. The red crystals are sensitive to light.

§ 39. Nitrogen Peroxide or Tetroxide

The ruddy fumes of this compound always appear as a by-product in the old method of preparing nitric acid by heating a mixture of saltpetre with copperas, or alum. Consonant with the language of the alchemists, W. Clark[1] referred, in 1670, to the red vapours which are formed when saltpetre is heated in a retort as *the flying dragon*. In 1778, P. J. Macquer regarded the red vapours as an essential constituent of nitric acid itself, and asked : *Pourqoi les vapeurs de cet acide sont-elles rouges ?* He was not satisfied with the earlier explanations. About the beginning of the eighteenth century, both C. A. Baldiun, and G. E. Stahl had attributed the red fumes to the presence of a peculiar substance—*anima nitri*—in saltpetre. About twenty years later, J. H. Pott said that the red fumes are of an oily, sulphurous nature because charcoal burns with a flame in the vapours. J. C. Wiegleb attributed the red colour to the presence of elemental fire. In 1736, J. Hellot mistook an accidental impurity for an essential constituent, for he said that the colour is due to the rarefaction of the ferruginous particles in *les vapeurs de l'esprit de nitre* during the distillation. C. W. Scheele inquired whether the vapours of nitric acid are naturally red, and he inferred from his experiments that if nitric acid be associated with a little phlogiston, it furnishes the red vapours ; but if it be associated with more phlogiston, it forms a colourless gas (nitric oxide). This explanation, translated into modern language, was getting nearer the truth, for it means that the red gas is an intermediate stage of oxidation between that of nitric acid and that of nitric oxide. Pure colourless nitric acid was called dephlogisticated nitric acid. J. Priestley, and H. Cavendish showed that the red fumes obtained when nitrous air comes in contact with atmospheric air have an acidic nature ; and J. Priestley called the red gas *nitrous acid air*. A. L. Lavoisier inferred from his experiments : *Sur l'existence de l'air dans l'acide nitreux*, that nitric acid is a compound of nitric oxide and oxygen, while the red fume is a compound of nitric oxide and nitric acid. In 1816, the work of J. L. Gay Lussac, J. J. Berzelius, P. L. Dulong, and E. Péligot established the relations between the red vapours, nitric oxide, nitrous oxide, and nitrous and nitric acids. They called the gas *l'acide hypoazotique;* it is now known as **nitrogen peroxide,** or **nitrogen tetroxide,** N_2O_4, or NO_2.

The preparation of nitrogen peroxide.—The oxidation of nitric oxide to nitrogen peroxide has been previously discussed. Some of the methods indicated in connection with the oxidation of nitrogen furnish nitrogen peroxide. Thus, the Société d'Études Minières et Industrielles[2] prepared nitrogen peroxide by the interaction of ammonia and oxygen, air, or oxygenated air in the presence of rhodium as catalyst. S. Genelin said that half an hour's sparking of air in a eudiometer tube can be arranged so as to show the formation of nitrogen peroxide by the colour of the vapour. J. L. Gay Lussac prepared nitrogen peroxide by mixing nitric oxide with half its vol. of oxygen. P. L. Dulong passed the dry-mixed gases through a tube packed with pieces of porcelain, and then through a U-tube cooled to about 20°. The green liquid becomes yellow even on decantation. E. Péligot said that the gases cannot be properly dried by calcium chloride, and he recommended passing the mixed gases first through conc. sulphuric acid, then through a tube packed with solid, recently fused, potassium hydroxide, and lastly into a receiver cooled to —15° or —20°. Under these conditions, the product forms colourless crystals. After a time, the potassium hydroxide loses its desiccating powers, and if the operation is continued, the crystals deliquesce, forming a green liquid which gradually darkens in colour and becomes more volatile.

According to F. Raschig, the red vapours formed by the action of air on nitric oxide are different from ordinary nitrogen tetroxide and he called the product *nitrogen isotetroxide,* N=O=O, to distinguish it from the ordinary tetroxide. He said that the isoperoxide is the primary product when nitrogen is burnt in the high-tension arc, or when ammonia is burnt with a platinum catalyst at a low red-heat. This is contrary to the idea that nitric oxide is the only nitrogen oxide stable at a high temp. The lighter colour observed when nitrogen peroxide is passed through a hot tube is not to be attributed to its decomposition into nitric oxide and oxygen, but to the formation of the lighter coloured isoperoxide. While the ordinary tetroxide reacts with sodium hydroxide: $N_2O_4+2NaOH=NaNO_2+NaNO_3+H_2O$, he said that the iso-compound reacts: $N_2O_4+2NaOH=2NaNO_2+H_2O+O$. If a large excess of oxygen is used in oxidizing the nitric oxide, he added that a *nitrogen isopentoxide* as well as *nitrogen hexoxide,* N_2O_6, reacts with alkali-lye: $N_2O_5+2NaOH=NaNO_2+NaNO_3+H_2O+O$; $N_2O_6+2NaOH=2NaNO_2+H_2O+3O$; and $N_2O_7+2NaOH=NaNO_2+NaNO_3+H_2O+3O$. These hypothetical compounds were not confirmed by E. Müller.

J. L. Gay Lussac made nitrogen peroxide by heating dry lead nitrate in a retort connected with a cooled receiver. P. L. Dulong said that the liquid so obtained is anhydrous, or contains at most 0·6 per cent. of water. E. Péligot found that a greenish liquid first passes over, then a colourless liquid containing but a small proportion of water, and lastly the anhydrous compound which solidifies in crystals. K. Heumann recommended mixing the lead nitrate with its own vol. of sand previously calcined. When nitrogen trioxide is decomposed, nitrogen peroxide is formed; and the same remark applies to other nitrogen oxides, to nitrous acid, silver nitrite, and many nitrates. L'Azote Français Société Anon. obtained nitrogen peroxide by heating calcium nitrate above 500° and below 650° in the presence of oxygen. M. Berthelot found nitrogen pentoxide decomposes into nitrogen peroxide when exposed to light; and the gas is also formed when nitric acid vapour is passed through a red-hot tube. A. Bogorodsky found that fused alkali nitrates give off nitrogen peroxide when electrolyzed. P. Winand obtained nitrogen peroxide by the addition of fuming sulphuric acid to a fused mixture of alkali nitrite and nitrate: $NaNO_2+NaNO_3+H_2S_2O_7=2NaHSO_4+2NO_2$—sufficient sodium hydrosulphate is added from a previous preparation to fix any free sulphur trioxide, $2NaHSO_4+SO_3=Na_2S_2O_7+H_2SO_4$.

According to E. Mitscherlich, when fuming nitric acid is gently heated in a retort connected with a receiver surrounded by a freezing mixture, two immiscible layers of liquid are obtained. The lower one is a soln. of nitrogen peroxide in some hydrated nitric acid, and the upper one, a soln. of monohydrated nitric acid in nitrogen peroxide. When the latter is redistilled, nitrogen peroxide of a high degree of purity is obtained. J. Fritzsche said that in the preceding preparations, the nitric acid should be removed from the nitrogen peroxide by redistillation. C. W. Hasenbach, A. Guether, and G. Lunge obtained nitrogen peroxide by the action of conc. nitric acid of sp. gr. 1·38, or of red fuming nitric acid of sp. gr. 1·45 to 1·40, on arsenic trioxide, and condensing the product in the usual way—*vide supra,* nitrogen trioxide. According to C. W. Hasenbach, the nitrogen trioxide can be removed from the condensed liquid by passing oxygen through it; or, according to L. Playfair and J. A. Wanklyn, by distillation from potassium chlorochromate. C. W. G. Nylander believed that an isomeric form of the peroxide is obtained by this process; but C. W. Hasenbach denied this. G. Lunge used starch in place of arsenic trioxide—*vide supra,* nitrogen trioxide; and L. Vanino recommended formaldehyde or paraformaldehyde in place of arsenic trioxide. P. C. Freer and G. O. Higley obtained the gas by dissolving many metals—copper, silver, iron, etc.—in nitric acid of a suitable conc.—*vide* the metals. The gas is also formed when straw, sawdust, and various organic substances are treated with fuming nitric acid.

W. Ramsay showed that nitrogen peroxide is formed by mixing nitrogen tri- and penta-oxides. It suffices to pour a soln. of phosphorus pentoxide in well-cooled nitric acid into liquid nitrogen trioxide. The blue colour disappears, and the liquid can be decanted off and distilled. A. C. Girard and J. A. Pabst, and J. P. Park and J. R. Partington obtained nitrogen peroxide by heating nitrosyl sulphonate (chamber crystals) with potassium nitrate: $NO_2.HSO_3+KNO_3=2NO_2+KHSO_4$; by treating nitrous acid or a nitrite with nitric acid: $HNO_3+RNO_2=2NO_2+R.OH$; or by treating nitrosyl chloride with nitric acid: $NOCl+HNO_3=2NO_2+HCl$; A. Exner, by the action of nitroxyl chloride on silver nitrite: $NO_2Cl+AgNO_2=AgCl+2NO_2$; C. Weltzien, by the action of iodine on silver nitrate; and F. Kuhlmann, by passing a mixture of cyanogen and air through a red-hot tube containing platinum sponge. A. Stavenhagen and E. Schuchard observed that some nitrous oxide is transformed into nitrogen peroxide during the combustion of sulphur in that gas (*q.v.*).

The physical properties of nitrogen peroxide.—Nitrogen peroxide forms a yellowish-red vapour which was formerly regarded as a permanent gas because it was not readily condensed by cold. This was due to the fact that the vapour was mixed with air. The **colour** undergoes some extraordinary changes with variations of temp. P. L. Dulong[3] said that the liquid at —20° is colourless; at —10°, almost colourless; between 0° and 10°, pale yellow; and from 15° to 28°, orange-yellow. As the temp. rises, the colour becomes darker and darker. C. F. Schönbein found that at —50°, the crystals are colourless; between —40° and —30°, pale yellow; between —30° and —20°, pale lemon-yellow; and at the m.p., —20°, pale honey-yellow. H. St. C. Deville and L. Troost, and C. F. Schönbein said that the vapour at —10° is faintly yellow, and with rise of temp. the colour deepens; it is reddish-brown, and at 183°, a 2-cm. layer of the gas is opaque and almost black. At higher temp., the colour becomes paler because the gas is then decomposed into oxygen and nitric oxide. The colour changes are all reversed by cooling. L. Playfair and J. A. Wanklyn found the **vapour density** fell from 2·588 at 4·2° to 1·783 at 97·5°. Related observations were made by R. Müller, H. St. C. Deville and L. Troost, E. and L. Natanson, K. Schreber, M. Bodenstein and M. Katayama, J. W. Gibbs, A. J. Swart, W. L. Argo, S. Dushman, L. Troost, A. Naumann, and A. Richardson. It is assumed that the colour changes, and the variation in the vapour density are due to the variation in the state of equilibrium with temp.: $N_2O_4 \rightleftharpoons 2NO_2$. The condition of equilibrium is $K=C^{\frac{1}{2}}/C_1$, where C denotes the conc. of the N_2O_4-mols., and C_1, that of the NO_2-mols. It is found that at 0°, K=8·060; at 18·8°, 3·710; at 49·9°, 1·116; at 73·6°, 0·544; and at 99·8°, 0·273. The compound with the more complex mol. N_2O_4 is colourless, and with the simpler mol. NO_2, black. This phenomenon is difficult to explain by the theories on the relation between colour and chemical constitution. Assuming that the vapour density is dependent on the degree of **dissociation**, H. St. C. Deville and L. Troost calculated the percentage dissociation, α, from the vapour density, D, and also the change in the degree of dissociation, $\delta\alpha/\delta t$, per 10° rise of temp.:

	26·7°	39·8°	60·2°	80·6°	100·1°	121·5°	135·0°
D . .	2·65	2·46	2·08	1·80	1·68	1·62	1·60
α . .	19·96	29·23	52·84	76·61	89·23	96·23	98·69
$\delta\alpha/\delta'$ . .	6·5	11	13	10·4	4·4	3·5	1·8

The vapour density at 183·2° was 1·57. G. Salet compared the colour changes at different temp. on the assumption that the gas with N_2O_4 mols. alone is colourless, and found the calculated proportions agreed with those obtained by the vapour density method. The other physical properties of the gas agree with the assumed polymerization. J. T. Cundall found that polymerization occurs with the soln. of the gas in chloroform, bromoform, methylene chloride, ethylene chloride, ethylidene chloride, ethylene bromide, ethyl bromide, carbon tetrachloride, carbon disulphide, acetic acid, benzene, chlorobenzene, bromobenzine, and silicon tetrachloride. The nitrogen peroxide dissociates when diluted with chloroform just as the gas does when diluted with an indifferent gas, or when the press. is reduced. Similarly, the dissociation increases with rise of temp. Only 1·22 per cent. of the peroxide is dissociated into NO_2-mols. at 25°. At 10°, 20°, and 30°, the dissociation with chloroform is 7·7, 14·5, and 26·2 respectively; and it is nearly the same with the other solvents except that with acetic acid, it is 2·3, 4·6, and 8·5 respectively; with carbon disulphide, 12·2, 22·5, and 38·3 respectively; and with silicon tetrachloride, 15·7, 26·0, and 52·0 respectively. W. Ramsay found the mol. wt. of nitrogen peroxide in acetic acid agrees with the value for the N_2O_4-mol. W. Ostwald represented the amount of dissociated peroxide by s; the undissociated peroxide, by $1-x$; the vol. of unit mass by v; the equilibrium constant by K; and found that for equilibrium, $x^2=v(1-x)K$. Using J. T. Cundall's results for dil. soln.:

v .	3·8	4·4	5·7	6·5	7·0	8·7	11·2
x .	0·00178	0·00206	0·00657	0·00304	0·00328	0·00407	0·00524
K .	$0·0_6312$	$0·0_6254$	$0·0_6257$	$0·0_6231$	$0·0_6215$	$0·0_6228$	$0·0_6220$

The constancy of K within the limits of experimental error, shows that nitrogen peroxide dissociates in accord with the law of mass action whether in dil. soln., or in the gaseous state. A. Colson's results did not agree with the simple equation $N_2O_4 \rightleftharpoons 2NO_2$; A. Langevin attributed this to A. Colson not having worked with sufficiently dil. soln. Complex addition products of nitrogen peroxide are known to exist, and accordingly, P. Paschal was led to try if, at low temp., it can be obtained in a higher state of polymerization than N_2O_4; but he found that even at −68°, there is no evidence that the molecules are more complex than they are in the ordinary liquid state. E. Grüneisen and E. Goens calculated that every N_2O_4-molecule on the average dissociates at least once every ten-thousandth of a second; and H. Selle, that a mol of N_2O_4 at 21° and 500 mm. press. dissociates to the extent of 4·4 per cent. in 10^{-4} second, and a mol of NO_2 associates to N_2O_4 to the extent of 4·6 per cent. in 10^{-8} second. A. K. Brewer noticed ionization occurs during the decomposition of the peroxide at 385°; H. Staudinger and W. Kreis tried unsuccessfully to isolate solid NO_2 by suddenly chilling the gas from 1000° to −190°.

According to A. Richardson, the vap. density of nitrogen peroxide at 140° corresponds exactly with the formula NO_2, and at higher temp., the vap. density becomes smaller until 5 per cent. of the peroxide is dissociated at 184°; 13 per cent. at 279°; 56·5 per cent. at 494°; and at 619·5°, it corresponds with the completion of the change $2NO_2 \rightarrow 2NO+O_2$. Hence, as soon as the change $N_2O_4 \rightarrow 2NO_2$, is nearing completion, the decomposition of the product begins. W. Ramsay and J. T. Cundall also showed that the bleaching of the black NO_2-gas at elevated temp. is due to its dissociation $2NO_2 \rightleftharpoons 2NO+O_2$. M. Bodenstein and M. Katayama represented the equilibrium conditions of this reaction by $[NO_2]^2K=[NO]^2[O_2]$, and found for the percentage dissociation at different temp.:

	222°	279°	390°	448°	485°	494°	619°
Dissociation . .	4·17	13·10	35·05	40·63	57·48	58·71	100
log *K* . . .	−6·029	−4·523	−3·110	−2·776	−2·167	−2·159	—

The equilibrium constant for partial press. is $\log K = -27400/4{\cdot}571T + 1{\cdot}75 \log T + 3$; or for conc., $\log K_2 = -27400/4{\cdot}571T + 1{\cdot}75T + 4{\cdot}086$. I. W. Cederberg used the equations $\log K_p = -6126T + 2{\cdot}5 \log T + 1{\cdot}316$; and $\log K_c = -6126 \mid T + 1{\cdot}5 \log T + 2{\cdot}402$. E. Wourtzel found that the dissociation constant between 0° and 86·5° can be represented by $\log K = 8{\cdot}9908T - 2810{\cdot}5$.

E. and L. Natanson measured the effect of temp., θ, and press., p mm., on the vap. density, D, of the gas. The following is a selection from their results:

	0°				21°			
p .	37·96	86·57	172·48	250·66	491·60	516·96	556·50	639·70
D .	248·32	2·6737	2·8201	2·9028	2·6838	2·7025	2·7120	2·7459

	49·7°				73·7°			
p .	26·80	93·75	182·69	261·37	49·65	107·47	302·04	633·27
D .	1·6634	1·7883	1·8942	1·9629	1·6315	1·6601	1·7403	1·8534

	99·8°				129·9°			
p .	11·73	79·57	202·24	732·51	35·99	78·73	247·86	550·29
D .	1·6029	1·6179	1·6263	1·6923	1·5987	1·5986	1·6012	1·6084

at 151·40°, the value of p and D were respectively 117·98, 1·5907; 475·41, 1·5882; and 666·22, 1·5927. The **vapour pressure** of nitrogen peroxide has been measured by P. A. Guye and G. Drouginine, F. Russ and E. Eberwein, etc. A. C. G. Egerton found for the vap. press., p mm., of the solid, between −30° and −100°:

	−30°	−40°	−50°	−60°	−70°	−80°	−90°	−100°
p . .	39·24	9·77	2·44	0·605	0·151	0·036	0·0093	0·0023

which he represented by $\log p = 14{\cdot}9166 + 0{\cdot}0604\theta$; or $\log p = -2069T^{-1} + 1{\cdot}75 \log T - 0076T + 4{\cdot}6$; and for the liquid, he gave $\log p = -2211T^{-1} + 1{\cdot}75 \log T - 0{\cdot}0049T + 4{\cdot}6$; and $\log (147/p) = 4{\cdot}2\{(171{\cdot}2/T) - 1\}$. F. Russ and E. Eberwein gave for the vap. press. of the liquid $\log p = -2625{\cdot}2T^{-1} + 1{\cdot}75 \log T - 0{\cdot}007T$ between −80° and −10·8°. F. E. C. Scheffer and J. P. Treub observed the vap. press., p mm., of the liquid to be:

	−36°	−23°	−23°	−10°	−0·6°	7·7°	15°	27·4°	43·2°
p .	18	53	70	146	180	293	565	1007	1982
	Solid.		Liquid.						

A. Mittasch and co-workers found the vap. press. of the liquid to be:

	3·2°	10·3°	19·9°	29·95°	39·85°	48·95°
p . .	319·5	455·5	721	1133·5	1737	2522 mm.

After an intensive drying of nitrogen tetroxide for 25 months, A. Smits and co-workers found that the vap. press. rose to 19 mm. A part of the liquid was distilled off and the increase in vap. press. then fell to 4 mm., but after a further 11 days this had risen to 14·7 mm., *i.e.* it had nearly regained its value before distillation. The colour of the intensively dried liquid was a deeper brownish-red than of the "moist" liquid. The changes of both the vap. press. and the colour agree with the assumption that the drying process had effected a displacement of the internal equilibrium in the direction $N_2O_4 \rightarrow 2NO_2$. J. W. Smith also observed an increase in the vap. press. of nitrogen tetroxide during intensive drying; this amounted to about 25 mm. The change is slow. If the temp. be suddenly changed it requires some hours for equilibrium to be attained. P. L. Dulong gave 1·451 for the **specific gravity** of liquid nitrogen peroxide; A. Geuther found 1·5035 at −5°; 1·4935 at

0° ; 1·4880 at 5° ; 1·4770 at 10° ; and 1·4740 at 15° ; O. Scheuer, 1·4905 at 0° ; T. E. Thorpe, 1·4903 at 0°, and 1·43958 at 21·6° ; and W. Ramsay and J. Shields, 1·4856 at 1·6°, and 1·444 at 19·8°. A. Mittasch and co-workers gave for the sp. gr., *D*, of the liquid :

	(0°)	10·3°	21·05°	29·95°	39·9°	48·95°	54·4°	(60°)
Sp. gr. .	1·4906	1·4688	1·4433	1·4227	1·3976	1·3745	1·3562	1·3435

P. Pascal and M. Garnier represented the sp. gr., *D*, of liquid nitrogen peroxide at $\theta°$, between 0° and 21·5°, by $D=1·490-0·00215\theta$. W. R. Bousfield represented the specific volume of the liquid, at $\theta°$, between 0° and 20° by the equation Sp. vol.$=0·67027+0·0010075\theta+0·0_33\theta^2$. E. Rabinowitsch gave 63 for the mol. vol. T. E. Thorpe and J. W. Rodger represented the **viscosity,** η, at $\theta°$, by $\eta=28·155(140·89+\theta)^{-1·7349}$, when the observed values were 0·005220 at 0·72° ; 0·004720 at 9·15° ; and 0·00401 at 15·36°. W. Ramsay and J. Shields found the **surface tension** to be 29·52 dynes per cm. at 1·6°, and 26·56 at 19·8°. Hence the mol. **surface energy** $\sigma(Mv)^{\frac{2}{3}}$ is 29·52 ergs at 1·6°, and 26·56 ergs at 19·8°. Hence, the liquid is not further polymerized than N_2O_4. A. C. G. Egerton gave 4·6 for the **chemical constant.** Measurements of the **velocity of sound** in the gas were made by W. L. Argo, E. and L. Natanson, and F. Keutel. H. Selle obtained 186·41 metres per second, and E. Grüneisen and E. Goens, 184·3 metres per second. E. Grüneisen and E. Goens measured the velocity of sound in the gas at various temp. and press., and found that with frequencies of the order 15,000 per second, there is no indication that the velocity of sound depends on the frequency, as should be the case if the time required for setting up the dissociation equilibrium were comparable with the vibration period of sound. The absolute value of the velocity of sound agrees much better with the assumption that the time required for the setting up of a dissociation equilibrium is small in comparison with the vibration period. Measurements at 25° and 760 mm. show that the velocity constant of the decomposition, *k*, under the experimental conditions is larger than 10,000 ; consequently, every mol. of nitrogen peroxide dissociates on the average at least once in every 10^{-4} sec. E. Drion, and T. E. Thorpe measured the **thermal expansion** of the liquid. The latter found by interpretation, starting with unit vol. at 0° :

	0°	5°	10°	15°	20°	21·64°
Vol. . .	1·00000	1·00789	1·01573	1·02370	1·03196	1·02523

and he represented the vol., *v*, at $\theta°$, by $v=1+0·0015910\theta-0·0_5397015\theta^2+0·0_62153\theta^3$. C. Feliciani found 0·0033 for the coeff. of **thermal conductivity** at 150°, and said that at all press. the conductivity rises from 18° to a maximum at 65° ; this is followed by a decrease to a minimum, with a second maximum between 120° and 130°. The conductivity increases with press., and the conductivity and dissociation follow the similar courses ; for press. not less than 60 mm., the conductivity of nitrogen peroxide up to 90° is larger than that of any non-dissociating gas previously examined. The results by G. Magnanini and G. Malagnini, and W. Nernst are considered to be unsatisfactory.

M. Berthelot and J. Ogier gave for the **specific heat** of nitrogen peroxide $c_p=1·625$ between 27° and 67° ; 1·115 between 27° and 150° ; and 0·65 between 27° and 280°. K. Schreber calculated from M. Berthelot and J. Ogier's results that the molecular heats of N_2O_4-gas are $C_p=14·85$ Cals. ; $C_v=12·85$; and the ratio of the two sp. hts., 1·555 ; while for NO_2-gas, $C_p=8·43$; $C_v=6·43$; and for the ratio of the two sp. hts., 1·31. According to E. D. McCollum, the mol. ht. of N_2O_4 is slightly greater than that of NO_2. E. and L. Natanson obtained 1·172 for the ratio of the two sp. hts., at about 20°, of the gas when 15·07 per cent. was dissociated, and 1·274 when 56·99 per cent. was dissociated. They also found for NO_2, 1·31. The value 1·172 is near that usually obtained for gases with pentatomic or polyatomic molecules, while 1·274 comes near that usually obtained for gases with triatomic molecules. Measurements of the ratio of the two sp. hts. were made by J. A. Swart, F. Keutel, W. L. Argo, H. Selle, and E. Grüneisen and E. Goens, making allowance for the degree of dissociation of the gas. W. Ramsay found that liquid nitrogen peroxide has a sp. ht. 0·477 ; and the solid, 1·0. G. Piccardi studied the thermal capacity of nitrogen peroxide.

E. Péligot gave 22° for the **boiling point** ; J. L. Gay Lussac, 26° ; P. L. Dulong, 28° at 760 mm. ; and C. W. Hasenbach prepared 22° for the gas obtained from lead nitrate, and this value was raised to between 25° and 26° after the passage of oxygen through the liquid. G. Lunge and E. Berl, 20° at 720 mm. ; G. Oddo, 22°–23° ; A. Nadejdine, 22·5° at 750·4 mm. ; A. Geuther, and G. Bruni and P. Berti, 26°. T. E. Thorpe gave 21·64° at 760 mm. ; T. E. Thorpe and J. W. Rodger, 21·97° ; and F. E. C. Scheffer and J. P. Treub, 21·2° ; P. A. Guye and G. Drouginine, 22° ; and W. R. Bousfield, 21·9°±0·1°. These numbers are not very concordant. H. B. and M. Baker found that when the liquid is thoroughly dried it suffers no apparent change at the b.p., and liquid is still visible at 69° and 757 mm., when no boiling occurred, though evaporation occured. A. Smits attributed the phenomenon to the presence of active and inactive molecules : $\alpha\text{-}N_2O_4 \rightleftharpoons \beta\text{-}N_2O_4$, and assumed that intense drying resulted in the shifting of the equilibrium to the inactive side. E. Péligot said that the liquid freezes to colourless prisms at —20° ; and he gave —9° for the **melting point** ; J. Fritzsche gave —13·5° ; R. Müller, —11·5° to —12° ; W. Ramsay, —10·14° ; G. Bruni and P. Berti, —10·95° ; H. St. C. Deville and L. Troost, —10° ; F. E. C. Scheffer and J. P. Treub, —10·8° ; G. Oddo, —9·04° ; A. C. G. Egerton, —10·5° ; and P. A. Guye and G. Drouginine, —9·6°. E. Péligot said that after being melted, the peroxide requires a much lower temp. for its solidification, for at —16° the compound remains liquid, and J. Fritzsche said that it can be re-solidified only at —30° because a little nitric acid has been formed, and this also accounts for the turbidity of the cooling liquid. For the fusion curve with nitric oxide, *vide supra*, nitrogen trioxide. P. Pascal studied the f.p. of binary systems of nitrogen peroxide with bromoform, chloroform, carbon tetrachloride, bromobenzene, methyl iodide, chloropicrin, and camphor. F. E. C. Scheffer and J. P. Treub gave 158·2° for the **critical temperature,** and 100 atm. for the **critical pressure** ; and it was estimated that at the critical temp. the molecules are all NO_2. W. Ramsay calculated that the latent **heat of fusion** is between —32·2 Cals. and —37·2 Cals. A. C. G. Egerton calculated 9·586 Cals. between —23° and —26°. The latent **heat of vaporization** is 4·3 Cals. at 180° ; F. E. C. Scheffer and J. P. Treub gave 9·2 Cals. at the b.p. ; and A. C. G. Egerton, 9·458 Cals. N. de Kolossowsky gave 1·37 to 2·58 for the **ebulliscopic constant.**

M. Berthelot gave for the **heat of formation,** $(N,O_2)=-7{\cdot}6$ Cals. in the gaseous state ; and 3·4 Cals. in the liquid state. J. Thomsen gave $(2N,4O)=-3{\cdot}9$ Cals. ; $(NO,O)=19{\cdot}568$ Cals. M. Bodenstein and M. Katayama gave $(2NO,O_2)=-27{\cdot}4$ Cals. ; M. Berthelot, 28 Cals. W. Vaubel calculated the **heat of dissociation** of N_2O_4 to be 104·9 Cals. ; M. Berthelot and J. Ogier, 106 Cals. ; and K. Schreber obtained —12·9 Cals. or at T° K, $Q=13132+2T$ cals. ; and J. Thomsen, —13 Cals. M. Berthelot calculated for undissociated N_2O_4, —2·65 Cals. ; and for NO_2, —8·125 Cals. The heat of formation of the liquid is —2·2 to —2·5 Cals. E. Wourtzel gave 12·85 Cals. for the heat of polymerization. J. C. Thomlinson calculated what he called the thermochemical eq. and used the results in comparing the valency of the nitrogen atom in the different nitrogen oxides.

The **index of refraction** of the vapour of nitrogen peroxide at 36° was found by P. L. Dulong to be 1·000503 ; and by C. and M. Cuthbertson, who estimated from their results that the NO_2-gas has the index of refraction $\mu=1{\cdot}000509$, and the N_2O_4-gas $\mu=1{\cdot}001123$, showing that polymerization increases the refractivity $(1-\mu)$ by about 10·5 per cent. The dispersion power of the NO_2-gas in the red and green is much greater than for the N_2O_4-gas. J. H. Gladstone found the **atomic refraction,** 11·8 ; and the **atomic dispersion,** 0·82. W. H. Bair, and H. O. Kneser studied the **spectrum** of the peroxide. The **absorption spectrum** of nitrogen peroxide was examined by A. J. Weiss, E. Luck, J. Zenneck and B. Strasser, F. Daniels, B. Hassenberg, D. Gernez, J. Chappius, and G. D. Liveing and J. Dewar. According to C. F. Schönbein, the higher the temp. of the gas, the greater the number of lines in the absorption spectrum ; and L. Bell said that the gas at 0° gives no absorption spectrum and inferred that the observed absorption spectrum of nitrogen peroxide is produced by the NO_2-mols. and not by the N_2O_4-mols. A. Kundt found that liquid nitrogen peroxide shows five absorption bands between the green and the red ; and these coincide with the strong marked lines in the spectrum of the gas. If the liquid is cooled, two more bands appear in the green ; and if warmed, bands appear in the red as the liquid becomes brown. Beyond the green there is complete absorption. W. N. Hartley, and S. W. Leifson studied the ultra-violet spectrum ; and F. Daniels, the ultra-red spectrum between 2μ and 7μ, and found that the maxima of the absorption bands are not shifted by the process of dissolution in organic liquids—*e.g.* chloroform, and dichloroethane—the slight shifts of $0{\cdot}05\mu$ observed are due to concentration effects. The results are supposed not to support the radiation hypothesis of chemical action.

J. J. Bogusky found that the **electrical conductivity** of nitrogen peroxide gas is poor, and it is an insulator above 70°. L. Bleekrode also found that the liquid is a poor conductor. In 1840, M. Faraday found the liquid obtained by distilling dry lead nitrate was a poor conductor, but readily conducted when water was present. J. J. Bogusky showed that if the liquid is warmed from 0° to 1°, there is an abrupt change in the resistance which is supposed to be due to the dissociation of the N_2O_4-mols. R. Heberlein observed a continuous change in the conductivity with temp. :

	−10°	0°	10°	20°	30
Resistance .	8·6	12·8	10·2	7·0	$5{\cdot}7 \times 10^6$ ohms
Conductivity	1·16	7·83	9·75	14·2	$17{\cdot}6 \times 10^{-8}$ mho

M. Tenani found that the presence of nitrogen peroxide facilitates the discharge of an insulated positively charged disc, but impedes that of a negatively charged disc. This is attributed to the absorption of light by the nitrogen peroxide which prevents it reaching the metallic disc, the conduction being affected only by the ions formed by the action of the absorbed light in the body of the gas. G. Gehlhoff studied the cathode fall of potential of the gas in a vacuum tube. K. Bädeker found that for the press. ranging from 741 to 747 mm., the **dielectric constants** of the system $N_2O_4 \rightleftharpoons 2NO_2$ with 31, 55, and 85 per cent. dissociation are 1·00229, 1·00144, and 1·00128 respectively at 42·5°, 63·1°, and 92·1°. T. Soné gave $4{\cdot}5 \times 10^{-6}$ for the sp. **magnetic susceptibility** of nitrogen peroxide, NO_2, and $-0{\cdot}28 \times 10^{-6}$ for liquid N_2O_4.

The chemical properties of nitrogen peroxide.—The gas has a sweetish yet sharp odour ; and it tastes and reacts acidic. It colours the skin yellow. The vapour is very injurious, it produces inflammation of the respiratory organs, and death. The physiological action was discussed by C. Duisburg.[4] J. Priestley, J. Raon de Luna, and O. Rebuffat used it as a disinfectant ; and B. Moore and J. T. Wilson, for bleaching flour ; and for explosions, *vide infra*, the action of carbon disulphide. W. Ramsay, and G. Bruni and P. Berti found that liquid nitrogen peroxide acts as **an associating solvent.** P. F. Frankland and R. C. Farmer studied the electrical conductivity of soln. of various compounds in liquid nitrogen peroxide. They found that it is not an ionizing solvent, and b.p. determinations showed that many substances are associated to double molecules in this solvent. C. D. Niven discussed the electronic structure.

M. Berthelot [5] said that nitrogen peroxide is stable as such towards 500°, but this does not agree with the observation of A. Richardson, C. W. Hasenbach, and W. Ramsay and J. T. Cundall—*vide supra.* R. G. W. Norrish found that there is a slow increase in the press. of nitrogen peroxide illuminated by means of a mercury vapour lamp. The press. becomes normal in the dark ; the change is rapid at first, and afterwards slow. The suppression of the effect by the addition of excess of nitric oxide or oxygen, coupled with the fact that nitric oxide is the more effective agent, points to the establishment of a photochemical equilibrium, $2NO_2 \rightleftharpoons 2NO + O_2$.

Since no atomic oxygen could be detected in the reaction mixture, the reaction appears to be bimolecular, probably by collision between photoactive and an inactive molecules of nitrogen peroxide. A heating effect, due to the recombination of nitric oxide and oxygen and to the absorbed radiation, is also involved. M. Berthelot also found that the electric sparking of the gas results in its decomposition into nitrogen and oxygen. J. Zenneck and B. Strasser found that when a current of the gas is drawn through a long narrow discharge tube while an electrical current from an induction coil is passing, the colour of the glow of nitrogen peroxide varies in different parts of the tube; the succession of colours is orange-yellow, bluish-violet, greenish-yellow, and bright red. J. Zenneck and B. Strasser found that the orange-yellow, greenish-yellow, and bright red glows of the first, third, and fourth stages exhibit spectra which have been recognized as due to nitrogen peroxide, nitric oxide, and nitrogen respectively. In the fourth stage, some oxygen lines are also present. The violet-blue glow of the second stage is probably due to an intermediate labile oxide, its spectrum differing from that of the peroxide by a difference in the relative portion, and from that of nitric oxide by a difference in the relative intensities of the lines. M. Faraday also observed that during the electrolysis of nitrogen peroxide, it is slowly decomposed.

F. Kuhlmann found that when the gas is mixed with an excess of **hydrogen,** and passed over red-hot platinum sponge, it furnishes water and ammonia (*q.v.*). C. W. Hasenbach said that nitrogen peroxide does not unite with **oxygen** either at a high or at a low temp. D. Helbig, and F. Förster and M. Koch said that it is oxidized to nitrogen pentoxide (*q.v.*) by **ozone.** C. F. Schönbein found that with **hydrogen dioxide,** nitric acid is formed. Nitrogen peroxide is decomposed by **water.** R. Weber showed that the gas is completely absorbed by water without the evolution of any nitric oxide; and the soln. contains both nitrous and nitric acids. Nitrogen peroxide has thus the character of a mixed oxide. The reaction with liquid nitrogen peroxide was studied by J. L. Gay Lussac, P. L. Dulong, E. Péligot, and C. F. Schönbein. According to P. L. Dulong, when a small proportion of water is added to the liquid, the blue liquid becomes dark green, but no gas in disengaged; the green colour is due to the formation of nitric oxide which dissolves in the nitrous and nitric acids simultaneously. J. L. Gay Lussac found that as water is gradually added to the blue liquid, the colour changes to green and then to orange-yellow; nitric oxide is copiously evolved during the early additions of water, but none, later on. The first action of water is assumed to result in the formation of nitrous and nitric acids: $2NO_2+H_2O=HNO_2+HNO_3$; the nitrous acid then decomposes: $3HNO_2=H_2O+2NO+HNO_3$. The resultant of these two reactions is then represented: $3NO_2+H_2O=2HNO_3+NO$. A. Sanfourche said that nitrogen peroxide originally forms with water or dil. nitric acid equimolecular quantities of nitrous and nitric acids; the subsequent decomposition of the nitrous acid thus formed is complete only when the concentration of the nitric acid does not exceed 20 per cent.; beyond this, the oxidizing action of the nitric acid on the nitric oxide formed in the decomposition was observed, whilst with 70 per cent. nitric acid simple soln. of the peroxide takes place. C. L. Burdick and E. S. Freed measured the partial equilibrium constant $K=[NO][HNO_3]^2/[NO_2]^3[H_2O]$, for the reaction $3NO_2+H_2O=2HNO_3+NO$, when the concentrations are expressed as partial press. They found, for log K, at 25°, 50°, and 75°, for nitric acid containing p per cent. HNO_3:

HNO_3		24·1	33·8	40·2	45·1	49·4 per cent.
log K	25°	−2·40	−2·39	−2·21	−2·30	−2·38
	50°	−2·55	−2·47	−2·28	−2·34	−2·26
	75°	−2·49	−2·47	−2·35	−2·32	−2·34

The percentage conversion of nitrogen peroxide into nitric acid for different concentrations of nitric acid—per cent. HNO_3 by wt.—with gas containing different proportions of nitrogen peroxide is given in Table XXX. Nitric acid above 50 per cent. HNO_3 is a very poor medium for absorbing and converting the oxides produced when ammonia or nitrogen is oxidized by the usual nitrogen fixation processes. The decomposition of the nitrous acid is favoured by heat; and the evolution of nitric oxide, by the addition of substances which promote the formation of gas bubbles—thus, C. F. Schönbein found that after the evolution of nitric oxide from a mixture of liquid nitrogen peroxide with 5 times its vol. of water has ceased, the evolution of nitric oxide is very violent; if heat be applied, the introduction of pumice-stone, charcoal, or platinum wire is attended by a further evolution of gas. The metals silver, copper, brass, and iron act more rapidly than platinum although these metals are very slightly attacked during the operation. According to J. Fritzsche, if one part of water be added in a fine stream to ten parts of liquid nitrogen peroxide at —20° very little nitric oxide is evolved, and two strata of liquid are formed; the upper one is dark green, the lower one lighter green. The upper liquid begins to boil at 20°, but the b.p. quickly rises to 120°, and a blue liquid collects in the receiver. The lower liquid begins to boil at 17°, but the b.p. rises to 28°, and a greenish-blue liquid collects in the receiver. If the liquid nitrogen peroxide be mixed with more water, very little nitric oxide is evolved, and the lower layer becomes a very dark bluish-green colour; it is then transparent only in very thin layers. R. Heberlein found the electrical resistance, *R* ohms, of mixtures of nitrogen peroxide and water shows a minimum value:

TABLE XXX.—PERCENTAGE CONVERSION OF NITROGEN PEROXIDE TO NITRIC ACID BY ABSORPTION IN AQUEOUS SOLN. OF NITRIC ACID AT ATMOSPHERIC PRESSURE.

E. T. Chapman supposed that nitrogen peroxide reacts with water, forming nitric acid and nitric oxide: $3N_2O_4+2H_2O=4HNO_3+2NO$; A. V. Harcourt emphasized the fact that some nitrous acid is always formed: $N_2O_4+H_2O=HNO_3+HNO_2$, and that afterwards the nitrous acid is slowly oxidized to nitric acid. The rate of oxidation depends on the temp. and conc. of the acid liquor. L. Troost and P. Hautefeuille said that the heat of oxidation of nitrogen peroxide to nitric acid is 23·5 Cals. per eq. The converse change, the reduction of nitric acid to nitrogen peroxide depends on the conc. of the acid, being 17·5 Cals. per eq. for an acid of maximum sp. gr., 17·1 Cals. for an acid of sp. gr. 1·48, 16·9 Cals. for an acid of sp. gr. 1·46; and 15·3 Cals. for an acid of sp. gr. 1·43. F. Förster and M. Koch showed that the reactions between water and nitrogen peroxide gas are reversible: $2NO_2+H_2O\rightleftharpoons HNO_3+HNO_2$, and $3HNO_2\rightleftharpoons HNO_3+2NO+H_2O$; or summated into one equation, $3NO_2+H_2O\rightleftharpoons 2HNO_3+NO$. Consequently, the partial press. of the nitrogen peroxide, and the nitric oxide correspond with a given conc. of nitric acid. These partial press. are, however, influenced by the equilibrium $NO+NO_2\rightleftharpoons N_2O_3$, and the solubility of the nitrogen trioxide in conc. nitric acid at low temp. In the presence of oxygen, also, there is the disturbance due to the reaction $2NO+O_2=2NO_2$, so that with a given quantity of nitrogen peroxide, the ultimate product is nitric acid. The conc. of the nitric acid formed by the action of a mixture of nitrogen peroxide and oxygen or air on water reaches a limit $2NO_2+H_2O\rightleftharpoons NO_3+HNO_2$, which is a function of the conc. of the nitrogen peroxide, since the lower the partial press. of the peroxide, the smaller the conc. of its soln. in water, and also of its reaction with water. The larger vol. of undissolved gases passing through the soln. causes a more rapid evaporation of water and nitric acid. When soln. containing over 68 per cent. nitric acid are evaporated, the acid volatilizes more rapidly than the water. Consequently, the maximum conc. of nitric acid which can be obtained by the action of a mixture of nitrogen peroxide and oxygen or air on water must be somewhere about this percentage. The limiting conc. of acid must be smaller the more rapid the current of gas. With air containing 1, 2, and 5 per cent. of nitrogen peroxide, the limiting conc. of the resulting nitric acid is about 46, 52, and 55 per cent. respectively. Therefore, the gases obtained by the combustion of nitrogen in the electric arc, containing about 1 or 2 per cent. of nitrogen peroxide, could give 46–52 per cent. nitric acid when absorbed by water. If ozone be present, some nitrogen peroxide is oxidized to pentoxide, and a greater conc. would be attained. E. Briner and E. L. Durand consider that the equilibrium between nitrogen trioxide and peroxide and nitrous and nitric acids involves a trio of reversible processes: $H_2O+N_2O_3=2HNO_2$; $2NO_2+H_2O\rightleftharpoons HNO_3+HNO_2$; and $3HNO_2=HNO_3+2NO+H_2O$. Nitric oxide also reduces nitric acid, and this the more the greater the partial press. of the nitric oxide, and the greater the conc. of the nitric acid. The heats of the reactions are endothermic so that a rise of temp. increases the ratio $HNO_3:HNO_2$. Consequently, a high press. and low temp. favour the formation of nitrous acid, and conversely for nitrous acid. The equilibrium conditions for the reaction $3HNO_2\rightleftharpoons HNO_3+2NO+H_2O$, have been studied by A. V. Schaposhnikoff, and G. N. Lewis and A. Edgar—*vide supra.* O. R. Wulf and co-workers found that the oxidation of nitrogen peroxide by **ozone** at 25° is instantaneous, and the reaction is: $N_2O_4+O_3=N_2O_5+O_2$. A. Pinkus and M. de Schulthess found that the reaction between ozone and nitrogen peroxide takes place with the evolution of light, and very often partakes of the character of an explosion, even when the quantity of ozone present is very small. A very strong bi-polar ionization accompanies the reaction, which appears to be due entirely to the reaction itself, but this is not quite certain, because the product of the reaction, nitrogen pentoxide, is solid, and because of the violence with which the reactions take place.

J. L. Gay Lussac, P. L. Dulong, and F. Raschig showed that aq. soln. of the **alkali hydroxides** react with nitrogen peroxide very much like water. With conc. alkali-lye, a mixture of alkali nitrite and nitrate is formed accompanied by a slight evolution of nitric oxide. The primary reaction is: $2NO_2+2KOH=KNO_3+KNO_2+H_2O$. G. Lunge, and E. Berl found that equimolar proportions of nitrite and nitrate are obtained with dil. soda-lye only when the nitrogen peroxide is in the liquid state, or is diluted with an inert gas. If mixed with air or oxygen, the nitrite is partially oxidized to nitrate. According to M. le Blanc, a mixture of nitric oxide and nitrogen peroxide in equimolar proportions behaves like nitrogen trioxide, which forms with alkali-lye almost pure nitrite: $N_2O_3+2KOH=2KNO_2+H_2O$, while a little nitrate and nitric oxide are formed at the same time. Again, if nitric oxide mixed with air or oxygen be undergoing oxidation, alkali nitrite may predominate, and the shorter the interval of time between the mixing of the gases and the absorption of alkali-lye, the greater the proportion of alkali nitrite formed. The following reactions are supposed to be concerned in the absorption of alkali-lye of a mixture of air and nitric oxide when the latter gas is undergoing oxidation to nitrogen peroxide: (i) $2NO+O_2\rightleftharpoons 2NO_2$; (ii) $NO+NO_2=N_2O_3$; (iii) $2NO_2+2KOH=KNO_3+KNO_2+H_2O$; and (iv) $N_2O_3+2KOH=2KNO_2+H_2O$. The second and last of these reactions take place rapidly. The conc. of nitrogen trioxide is always very small, but, directly the equilibrium is distributed by the absorption of nitrogen trioxide, more trioxide is formed, and this continues until one of the components is exhausted. The third reaction is comparatively slow. F. Förster and A. Blich confirmed these assumptions, and showed that nitrogen trioxide is absorbed by alkali-lye more rapidly than nitrogen peroxide; and consequently, alkali-lye absorbs a mixture of nitric oxide and nitrogen peroxide more rapidly than the latter alone. A. Sanfourche observed that the action of oxides of nitrogen on soln. of alkali hydroxide in which the calculated proportions of nitrate and nitrite are formed only occurs if the alkali is in excess at all points in the soln. Otherwise, a reaction with the water takes place with formation of nitric acid and nitric oxide, the latter being further oxidized if oxygen is present. Moreover, if all the oxides of nitrogen are not absorbed in their first passage through the soln., this reaction with water continues in the gaseous phase with water vap. This is shown by the formation of a nitric acid mist and by its subsequent deposition as acid dew on the upper portion of the walls of the vessel in spite of the presence of excess of alkaline soln. R. Weber showed that salts with **water of crystallization**—*e.g.* alum—slowly decolorize nitrogen peroxide. G. Oddo found that with soln. of water in nitrobenzene, the water forms simple mols. at low conc., and more complex mols. at higher conc.; but with soln. of nitrogen peroxide in nitrobenzene, water gives values for the mol. wt. which at small conc. approaches and subsequently exceeds three times the theoretical number. It is therefore inferred that the gas tends to form **hydrated nitrogen peroxide,** $N_2O_4.H_2O$, which he called **nitrosic acid,** $H_2N_2O_5$. He represented this acid by the formula $O:N(OH):O_2.N(OH)$, and considered its constitution to be related to that of nitrogen peroxide:

$\begin{smallmatrix}O\\HO\end{smallmatrix}\!>N<\begin{smallmatrix}O\\O\end{smallmatrix}\!>N{-}OH$

Nitrosic acid, $H_2N_2O_5$.

$O{=}N<\begin{smallmatrix}O\\O\end{smallmatrix}\!>N{=}O$

Nitrogen peroxide, N_2O_4.

Nitrosic acid can be regarded as a combination of a mol each of nitric and nitrous acids: $HNO_2+HNO_3=H_2N_2O_5$. This is supported by V. H. Veley's observation that lead is attacked to a greater degree by mixtures of nitric and nitrous acids than by either alone, and the reaction with the mixture of acid is the more intense the more nearly equal is the proportion of nitric and nitrous acids. G. Oddo said that the basic function of the :N.OH-group tends to convert nitrosic acid by way of the ammonium salt into the anhydride; nitrogen peroxide can thus be regarded as nitrosic anhydride. Although this acid has not been isolated, its existence is confirmed by the behaviour of water in benzene or acetic acid soln. of nitrogen peroxide, and by that of alcohol in benzene soln. of the peroxide. The organic nitrosates furnished by the action of nitrogen peroxide on ethylenic compounds can be regarded as derivatives of nitrosic acid.

H. Moissan and P. Lebeau found that nitrogen peroxide does not react with **fluorine** at ordinary temp. P. F. Frankland and R. C. Farmer found that chlorine is slightly soluble in the liquid peroxide. C. W. Hasenbach showed that **chlorine** has scarcely any action on well-cooled nitrogen peroxide, but if a mixture of the two gases be passed through a heated tube, presumably *chloronitric acid* is formed; **bromine** vapour and nitrogen peroxide gas when passed through a heated tube form a dark brown liquid boiling at 19°–20°, and containing 32·2–34·7 per cent. of bromine; it is thought to contain a *bromonitric acid* which is decomposed by distillation. P. F. Frankland and R. C. Farmer found bromine is miscible in all proportions with liquid nitrogen peroxide, forming a brown soln.; and **iodine** readily dissolves, forming a purple-brown soln. Iodine does not react with nitrogen peroxide under the same conditions as chlorine or bromine. P. L. Dulong said that iodine may be distilled in the gas without chemical action. A. Geuther and A. Michaelis observed that **hydrogen chloride** reacts with nitrogen peroxide, forming nitrosyl and nitroxyl chlorides. J. L. Gay Lussac said that **hydrochloric acid** furnishes nitric oxide and aqua regia. P. F. Frankland and R. C. Farmer found dry hydrogen bromide and the dry liquid peroxide are entirely without action. A. J. Balard observed that an aq. soln. of **hydrochlorous acid** gives nitric acid and chlorine. According to A. Gautier, an aq. soln. of **iodic acid** forms nitric acid and free iodine. P. F. Frankland and R. C. Farmer found that iodic acid is neither attacked nor dissolved by liquid nitrogen peroxide.

P. L. Dulong said that strongly heated **sulphur** burns in the vapour of nitrogen peroxide, but others found that the flame of burning sulphur is extinguished by the gas. P. F. Frankland and R. C. Farmer observed that sulphur is slightly soluble in the liquid peroxide without chemical action. C. Leconte found that with **hydrogen sulphide,** sulphur, water, and nitric oxide are formed; nitrogen peroxide precipitates sulphur from an aq. soln. of hydrogen sulphide and ammonia is formed. R. Weber found that if a mixture of **sulphur dioxide** and nitrogen peroxide be passed through a red-hot tube, yellow crystals of nitropyrosulphuric anhydrides are formed provided the tube is hot enough, otherwise the gases suffer no change; but at ordinary temp., C. W. Hasenbach found that they unite to form sulphuryl dinitroxyl, $SO_2.N_2O_4$, which R. Weber found is decomposed by water to form nitrosulphuric acid. W. Manchot said that at 200° to 300°, sulphur dioxide and nitrogen peroxide unite to form nitrosylsulphur trioxide, $2SO_3.NO$; and if the gases are moist nitrosylsulphuric acid is formed. F. Raschig said that in the presence of water, nitrogen peroxide does not act directly on sulphur dioxide, but rather dissolves in the water to form nitric and nitrous acids, and only the latter acts on the sulphur dioxide. L. H. Friedburg observed that nitroxylsulphonic acid is formed by the action of sulphur dioxide on a soln. of nitrogen peroxide in carbon disulphide. G. Oddo and A. Casalino found that **sulphur trioxide** reacts with nitrogen peroxide, forming **nitrosyl pyrosulphate,** $O(SO_2.O.NO)_2$. R. Weber, C. A. Winkler, C. W. Hasenbach, and L. H. Friedburg observed that **sulphuric acid** absorbs nitrogen peroxide, forming a series of substitution products (*q.v.*); G. Lunge showed that nitroxyl sulphonic and nitric acids are formed: $H_2SO_4+N_2O_4 \rightleftharpoons HNO_3+SO_2(OH)(NO_2)$; and G. Lunge and E. Weintraub further showed that the reaction is reversible. P. F. Frankland and R. C. Farmer found the liquid peroxide has at first no visible action on sulphuric acid, but in time solid nitroxylsulphonic acid is formed.

M. Berthelot observed no reaction between **nitrogen** and nitrogen peroxide. Nitrogen peroxide reacts vigorously with aq. **ammonia**; and A. Besson and G. Rosset found that liquid ammonia reacts explosively with solid nitrogen peroxide at —80°, but if a current of gaseous ammonia at —20° is passed over the peroxide, the reaction is moderated and the products are nitrogen, nitric oxide, water, ammonium nitrate, and a trace of ammonium nitrite. Nitrogen peroxide reacts slowly with ammonium chloride in the cold; the reaction is, however, complete in sealed tubes at 100° with the formation of chlorine, nitrogen, nitrous oxide, nitrogen trioxide, nitrosyl chloride, water, and nitric acid. When ammonium nitrate or sulphate replaces the chloride in the above reaction, the products are nitrogen and nitric acid or nitrogen, and a mixture of nitric and sulphuric acids respectively. For the action of nitrogen peroxide on **nitric oxide,** see Fig. 71. According to R. Weber, and G. Lunge, nitrogen peroxide is readily dissolved by dil. and conc. **nitric acid.** G. Lunge and L. Marchlewsky found that the sp. gr. of nitric acid shows a marked increase with the addition of nitrogen peroxide; and P. Pascal and M. Garnier found that the maximum occurs with a mixture containing about 42·5 per cent. by weight of the peroxide, corresponding with the compound **dinitroxydinitric acid,** $N_2O_5.N_2O_4.H_2O$, or $2HNO_3.N_2O_4$, which is stable at —48·5°, but dissociates above that temp. According to E. K. Rideal, the absorption of nitrogen peroxide by conc. nitric acid in the presence of air proceeds most rapidly at low temp., but with water, the reverse occurs. The point of inversion, that is, where absorption is independent of temp., is reached with approximately 10 per cent. nitric acid. The limitation of the nitric acid conc. to 64 per cent. in absorption towers is caused by reduction of nitric acid by the nitrogen trioxide produced. By agitation with oxygen, the N_2O_3 is converted into NO_2, and a higher conc. of nitric acid is obtained, and by cooling a 12 per cent. NO_2-air mixture to 20° to remove excess of water above that required for the equation $2N_2O_4+2H_2O+O_2=3HNO_3$, and then refrigerating to —10°, nitric acid of 61·2 to 78·1 per cent. HNO_3 was produced. W. R. Bousfield measured the sp. gr., sp. vols., v, and contractions, of mixtures of the two constituents at 4°, 14°, and 18°; and found, at 14°:

NO . .	0	8·021	26·09	37·60	43·71	48·66	51·37	96·93	100
Sp. vol. . .	0·650	0·637	0·612	0·603	0·601	0·601	0·602	0·673	0·674
Contr. . .	—	0·0032	0·0724	0·0934	0·0997	0·1011	0·1005	0·0008	—

There is a gap in the curve with between 54 and 92 per cent. nitrogen peroxide corresponding with the separation of the liquid into two layers which are mutually saturated. He found for the mutual solubilities of nitric acid in liquid nitrogen peroxide:

	Sat. soln. HNO_3 in liquid N_2O_4			Sat. soln. liquid N_2O_4 in HNO_3		
	Sp. gr.	Sp. vol.	Per cent. HNO_3	Sp. gr.	Sp. vol.	Per cent. HNO_3
4° . .	1·48742	0·67231	4·90	1·65432	0·60448	54·4
11° . .	1·47351	0·67865	6·67	1·63942	0·60997	54·3
18° . .	1·45940	0·68521	8·05	1·62501	0·61538	54·0

W. R. Bousfield also measured the temp. coeff. and found evidence of the formation of two compounds: **tetranitroxyltrinitric acid,** $3HNO_3.2N_2O_4$; and dinitroxyltetranitric acid, $4HNO_3.N_2O_4$. P. L. Dulong found that **phosphorus** continues burning in nitrogen peroxide provided it is heated more strongly than is the case with oxygen. T. Graham observed that the gas has very little action on **phosphine**; T. E. Thorpe and A. E. H. Tutton, that no combination occurs with **phosphorous oxide**; E. Tassel, that at —10° it forms white crystals of **phosphorus dinitroxylpentafluoride,** $PF_5.N_2O_4$, when treated with **phosphorus pentafluoride**; A. Geuther and A. Michaelis, that it reacts with **phosphorus trichloride** in a similar way to nitrogen trioxide, forming pyrophosphoryl, phosphoryl, and nitrosyl chlorides, phosphorus pentoxide, nitrogen, and a little nitric oxide; R. Müller, and A. Geuther that with **phosphorus pentachloride,** it forms chlorine, nitrosyl, and phosphoryl chlorides; V. Thomas, that by strongly heating nitrogen peroxide with **phosphorus triiodide,** iodine and phosphoric acid are produced. P. F. Frankland and R. C. Farmer found that **phosphoric acid** slowly absorbs some liquid nitrogen peroxide, forming a *nitroxyl phosphoric acid* insoluble in the liquid. A. Besson observed that with **antimony pentachloride, antimony dinitroxyl-pentadecachloride,** $3SbCl_5.N_2O_4$, is formed; and V. Thomas observed that with antimony trichloride, a complex is formed, and if nitrogen peroxide vapour is absorbed **antimony trichloride,** and a white complex, $Sb_4O_{11}N_2Cl_4$, is formed; complexes were also obtained with **antimony bromide,** and **antimony iodide.** A. Besson, and V. Thomas also obtained a complex with **bismuth trichloride**; and V. Thomas, one with bismuth iodide.

P. L. Dulong found that ignited **charcoal** burns in nitrogen peroxide gas with a dull red flame. C. W. Hasenbach found that at ordinary temp. **carbon monoxide** is oxidized by nitrogen peroxide, forming carbon dioxide and a volatile liquid decomposed by water. R. Müller found that at ordinary temp. **calcium carbonate** is not decomposed by nitrogen peroxide. L. H. Friedburg said that **carbon disulphide** absorbs the gas copiously. E. Turpin, and B. Setlick prepared explosives from mixtures of carbon disulphide and nitrogen peroxide. E. Turpin called his mixture *panklastite;* it could be heated to 200° without explosion, but detonated with mercury fulminate. A mixture of the vapours of carbon disulphide burns with a brilliant flame once called in commerce *selenophanite,* and when phosphorus was present, *heliophanite.*

P. F. Frankland and R. C. Farmer reported that anhydrous liquid nitrogen peroxide is inert towards numerous organic compounds, and only in exceptional cases is the reaction violent. The presence of a small quantity of water increases the chemical activity of the peroxide. As a solvent, liquid nitrogen peroxide dissolves numerous organic compounds, and in some cases the crystals of the original solute can be recovered by evaporation. The unsaturated hydrocarbons readily unite with nitrogen dioxide—thus amylene forms $NO_2.O.C_5H_9 : N.OH$—a reaction studied by E. Berl. P. F. Frankland and R. C. Farmer found that both benzene and toluene dissolve without change; naphthalene dissolves and forms dinitronaphthalene; and anthracene is oxidized to anthraquinone. The nitro-derivatives are usually very stable, thus, nitrobenzene *m-dinitrobenzene, p-nitrotoluene,* and 1 : 5-*dinitronaphthalene* are easily soluble and can be recovered from the soln. unchanged. The halogen derivatives are usually stable—thus *ethylene dibromide, acetylene tetrabromide, benzyl chloride, chlorobenzene,* and *chloroform* dissolve unchanged. J. R. Park and J. R. Partington observed no reaction with *carbon tetrachloride,* but a slight reaction with chloroform. No *carboxylic acid* was found to react while being dissolved in the menstruum. *Formic, acetic, monochloroacetic, trichloroacetic, tribromoacetic, trichlorobutyric, tartaric, and benzoic acids* readily dissolved without change, although the slightly impure peroxide reacts with tartaric and benzoic acids. The three *nitrobenzoic acids,* the three *bromobenzoic acids,* and the three *bromotoluic acids,* as well as *succinic and phthalic acids,* dissolve only with difficulty. The hydroxy-compounds are less stable towards nitrogen peroxide; thus, *ethyl alcohol* readily forms ethyl nitrite; *cane sugar* dissolves readily in the menstruum, and is attacked only if moisture be present; *phenol* reacts vigorously with the peroxide; 2 : 4-*dinitrophenol,* and *trinitrophenol* or *picric acid* dissolve readily without change; *salicylic acid* first dissolves and is then quickly attacked; while 5-*nitrosalicylic acid* dissolves slowly and is not attacked. The *ammines* are quickly attacked by liquid nitrogen peroxide, thus the three *nitroanilines,* and *β-naphthylamine* form the corresponding diazo-compounds; *pyridine* and *quinoline* are violently attacked; while neither quinine nor anthraquinone are attacked, though the former is quickly and the latter slowly dissolved. Some phases of the subject were discussed by H. Wieland, F. Guthrie, P. Pascal, etc. J. Meisenheimer, and E. de Barry Barnett studied the action of nitrogen peroxide on *anthracene* derivatives. P. Pascal found eutectics with nitrogen peroxide and 23·5 per cent. of *bromoform* at —13·5°; 91·5 per cent. of chloroform at —68°; 90 per cent. of *methyl iodide* at 69·5°; 91·85 per cent. of *carbon tetrachloride* at —49°; 86 per cent. of *phenyl bromide* at —42·5°; 92 per cent. of *chloropicrin* at —79·5°; 29·4 per cent. of *picric acid* at —13·5°; and 29 per cent. of *trinitrotoluene* at —17°. *Camphor* forms three eutectics corresponding with the formation of two compounds. According to A. Schaarschmidt, saturated aliphatic hydrocarbons are but slowly attacked by nitrogen peroxide, fatty acids being first formed and then further oxidized to oxalic acid and carbon dioxide, whilst the peroxide is reduced to nitric and nitrous oxides and ultimately to nitrogen. With olefinic hydrocarbons, however, there is immediate formation of extremely unstable isomeric nitrosates and pseudonitrosites, accompanied, in some cases, by polymerization products. Nitrogen peroxide, in the cold, converts benzene very slowly into picric acid, and toluene more readily into trinitrotoluene, as well as forming nitronitrite compounds, which are decomposed by alkalies (*e.g.* to dinitrocresol). In the presence of metallic salts (*e.g.* aluminium or ferric chlorides) benzene forms with nitrogen peroxide complex additive compounds which are decomposed by water. A. Schaarschmidt found that saturated aliphatic hydrocarbons are but slowly attacked by nitrogen peroxide, fatty acids being first formed and then further oxidized to oxalic acid and carbon dioxide, whilst the peroxide is reduced to nitric and nitrous oxides and ultimately to nitrogen. Branched-chain paraffins are less resistant than straight-chain paraffins. When the reaction occurred in a closed glass tube, there was no evolution of heat, but, even after the appearance of nitrogen trioxide in the tube, the mixture cooled as soon as the source of the external heat was removed. With olefinic hydrocarbons (*e.g.* amylene, cyclohexene), there is immediate formation of extremely unstable isomeric nitrosates and ψ-nitrosites, accompanied, in some cases, by polymerization products. Nitrogen peroxide, in the cold, converts benzene very slowly into picric acid, and toluene more readily into trinitrotoluene. At the same time, nitro-nitrite compounds are formed, which are decomposed by alkalies (*e.g.* to dinitrocresol). A. Schaarschmidt and E. Smolla attributed the explosives, which have been known to occur in nitrogen fixation plants, to the action of nitrogen peroxide on the olefinic constituents of benzene. E. Berl did not agree with this.

The adsorption of nitrogen peroxide by the hydrogel of **silica** has been studied by P. C. Ray, J. A. Almquist and co-workers, and C. M. Faber and co-workers. N. W. Krase proposed to use silicagel for separating nitrogen peroxide from the gases obtained in the oxidation of ammonia. Liquid nitrogen peroxide can be transported in steel containers, and it is a more convenient form for transporting nitric nitrogen than is nitric acid. A. Geuther found that **boron trichloride** forms oxide and **boron nitrosyltetrachloride,** $BCl_3.NOCl$; and P. F. Frankland and R. C. Farmer showed that liquid nitrogen peroxide neither attacks nor dissolves **boric acid.**

According to P. L. Dulong, **potassium** takes fire in the vapour of nitrogen peroxide at ordinary temp., and burns with a red flame; **sodium** also decomposes the vapour without disengaging heat or light; **copper** acts on the vapour slowly at ordinary temp., and rapidly when heated, forming copper oxide and nitric oxide. P. Sabatier and J. B. Senderens observed that finely divided copper in the cold absorbs nitrogen peroxide—freed from all traces of nitric acid—forming what they called *cuivre nitré*. *Nitrocopper* was represented by the formula Cu_2NO_2, and considered to be a chemical compound. Its properties were described, but these are all characteristic of the properties of nitrogen peroxides. H. V. Tartar and W. L. Semon showed that the alleged compound is not formed by the action of nitrogen peroxide on copper, and they consider that the product is a film of anhydrous cuprous nitrate on the surface of copper. J. R. Park and J. R. Partington measured the rate of absorption of nitrogen peroxide by copper, and showed that the first action probably involves the formation of cuprous oxide with the evolution of heat, $2Cu+NO_2=Cu_2O+NO$; the cuprous oxide then absorbs nitrogen peroxide up to the saturation point—33 per cent. nitrogen peroxide. On heating, the gas is given off and cuprous oxide remains; the gas is re-adsorbed on cooling. The nitrogen peroxide can be all removed by carbon tetrachloride at 65°–70°. The alleged nitrocopper is therefore an adsorption complex of nitrogen peroxide in cuprous oxide. A. Klemenc and A. Schroth confirmed this conclusion, saying that the *Nitrokupfer und wahrscheinlich auch die anderen Nitrometalle sind als chemische Verbindungen aus der Literatur zu streichen.* E. Divers and T. Shimidzu poured liquid nitrogen peroxide on reduced copper and observed a brisk effervescence with the evolution of nitric oxide, and the formation of what was thought to be cuprous nitrate mixed with cupric nitrate. R. Müller showed that at $-10°$, liquid nitrogen reacts with many **metals,** forming the metal nitrate and nitric oxide; the latter uniting with the excess of nitrogen peroxide forms the trioxide. P. Sabatier and J. B. Senderens found that finely divided **silver** reacts with nitrogen peroxide, forming nitric oxide and silver nitrate; copper under similar conditions gives cuprous nitrate. They found that **magnesium** filings burn vigorously when heated to dull redness in an atm. of nitrogen peroxide; and **zinc** at about 300° forms zinc oxide. P. L. Dulong observed that **mercury** is slowly attacked by the vapour of nitrogen peroxide, while E. Divers and T. Shimidzu found that the liquid reacts with mercury, forming a mixture of mercurous and mercuric nitrates. The reaction was studied by W. A. Noyes. P. Sabatier and J. B. Senderens said that **aluminium** filings are not perceptibly attacked by the gas at 500°. P. L. Dulong observed that **tin** is slowly attacked by nitrogen peroxide at ordinary temp.; and P. Sabatier and J. B. Senderens, that at about 200°, **lead** forms a basic nitrate. According to A. Guntz, pyrophoric **manganese** inflames in the gas; but the non-pyrophoric metal reacts at a suitable temp. thereby forming a mixture of manganese oxides, while a trace of nitrite is simultaneously produced. P. L. Dulong observed that **iron** is slowly attacked by nitrogen peroxide at a red-heat, forming ferric oxide, and nitric oxide; P. Sabatier and J. B. Senderens said that the reaction with reduced iron begins at about 350°; reduced **cobalt** at a suitable temp. burns in the gas, forming cobaltosic oxide; and reduced **nickel,** at 250°, forms nickel monoxide. It was also found that the finely divided metals in the cold absorb nitrogen peroxide, forming *nitro-iron*, Fe_2NO_2; *nitrocobalt*, Co_2NO_2; and *nitronickel*, Ni_4NO_2. The observations made above on the nitrocopper are almost certain to be valid also for these substances.

P. L. Dulong reported that when the vapour of nitrogen peroxide is passed over **barium oxide** at ordinary temp., the gas is absorbed; at 200°, the baryta suddenly becomes red-hot and fuses, forming a mixture of nitrite and nitrate. J. R. Partington and F. A. Williams found that nitrogen peroxide reacts with **calcium oxide** at all temp. up to 400°, giving primarily calcium nitrite and nitrate. Secondary reactions, however, occur at higher temperatures; above 230°, calcium nitrite decomposes, $Ca(NO_2)_2=CaO+NO+NO_2$, and in the presence of nitrogen peroxide undergoes oxidation at lower temp. in the following ways: (1) $Ca(NO_2)_2+2NO_2=Ca(NO_3)_2+2NO$, (ii) $Ca(NO_2)_2+NO_2\rightarrow Ca(NO_3)_2+0{\cdot}5N_2$. At 450°, the mol. proportions of the decomposition are represented by $12{\cdot}02$ mols. $Ca(NO_2)_2\rightarrow 7{\cdot}68CaO+4{\cdot}34Ca(NO_3)_2+14{\cdot}40NO+N$, nitrogen and nitric oxide alone being evolved. Above 480°, nitrogen peroxide is, in addition, given off, and at 495° calcium nitrate begins to decompose. I. Guareschi found that **soda-lime** or **potash-lime** readily absorbs nitrogen peroxide at ordinary temp. R. Müller said that in general the liquid peroxide reacts with the **metal oxides,** forming the metal nitrate and nitrogen trioxide. A. Klemenc and A. Schroth found that the adsorption of nitrogen peroxide by a mixture of copper and **cuprous oxide** is less at higher than at lower press. They found the absorption equilibrium, with cuprous oxide:

	0°	11·5°	20°	26°	30°	40°
$p_{NO_2-N_2O_4}$.	0·338	0·620	0·900	1·15	1·35	2·27 atm.
NO_2 per cent. .	1·41	3·24	4·08	—	5·27	5·11

If *a* c.c. of nitrogen peroxide are absorbed per gram at 0° and 760 mm., when the press is *p* atm., at 40°:

p . . .	0·338	0·620	0·900	1·15	1·35	2·27 atm.
a . . .	6·8	15·6	19·6	23·8	25·9	24·5

The results plotted on a smoothed curve in Fig. 88, show that the adsorption isotherm passes through a maximum at about 1·6 atm. press. P. Sabatier and J. B. Senderens found that black cuprous oxide reacts at 300°, forming cupric oxide; **stannous oxide** forms stannic oxide; **lead oxide,** a basic nitrate; **titanium sesquioxide,** white titanic oxide; **vanadium trioxide,** the brown pentoxide; **tungsten dioxide,** yellow tungstic oxide; **manganous oxide,** manganese sesquioxide; and **uranium dioxide,** a basic nitrate. D. Tommasi found that with a boiling soln. of **potassium dichromate,** a complex *potassium chromochromate,* $[(CrO_2)_3(CrO_3)_2K_2O]H_2O$, is formed. The *potassium nitrodichromate* or *potassium nitroxyldichromate,* $KO.Cr_2O_5.NO_2$, of L. Darmstädter could not be prepared by G. C. Schmidt, and G. N. Wyrouboff.

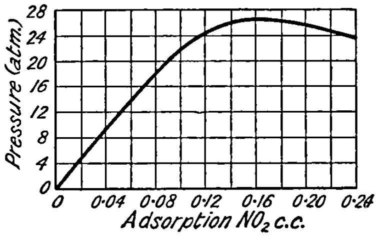

FIG. 88.—Adsorption Isotherm for Cuprous Oxide and Nitrogen Peroxide at 40°.

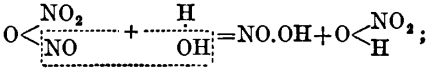
P. F. Frankland and R. C. Farmer observed no case in which an inorganic salt was dissolved by liquid nitrogen peroxide, provided the liquid is purified. If moisture be present, many chlorides are attacked rather quickly. The **alkali chlorides and fluorides** are not attacked by the dried liquid, but if moisture be present, **potassium chloride** is attacked and chlorine is set free to be dissolved by the liquid; **potassium bromide and iodide** are attacked by the dry or moist liquid, setting free the halogen. The liquid peroxide does not dissolve or attack **potassium nitrate, sulphate,** or **chlorate,** and the same remark applies to **sodium nitrite,** and **hydrazine sulphate.** V. Thomas prepared addition compounds of nitrogen peroxide with **copper chloride,** and **copper bromide**; E. Luck, one with **magnesium phosphate** and nitrogen peroxide; V. Thomas, with **zinc chloride, zinc bromide, zinc iodide, cadmium chloride, cadmium bromide,** and **cadmium iodide.** V. Thomas described a complex $SnOCl_2.3SnCl_4.N_2O_5$, or $Sn(NO_3)_2Cl_2.3SnCl_4$, *stannic nitratochloride* as a product of the action of nitrogen peroxide on a dil. chloroform soln. of stannic chloride. P. F. Frankland and R. C. Farmer found that **mercuric nitrate,** and **cyanide** are neither dissolved nor attacked by liquid nitrogen peroxide. A. Besson obtained a complex with **aluminium chloride.** If nitrogen peroxide acts for a short time on **titanic chloride,** unstable *titanic nitroxyl chloride,* $2TiCl_4.3N_2O_4$, is formed; with a more prolonged action titanic nitrate, $Ti(NO_3)_4$, is produced. V. Thomas obtained complexes with **stannic chloride,** and **stannic bromide.** H. Reihlen and A. Hake found that when a soln. of nitrogen peroxide in carbon disulphide acts on an excess of stannic chloride, at 0°, brown *stannic nitroxyl chloride,* $3SnCl_4.2NO_2$, is formed; it decomposes on warming. If an excess of nitrogen peroxide is used, at $-60°$, yellow $2SnCl_4.3N_2O_4$ is formed; and if nitrogen trioxide acts on stannic chloride, $3SnCl_4.4NO_2$ is formed. V. Thomas prepared complexes with **lead chloride, lead bromide,** and **lead iodide**; E. Späth, with **uranyl nitrate,** namely, **uranyl dinitrosylnitrate,** $UrO_2(NO_3)_3(NO_2)_2$. P. F. Frankland and R. C. Farmer found that **iron acetonylacetone,** $Fe(C_6H_9O_2)_3$, and **iron benzylacetone,** $Fe(C_{10}H_9O_2)_3$, were quickly attacked by the liquid peroxide, but no iron passed into soln.; **ferric chloride** was not attacked by the dry liquid, but if moisture be present, the salt is attacked and iron passes into soln. F. Besson, and V. Thomas obtained complex salts with ferric chloride; and V. Thomas, with **ferric bromide.** M. Berthelot passed **nickel carbonyl** into liquid nitrogen peroxide, or mixed the vapours of the two compounds and obtained a blue vapour.

The constitution of nitrogen peroxide.—The analyses of J. L. Gay Lussac,[6] P. L. Dulong, and E. Péligot agree with the empirical formula NO_2, and, as indicated above, the density of the gas shows that there are two forms of the oxide N_2O_4 predominating at low temp., and NO_2 at higher temp. The constitution is doubtful. J. Priestley, C. L. Berthollet, H. Davy, and T. Thomson considered that nitrogen peroxide is a combination of nitric acid with nitric oxide, and not a direct combination of oxygen with nitrogen because (i) nitric oxide converts nitric acid into nitrogen peroxide; and (ii) nitrogen peroxide is decomposed by water into nitric acid and nitric oxide—they did not take into account the intermediate formation of nitrous acid. There are several possibilities for the structure of the low temp. form, thus, it may be regarded as *nitrosyl nitrite*, $O:N.O.NO_2$; *dinitroxyl*, $O_2N.NO_2$; or as *nitrosyl dioxide*, $ON.O.O.NO$. The evidence is very indecisive. A. Exner argued in favour of $O:N.O.NO_2$ because of the reaction $NO_2Cl+AgNO_2=AgCl+N_2O_4$; and also because of its decomposition by water into nitrous and nitric acids, $NO.O.NO_2+H.OH=NO.OH+NO_2.OH$, or by alkali-lye into alkali nitrite and nitrate



$$O<^{NO_2}_{NO} + {}^{H}_{OH} = NO.OH + O<^{NO_2}_{H};$$

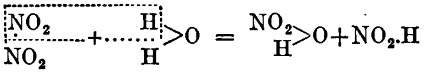
L. Henry, because of the production of alkyl nitrates and iodine when nitrogen peroxide acts on the alkyl iodides; A. C. Girard and J. A. Pabst, because of its formation from potassium nitrate and nitroxylsulphuric acid: $NO_2HSO_3+KNO_3=N_2O_4+KHSO_4$; O. N. Witt, because of the formation of diazobenzolnitrate and water by the action of nitrogen peroxide on aniline: $NO_2.O.NO+C_6H_5.NH_2=C_6H_5:N_2O.NO$; and H. Reihlen and A. Hake, because it forms a complex with stannic chloride,

$$Cl_4Sn\left[O:N.O.N<^{O}_{O}>SnCl_4\right]_2, \quad \text{not} \quad Cl_4Sn\left[<^{O}_{O}>N-N<^{O}_{O}>SnCl_4\right]$$

which it would do if it had the symmetrical structure $O_2N.NO_2$. This hypothesis would relate the three higher oxides of nitrogen:

$$\underset{N_2O_3}{NO.O.NO} \qquad \underset{N_2O_4}{NO_2.O.NO} \qquad \underset{N_2O_5}{NO_2.O.NO_2}$$

R. Günsberg, and E. Müller favoured the second formula $O_2N.NO_2$, because of the reaction of nitrogen peroxide with water which he represented:



$${}^{NO_2}_{NO_2} + {}^{H}_{H}>O = {}^{NO_2}_{H}>O+NO_2.H$$

H. Wieland added that while the conception of nitrogen peroxide as a mixed anhydride of nitrous and nitric acids $O=N-O-NO_2$ is in harmony with its action on alkali-lye, yet a similar conception for nitrogen trioxide, $ON.O.NO$, is not in harmony with the blue colour assumed to be in accord with the tinctorial qualities of a nitroso-derivative, $ON.NO_2$. The corresponding formula $O_2N.NO_2$ is in harmony with many of its reactions; its dissociation by heat; and the action of water and alkali-lye which is analogous to that of the other symmetrically paired atoms or radicles—*e.g.* cyanogen to cyanide and cyanate; and chlorine to chloride and hypochlorite. For G. Oddo's view of the structure, *vide supra*, hydrated nitrogen peroxide. J. C. Thomlinson assumed the oxygen atoms to be quinquevalent in order to explain the thermochemical data. V. Meyer considered that the third formula, $ON.O.O.NO$, is in keeping with the union of amylene and nitrogen peroxide to form $C_5H_{10}(NO_2)_2$, which by reduction gives ammonia, showing that the carbon is not directly attached to the nitrogen, but to oxygen. This gives the formula $ON.O.C_5H_{10}.O.NO$. E. Divers, and J. J. Sudborough and J. H. Millar also regarded nitrogen peroxide as a nitrosyl peroxide. G. Kirsch, and H. Henstock discussed the electronic structure.

The dissociation product NO_2 behaves in many respects as a univalent radicle with one free valency. O. Piloty and B. G. Schwerin consider the nitrogen atom is quinquevalent, $O=N=O$, or may be tervalent, ${}^{O}_{O}>N-$. L. Spiegel favoured the former hypothesis; E. Divers, and J. J. Sudborough and J. H. Millar, tervalent $O=N-N-$. A. Schaarschmidt considers that the various ways nitrogen peroxide can react with organic compounds—*vide supra*—favour the assumption that it occurs as an equilibrium mixture of the three forms:

$$\begin{array}{l} O\text{—}N{=}O \\ \dot{O}.N{=}O \end{array} \rightleftharpoons \begin{array}{l} O{=}\underset{\cdot}{N}{=}O \\ \quad\ \dot{O}\text{—}N{=}O \end{array} \rightleftharpoons \begin{array}{l} O{=}N{=}O \\ O{=}\dot{N}{=}O \end{array}$$

§ 40. Nitrogen Pentoxide

In 1840, H. St. C. Deville[1] discovered that **nitrogen pentoxide,** N_2O_5, or **nitric anhydride** is formed when dried chlorine is passed over dried silver nitrate contained in a U-tube, heated on a water-bath. The reaction begins at 95°, and then proceeds regularly at 60°. The pentoxide can be collected as a colourless solid in a bulb-tube surrounded by a freezing mixture. The reaction is symbolized $4AgNO_3+2Cl_2=4AgCl+2N_2O_5+O_2$. M. Odet and L. Vignon added that it is advisable to eliminate all joints of rubber or cork from the apparatus, and to connect the glass parts of the apparatus by fused or ground-in points, or else by placing one tube inside the other and filling in the intermediate space with asbestos and paraffin. M. Odet and L. Vignon assumed that in the reaction between chlorine and silver nitrate, nitroxyl chloride is formed as an intermediate product, $AgNO_3+Cl_2=AgCl+NO_2Cl+O$; and they obtained the pentoxide by passing nitroxyl vapour over silver nitrate at 60° to 70°, and collecting the products of the reaction in a cooled vessel: $AgNO_3+NO_2Cl=N_2O_5+AgCl$. C. Weltzien found that if iodine is used in place of chlorine, silver iodide and iodate, and nitrogen peroxide are formed. D. Helbig made nitrogen pentoxide by the action of ozone on nitrogen peroxide; and the reaction was studied by F. Förster and M. Koch, and F. Daniels, O. R. Wulf, and S. Karrer. The results show that one mol. of ozone is required to oxidize one mol. of nitrogen tetroxide at 25°; thus only one atom of the ozone mol. is available in the oxidation at this temp. This result is in striking contrast to the oxidation of sulphur dioxide to the trioxide by ozone at temp. below 40°, in which one mol. of ozone oxidizes three mols. of sulphur dioxide, all three atoms of the ozone mol. being available for oxidation. According to F. O. Anderegg and co-workers, the fog formed when ozonized air is passed through an absorbent soln. is due chiefly to hygroscopic nitrogen pentoxide. The yields of ozone and nitrogen pentoxide in air are much more dependent on the nature and extent of the surface than on the amount of inductive capacity of the various materials placed in the discharge space. Glass wool is particularly active. An increase of voltage is accompanied by an increased formation of ozone, followed by that of nitrogen pentoxide, a high conc. of which lowers the yield of ozone. Thus the conc. of the latter reaches a first, second, and sometimes a third maximum. H. Fischer observed that some nitrogen pentoxide and ozone are formed when Tesla currents of 25,000 volts pass through mixtures of oxygen and nitrogen.

Nitrogen pentoxide is most conveniently made from anhydrous nitric acid which is obtained by the repeated distillation of a mixture of conc. sulphuric and nitric acids. The nitrous acid is removed by passing dry air through the nitric acid. The acid is cooled in a beaker, and phosphorus pentoxide added gradually with constant stirring, while the temp. is kept as low as possible. The addition of phosphorus pentoxide is continued until further additions produce but a small rise of temp. The cold, syrupy liquid is then added to a cooled retort, which is then gently heated, when an orange distillate collects in the receiver surrounded by cold water. On standing, the liquid distillate separates into two layers. The upper layer is decanted into a thin-walled tube, and cooled by iced water when crystals of the pentoxide soon separate out. The orange-coloured liquid is poured off, and the crystals are melted at as low a temp. as practicable ; the liquid is cooled and the mother-liquid again poured away from the crystals. J. Giersbach and A. Kessler said that if the nitric acid employed is free from water, it mixes with phosphorus pentoxide quietly without hissing. The yield with R. Weber's process is small. M. Berthelot obtained a 60–70 per cent. yield by working as follows :

> Rather more than its own weight of phosphoric anhydride is added in small quantities at a time to nitric acid, HNO_3, cooled in a freezing mixture so as to avoid any considerable rise in the temperature, which should not at any time be above zero. The pasty mass thus obtained is then rapidly transferred to a tubulated retort capable of containing 5 or 6 times the quantity, and distilled very slowly, collecting the product in stoppered bottles surrounded with ice. The anhydride condenses in long, transparent, colourless crystals which, when exposed to the air, slowly evaporate without deliquescing.

The process of R. Weber was also modified by L. Meyer, G. E. Gibson, and F. Daniels and A. C. Bright. According to F. Russ and J. Pokorny, the operation is facilitated by passing dry ozonized oxygen through the system during the distillation. This prevents the decomposition of the pentoxide into oxygen and the lower oxide of nitrogen. They also used solid carbon dioxide as the refrigerating agent. Some irregularities in the physical properties of ozone led V. H. Veley and J. J. Manley to the conclusion that 100 per cent. nitric acid is a mixture of nitric acid, HNO_3, nitrogen pentoxide, and water.

According to H. St. C. Deville, nitrogen pentoxide furnishes transparent, colourless, prismatic crystals of great brilliancy ; and, according to F. Daniels and A. C. Bright, they are hexagonal prisms, and grow several millimetres in length on standing for a long time at 0°. H. St. C. Deville found that when slowly deposited in a current of strongly cooled gas, the crystals attain considerable size. R. Weber said that molten nitrogen pentoxide is readily undercooled, and the liquid has a darker colour than when solid. J. B. A. Dumas found that the liquid obtained by melting the crystals in a sealed glass tube may explode when the tube is immersed in a freezing mixture. R. Weber found the sp. gr. of the crystals to be about 1·6 ; M. Berthelot, 1·63. I. I. Saslavsky discussed the mol. vol. H. St. C. Deville gave 29°–30° for the m.p. ; R. Weber, about 30° ; and M. Berthelot, 29·5°. F. Russ and J. Pokorny, and F. Daniels and A. C. Bright found that the m.p. lies above the sublimation point, and the observations on the m.p. must have been made with pentoxide contaminated with atm. moisture. The colour of the solid darkens when the temp. is raised, and the crystals become yellow just before melting, and the colour at the m.p. is orange. The colour becomes dark brown as the temp. rises, and at about 45°, the liquid boils with decomposition into nitrogen peroxide and oxygen. H. St. C. Deville said that the vap. press. at 10° is considerable; the measurements of the vap. press. p mm. by F. Russ and J. Pokorny below 10·5°, and of F. Daniels and A. C. Bright above that temp., are as follow:

	−33°	−21°	−10·7°	0°	10·5°	15°	25°	30°	32·5°
p . .	2·3	6·3	18·6	51·5	132	183	420	620	760

F. Russ and J. Pokorny found their results could be represented by $\log p = -3161{\cdot}2T^{-1}+1{\cdot}75 \log T - 0{\cdot}00606T + 10{\cdot}679$; and F. Daniels and A. C. Bright, by $\log p = 1244T^{-1}+34{\cdot}1 \log T - 85{\cdot}929$ mm. The calculated mol. heat of fusion is —8·28 Cals., and the mol. heat of sublimation, —4·84 Cals. The heats of sublimation calculated from the vap. press. are 12·36 Cals. at —10°; 12·76 Cals. at 0°; 13·36 Cals. at 10°; 14·14 Cals. at 20°; and 14·97 Cals. at 32·5°. M. Berthelot obtained 13·10 Cals. at 10°; he also gave for the heat of formation, $(N_2,5O) = -1{\cdot}2$ Cals. for the gas; $(N_2,5O)=3{\cdot}6$ Cals. for the liquid; $(N_2,5O)=11{\cdot}8$ Cals. for the solid; and $(N_2,5O)=28{\cdot}6$ Cals. for the heat of soln. J. Thomsen gave $(N_2,5O)=29{\cdot}82$ Cals.; $(N_2,5O,Aq.)=47{\cdot}56$ Cals.; $(2NO,3O,Aq.)=72{\cdot}97$ Cals.; $(N_2O_3,Aq.,O)=36{\cdot}64$ Cals.; $(2NO_2,O,Aq.)=33{\cdot}83$ Cals.; $(N_2,5O,H_2O)=14{\cdot}66$ Cals.; $(N_2O,4O,H_2O)=32{\cdot}4$ Cals.; $(2NO,3O,H_2O)=57{\cdot}81$ Cals.; and $(2NO_2,O_2,H_2O) = 18{\cdot}67$ Cals. J. C. Thomlinson calculated what he called the thermochemical eq. of oxygen in nitrogen pentoxide. F. Daniels found that the dissolution of nitrogen pentoxide in organic liquids—*e.g.* chloroform or dichloroethane—causes the absorption maxima of the bands of the ultra-red to shift from 5·65μ to 5·45–5·30μ. The results do not support the radiation hypothesis of chemical action. It is assumed that the relative position of the electron pair between the atoms of a molecule determines the ultra-red absorption spectra.

The analysis of H. St. C. Deville corresponds with the formula N_2O_5. The probable assumption that the contained nitrogen is quinquevalent agrees with the formula $O_2{\equiv}N{-}O{-}N{\equiv}O_2$. It can thus be regarded as *nitroxyl oxide*, $(NO_2)_2O$. L. Spiegel added that if the nitrogen atoms were tervalent, and the oxygen atoms bivalent, the graphic formula would be $O{=}N{-}O{-}O{-}O{-}N{=}O$; or

$$\genfrac{}{}{0pt}{}{O}{O}{>}N{-}O{-}N{<}\genfrac{}{}{0pt}{}{O}{O}$$

C. D. Niven, and H. Henstock discussed the electronic structure.

H. St. C. Deville said that if the temp. does not exceed 8°, the crystals can be kept for a month in diffuse daylight without decomposition; at 25°, in sunlight, the salt melts and decomposes explosively into nitrogen peroxide and oxygen. R. Weber kept the crystals for several days at 10° without any very marked decomposition. M. Berthelot said that the pentoxide decomposes rapidly when exposed to the direct rays of the sun, and it is not explosive either in the solid or gaseous state, but since it decomposes into nitrogen peroxide and oxygen at ordinary temp., it should not be kept in sealed tubes, but rather in stoppered bottles. F. Daniels and E. H. Johnston studied the thermal decomposition of nitrogen pentoxide between 0° and 65°, and the velocity constant, K, was found to have the values:

	0°	15°	20°	25°	35°	45°	55°	65°
K . .	$0{\cdot}0_4472$	$0{\cdot}0_3624$	0·00117	0·00203	0·00808	0·0299	0·0900	0·292

The decomposition at all temp. appears to be unimolecular. The large temp. coeff. of the reaction velocity shows that catalysis by the glass walls and diffusion are not factors in the reaction. The system studied was really $2N_2O_5 \rightarrow (2N_2O_4 \rightleftharpoons 4NO_2)+O_2$. M. Bodenstein regards the thermal decomposition as a purely unimolecular reaction, $N_2O_5 \rightarrow N_2O_3+O_2$. F. Daniels and co-workers found that a trace of ozone retards the thermal decomposition of the pentoxide. The reaction was discussed by M. Bodenstein. H. S. Hirst found that the thermal decomposition of nitrogen pentoxide is a true unimolecular reaction. The temp. coeff. of the velocity is large, being 300 per cent. for 10° rise of temp. so that the reaction is not a wall-effect. The decomposition at 80° is almost instantaneous. According to W. F. Busse and F. Daniels, the rate of the thermal decomposition of nitrogen pentoxide is not affected by the presence of bromine, chlorine, carbon monoxide or hydrogen; carbon disulphide gives an increase in the rate of decomposition. When ethyl ether is added to decomposing nitrogen pentoxide, a decrease in press. is produced, and then a rapid increase.

According to H. S. Hirst, the critical increment, E, in the photochemical equation (**4.** 25, 8) is 24,700 cals., and the rays of wave-length $1{\cdot}16\mu$ should be photochemically active; but they are not. Light in the region $400\mu\mu$ to $460\mu\mu$ accelerates the decomposition, but this does not occur unless nitrogen peroxide is present. The autocatalytic effect of nitrogen peroxide is negligible in the dark. F. Daniels said that the photochemical decomposition of the pentoxide is not brought about by the ultra-red radiation; the slight decomposition observed at 25° is a thermal effect produced by the radiation, since at 0°, where the thermal decomposition is negligible, no decomposition occurs. At least 99·5 per cent. of the absorbed radiation is chemically inactive. It is inferred that absorptions in the ultra-red and ultra-violet have fundamentally different mechanisms. H. A. Taylor believed that nitrogen pentoxide is not decomposed by the absorption of 3 or 5 quanta of energy at 3·39 or $5{\cdot}81\mu$, at which wave-lengths this oxide possesses strong absorption bands. S. C. Roy studied the photochemical reaction from the point of view of the radiation hypothesis. R. H. Lueck found that the velocity constants in chloroform or carbon tetrachloride soln. at 25° and 55° approximate closely to those obtained by F. Daniels and co-workers. The energy of activation or critical increment is nearly independent of temp. The nitrogen peroxide formed in the reaction acts as an autocatalyst on the decomposition of the pentoxide. E. C. White and R. C. Tolman observed no evidence of autocatalysis in their study of the rate of decomposition of nitrogen pentoxide. H. S. Hirst and E. K. Rideal found that the surface of the containing vessel, or the presence of inert gases, or the presence of the products of the reaction do not disturb the unimolecular character of the thermal decomposition of nitrogen pentoxide. The high value of the heat of activation, *viz.* 24,700 cals. per mol, precludes the possibility of the energy of activation being supplied by inelastic thermal collisions, or by black-body radiation unless some chain mechanism is called into play. The decomposition is not retarded by reducing the press., but below a critical press. of about 0·25 mm., the velocity of the reaction increases, becoming, at 0·01 mm. press., approximately constant, and five times its normal value. This is considered to be irreconcilable with chain mechanism—such, for instance, as the passage of a radiation quantum through a chain of successive mols., each one re-emitting the quantum after reaction; or else by the production by the decomposition of an activated form of nitrogen dioxide which, on collision, causes further reaction. It is therefore supposed that a definite fraction of the activated mols. always undergoes decomposition irrespective of press., but that a larger fraction (about four-fifths) does not decompose if it collides within 10^{-6} sec. after activation, but is deactivated by collision. A possible explanation of the two different types of activated mols. is based on the fact that there are four NO linkings, and only one shared NO linking in the mol. of the pentoxide. Activation of one linking causes decomposition, activation of the shared linking invariably so; activation of the others, only after a time interval and if collisions do not intervene. J. J. Thomson, J. A. Christiansen, J. A. Christiansen and H. A. Kramers, G. N. Lewis and D. F. Smith, and R. C. Tolman and co-workers, discussed the theory of this reaction; and Y. K. Sirkin showed that the quantum theory—**4.** 25, 8—can be adapted to the decomposition of nitrogen pentoxide. C. S. Fazel and S. Karrer found that nitrogen pentoxide, in the presence of nitrogen peroxide, is decomposed by light. It is assumed that the chemical activity of the NO_2-mols. is excited by the absorption of blue light; but R. G. W. Norrish suggested that since nitrogen peroxide is decomposed by the light of a mercury lamp: $2NO_2=2NO+O_2$, the reaction proceeds: $NO+N_2O_5=3NO_2$. According to W. F. Busse and F. Daniels, the photochemical decomposition of nitrogen pentoxide in the presence of the photocatalyst nitrogen peroxide is not affected by the presence of oxygen, nitrogen, or hydrogen; bromine cannot be substituted for nitrogen peroxide in the photochemical decomposition of nitrogen pentoxide even though its absorption spectrum is similar, in fact, bromine decreases the catalytic efficiency of nitrogen peroxide, probably by screening out the effective light. A. K. Brewer noted that ionization occurs during the decomposition of the pentoxide at 385°.

F. W. Küster and S. Münch could not obtain molten nitrogen pentoxide without it showing a pale yellow colour. T. Soné gave $-0{\cdot}03\times10^{-6}$ mass units for the magnetic susceptibility of the solid pentoxide. H. St. C. Deville said that the pentoxide deliquesces rapidly in air, and dissolves in water with the evolution of much heat, but no gas, forming a colourless soln. of nitric acid, HNO_3. R. Weber found that when the pentoxide is in contact with sulphur, it gives off brown vapours and forms a white sublimate approximating $SO_3.N_2O_3$, *sulphatonitrous anhydride*; A. Pictet and G. Karl said that the pentoxide dissolves in freshly distilled and fused sulphur trioxide, forming *sulphatonitric anhydride*, $(SO_3)_4.N_2O_5$, or $O(SO_2.O.SO_2.O.ON_2)_2$. W. F. Busse and F. Daniels observed that nitric oxide reacts immediately with nitrogen pentoxide. R. Weber found that nitrogen pentoxide has no action on carbon, but in the vapour of the pentoxide carbon burns with as brilliant a light as in oxygen; potassium and sodium burn brilliantly in the gas; magnesium, zinc, and cadmium are slightly attacked; and the metals—copper, silver, aluminium, thallium, titanium, tin, lead, antimony, bismuth, tellurium, iron, nickel, and palladium—are passive towards the pentoxide; but arsenic, and mercury are vigorously oxidized. It reacts on many organic substances with great vigour—thus, it explodes in contact with naphthalene. G. E. Gibson recommended it as a nitrating agent.

§ 41. Nitric Acid—History and Occurrence

The alchemical writings between the twelfth and fifteenth centuries have been searched by the scholars for indications of a knowledge of the mineral acids. If saltpetre was not recognized as a chemical individual prior to the thirteenth century, nitric acid is not likely to have been made before that time. An ill-founded attempt has been made to trace the discovery of nitric acid to the ancient Egyptians. W. Herapath[1] inferred that some linen cloth marked with dark hieroglyphical characters indicated that the Egyptians, at the time of Moses, were acquainted with nitric and hydrochloric acids. Since the ashes of the cloth were found to contain silver, it was assumed that the markings were produced by silver nitrate. J. D. Smith said that W. Herapath's assumption is wholly gratuitous, since there are other means of getting silver into soln. without the intervention of any acid whatever. T. J. Herapath also showed that a chemical analysis of the markings is of no value.

According to H. Kopp,[2] the earliest known description of a method of making nitric acid appears in the twelfth-century Latin work *De inventione veritatis*, attributed to the eighth-century Arabian Geber. It says:

> Take a pound of Cyprus vitriol, a pound and a half of saltpetre, and a quarter of a pound of alum. Submit the whole to distillation in order to withdraw a liquor which has a high solvent action. The dissolving power of the acid is greatly augmented if it be mixed with some sal ammoniac, for it will then dissolve gold, silver, and sulphur.

The distillation of vitriol, alum, and saltpetre would provide nitric acid; and the addition of sal ammoniac would furnish aqua regia. A somewhat similar mode of making the acid is described in the *Compositum de compositis* attributed to the twelfth-century Albertus Magnus. Similarly in the *Testamentum novissimum*, attributed to the thirteenth-century Raymond Lully, the acid was prepared by distilling a mixture of saltpetre and clay. A description of these methods of making nitric acid was copied into other writings during the immediately succeeding centuries. Thus, it appeared in Agricola's *De re metallica* (Basilæ, 1546); in N. Lemery's *Cours de chimie* (Paris, 1675); and in J. R. Glauber's *Furnis novis philosophicis* (Amstelodami, 1648), the acid is said to be obtained by heating saltpetre with vitriol, or alum, or clay, or white arsenic. J. Kunckel, in his *Philosophia chemica experimentis confirmata* (Amstelodami, 1694), recommended the white arsenic process. As H. Boerhaave said in his *Elementa chemiæ* (Lugduni Batavorum, 1732): Joannes Rudolphus Glauberus was "the first of mortals" to prepare this acid by the action of sulphuric acid on saltpetre. J. R. Glauber[3] wrote:

> I know well that ignorant laborators which do all their work according to custom, without diving any further into the nature of things, will count me a heretic because I teach that the *aqua fortis* made of vitriol and saltpetre is of the same nature and condition as the *spiritus nitri* which is made without vitriol.

In his *Miraculum mundi* (Franckfurt, 1658), J. R. Glauber acutely added:

> Plainly after the very manner we have taught spirit of salt to be prepared, so may also *aqua fortis* be made. Instead of salt, take saltpetre, and you will have *aqua fortis*.

His detailed description of the preparation of nitric acid, by the action of sulphuric acid on nitre, is written in the absurdly quaint style of the older alchemists;

First a man is to be made of iron, having two noses on his head, Fig. 89, and on his crown a mouth which may be opened and again close shut. This if it be to be used for the conc. of metals is to be so inserted into another man made of iron or stone, that the inward head only may come forth of the outward man, but the rest of his body or belly may remain hidden in the belly of the exterior man. And to each nose of the head glass receivers are to be applied to receive the vapours ascending from the hot stomach. When you use this man you must render him bloody with fire to make him hungry and greedy of food. When he grows extremely hungry he is to be fed with a white swan. When that food shall be given to this iron man, an admirable water will ascend from his fiercy stomach into his head, and thence by his two noses flow into the appointed receivers; a water, I say, which will be a true and efficacious aqua-vitæ; for the iron man consumeth the whole swan by digesting it, and changeth it into a most excellent and profitable food for the king and queen, by which they are corroborated, augmented, and grow. But before the swan yieldeth up her spirit she singeth her swan-like song, which being ended, her breath expireth with a strong wind, and leaveth her roasted body for meat for the king, but her *anima* or spirit she consecrateth to the gods that thence may be made a salamander, a wholesome medicament for men and women.

FIG. 89.—The Iron Man with Two Noses.

The term commonly employed for nitric acid in the translations of Geber's writings is *aqua dissolutiva*, and less frequently, *aqua fortis;* Albertus Magnus called the acid *aqua prima*, and *aqua dissolutiva;* Raymond Lully, *aqua fortis, aqua acuta*, or *aqua calcinativa*; and G. Agricola (*De re metallica*, Basiliæ, 1546), *aqua valens*. V. Biringucci (*Pirotechnica*, Venezia, 1540), G. Agricola, and books on assaying which began to appear in the sixteenth century, describe the use of *Starkwasser* (nitric acid) in the inquartation of gold. B. Budé, in his *De asse et partibus ejus* (Paris, 1516), called it *chrysulca*—from χρυσός, gold; and ἕλκω, draw out—and also *eau de départ;* while Basil Valentine, in his *Offenbahrung der verborgenen Handgriffe* (Erfurth, 1624), called the acid *Scheidewasser*—in allusion to its use for parting gold and silver. J. R. Glauber called the acid made from saltpetre and sulphuric acid *spiritus acidus nitri;* and that made from saltpetre and alum, *aqua fortis*. The acid distilled from a mixture of saltpetre and sulphuric acid was often alluded to during the sixteenth and seventeenth centuries as *spiritus nitri fumans Glauberi*. H. Boerhaave called it *acidum nitri*, and during the next forty years, it was often termed *acide nitreux* or *nitrous acid*. O. Guttmann[4] described its manufacture in Birmingham in 1771. In the nomenclature recommended in 1787 by the French chemists, it received its present cognomen *acide nitrique*, or *nitric acid*.

About 1750, G. F. Rouelle[5] described an ingenious process for concentrating nitric acid—or, as he called it, *l'esprit de nitre ou acide nitreux*—by distilling a mixture of the dil. nitric acid with conc. sulphuric acid. J. Mayow,[6] in 1669, showed that saltpetre consists of an alkali salt and a salt of a volatile acid, which is expelled as *spirit of nitre* when saltpetre is treated with sulphuric acid. Spirit of nitre was also shown to be a compound of what he called nitro-aerial spirit with particles of a grosser nature. The nitro-aerial particles were supposed to be derived from the air, and to be necessary for the production of the flame. The clear advance made by J. Mayow on the nature of *spiritus nitri* seems to have been overlooked because during the next century the ideas of chemists on the nature of nitric acid seem to have undergone a process of involution; progress was backwards not forwards.

In 1734, G. E. Stahl propounded the hypothesis that like sulphurous acid, nitric acid is a compound of sulphuric acid and phlogiston, but the proportions of phlogiston in the two acids are different. In 1750, J. G. Pietsch wrote a thesis in support of this view; but in 1786, P. Thouvenal showed that while nitric acid is produced by the putrefaction of organic matter, sulphuric acid is never so formed. G. A. Saluzzo considered nitric acid to be a compound of an empyreumatic acid, an alkaline salt, lime, and a little silica; and T. Bergman regarded it as a dephlogisticated plant acid produced by fermentation.

In 1776, A. L. Lavoisier demonstrated the presence of oxygen in nitric acid, and this discovery recalls J. Mayow's nitro-aerial particles; in 1784, H. Cavendish synthesized it by the action of electric sparks in humid air, and proved that it contained oxygen and nitrogen; and in 1816, J. L. Gay Lussac, and C. L. Berthollet established its exact composition.

According to F. Goppelsröder,[7] free nitric acid does not occur in nature although A. Emmerling claimed to have observed it in plants where it was supposed to have been formed by the decomposition of calcium or alkali nitrates in plants by oxalic acid. On the other hand, several nitrates—ammonium, potassium, sodium, magnesium, aluminium, and iron—have been reported in numerous localities. There are, for instance, the nitre deposits near the west coast of South America, and the soil of Amu-Daria, Turkestan, found by N. Ljubawin to contain about 3 per ccnt. of nitrates. The presence of nitrates and nitrites in the atmosphere has been previously discussed in connection with atm. air (*q.v.*). In 1695, B. Ramazzini detected the presence of nitric acid in snow; and in 1751, A. S. Marggraf observed the acid in rain-water, and in snow. This subject has been discussed in connection with nitrous acid, atmospheric air, and the fixation of nitrogen by bacteria. A. S. Marggraf, H. Cavendish, and T. Bergman detected nitrates in spring waters. Nitrates have been detected in numerous forms of running water, particularly those carrying drainage waters from soils. W. Knop, C. Ekin, C. H. John, F. Goppelsröder, J. von Liebig, C. F. Schönbein, T. Schlösing, J. B. J. D. Boussingault, A. Müntz, V. Marcano and A. Müntz, A. Lévy, R. Otto and J. Troeger, C. H. John, etc., have discussed the occurrence of nitrates in natural waters—rivers, and oceans. The presence of nitrates has been reported in various organs of plants, and the nitrates appear to be connected with the assimilation of nitrogen by plants. The subject has been discussed by F. Goppelsröder, F. Schulze, A. Hosaeus, C. Ekin, M. Berthelot, M. Berthelot and G. André, V. Dessaignes, W. Knop, M. Serno, M. Vaudin, etc. The occurrence of nitrates in animals—urine, sweat, saliva, etc.—has been discussed by C. F. Schönbein, F. Goppelsröder, C. Wurster, T. Weyl, F. Röhmann, etc. According to H. B. Jones, nitrates are formed in the animal system by the oxidation of nitrogenous matters by the oxygen dissolved in the blood.

§ 42. Nitric Acid—Preparation

The production of nitric acid by the oxidation of nitrogen, either in the electric arc, or during the simultaneous oxidation of other substances, has been previously discussed in connection with the fixation of nitrogen. Nitric acid is the end-product of the oxidation of nitric oxide, and of nitrogen trioxide or peroxide ; and this subject has been discussed in connection with the individual compounds. S. Cloez and E. Guignet[1] and others have studied the oxidation of ammonium salts, and of nitrogenous organic matter to nitrates by digestion with potassium permanganate, and other oxidizing agents—*vide* the oxidation of ammonia. The nitrification of organic matter in soils, etc., to nitrates by bacteria has been discussed in connection with the fixation of nitrogen.

When potassium or sodium nitrate is mixed with dil. sulphuric acid in the cold, no obtrusive sign of chemical action occurs, although it can be proved that a reversible change has taken place so that the sodium is distributed between the sulphuric and nitric acids. The same mixture is obtained whether the original constituents are sulphuric acid and sodium nitrate or sodium hydrosulphate and nitric acid. The one reaction is endo- and the other exo-thermal. If a mixture of conc. sulphuric acid and sodium nitrate be heated to about 130°, nitric acid, HNO_3, is volatilized. The reaction is represented : $NaNO_3+H_2SO_4\rightleftharpoons NaHSO_4+HNO_3$. The two salts, sodium nitrate and sodium hydrosulphate, are not volatile ; the nitric acid, HNO_3, boils at 86° ; and the sulphuric acid at 330°. Hence, on warming to 100° in a retort, most of the nitric acid is volatilized and the state of equilibrium of the soln. is disturbed ; in consequence, the sodium nitrate is all decomposed. If the oily liquid in the retort be cooled, a little unchanged nitrate may be deposited along with the crystals approximating $NaH_3(SO_4)_3$. At 121°, the crystals are almost wholly sodium hydrosulphate. At a still higher temp., normal sodium sulphate is formed and hence less sulphuric acid is needed for a given yield of nitric acid: $2NaNO_3+H_2SO_4=Na_2SO_4+2HNO_3$. Appreciable quantities of the nitric acid are decomposed at the higher temp. Brownish-red fumes appear when the mixture is first heated, and the distillate is more or less coloured brown because of the soln. of the ruddy gas in the distillate. The brownish-red gas is a product of the decomposition of the nitric acid by heat; as represented by L. Carius,[2] $4HNO_3=2H_2O+4NO_2+O_2$. According to C. W. Cuno, if the reduction in the yield of nitric acid is due in part to this reaction brought about by the dehydrating action of sulphuric acid, the introduction of an excess of air or oxygen should lessen the loss. In fact, the brown fumes in the distillation can be nearly prevented in this way; the amount of oxygen required for the purpose increasing with the temp. of distillation.

If the proportions of sulphuric acid and sodium nitrate approximate $2NaNO_3+H_2SO_4=Na_2SO_4+2HNO_3$, the temp. required to complete the action is high—nearly 900°, and this results in heavy wear and tear on the apparatus; high fuel consumption; much loss by the thermal decomposition of the nitric acid; and the residual sulphate is difficult to remove from the retort. By sacrificing a portion of the sulphuric acid, and working more nearly to the equation: $NaNO_3+H_2SO_4=NaHSO_4+HNO_3$, the temp. need not exceed 200°, and the residue in the retort can be allowed to run from the retort. Rather less acid than that corresponding with this equation is employed in practice so that the residue is a mixture of sodium hydrosulphate and sulphate. It is known as *nitre-cake.* The composition and properties of nitre-cake have been discussed by H. W. Foote, H. M. Dawson, B. Saxton, and G. S. Butler and H. B. Dunnicliff. Trials with different proportions of acid and nitrate have been reported by G. C. Wittstein, N. A. E. Millon, E. Mitscherlich, R. Phillips, C. F. Bucholz, H. Hess, and P. L. Geiger. The early workers preferred potassium nitrate for making the acid on a small scale because that salt could be more easily purified than the sodium salt—Chili saltpetre.

The salts employed for making nitric acid should be as free as possible from halogen salts. Ordinary Chili saltpetre contains some iodine, and the resulting acid, as shown by M. Lembert,[3] and E. A. White, may contain this impurity. According to W. Stein, the iodine may be present in its elemental form or as iodine chloride. If the salts contain chlorides, the product may be contaminated with hydrochloric acid, or chlorine or nitrosyl chloride. For special purposes, the dil. acid may be treated with silver nitrate, and the clear liquor, free from silver chloride, redistilled for nitric acid. If any silver chloride is present in the retort, it will be partly decomposed by the hot acid. This subject was discussed by H. W. F. Wackenroder, F. Mohr, G. C. Wittstein, and E. Ohlert. J. Bescherer recommended distilling the acid over metallic silver, but the remedy is not effective. Lead oxide is inefficacious because some lead chloride dissolves in the nitric acid and is decomposed by heat. Commonly, the chlorides are volatilized early and collect in the first fraction, so that by rejecting the first third of the distillate, L. C. A. Barreswil, and N. A. E. Millon obtained an acid free from this impurity. P. Pascal, and J. Baumann studied the fractional distillation of nitric acid. R. Hirsch described a continnous process of rectifying nitric acid from the more volatile constituents. E. and R. Urbain described a rectifier in which water was extracted from the vapour by atmolysis through porcelain, and they thus made 99·6 per cent. nitric acid. H. J. M. Creighton showed that when nitric acid is electrolyzed in a cell with a porous diaphragm separating anode and cathode, the acid is concentrated by the electrolytic decomposition of water, and the concentration of the acid in the anolyte is increased at the expense of the catholyte, by the migration of the NO_3'-ions. He thus raised the conc. of 70–71 per cent. acid to 99·65 per cent. HNO_3. A. Erck added methyl or ethyl alcohol, before rectification, whereby he claimed that the halogen impurities and organic substances are volatilized more readily, and collected in the first fraction. The traces of sulphuric acid or sodium sulphate mechanically carried over from the vapours can be removed by redistillation which may or may not be preceded by treatment with barium nitrate to precipitate the sulphates. V. H. Veley and J. J. Manley obtained an acid of a high degree of purity by distilling, under reduced press., ordinary conc. acid mixed with small proportions of silver and barium nitrates to remove chlorides and sulphates respectively. The yellow or yellowish-red colour of the acid due to the presence of nitrogen peroxide was removed by N. A. E. Millon by heating the acid to near the b.p.—say 80° or 90°—and passing in a current of carbon dioxide until the acid is cold. H. E. Roscoe used air instead of carbon dioxide; and V. H. Veley and J. J. Manley, a stream of ozonized oxygen to remove the lower nitrogen oxides, and distilled the product under reduced press. N. A. E. Millon recommended distilling the acid with about a hundredth part of its weight of potassium dichromate; and J. Pelouze, lead or barium dioxides. This subject was further discussed by L. C. A. Barreswil, H. W. F. Wackenroder, F. Mohr, C. G. Wittstein, E. Ohlert, and O. Guttmann. W. G. Whitman and L. Evans found that the removal of the lower oxides of nitrogen from nitric acid by a current of air follows the equation $-dC/dt=\beta C$, where C denotes the conc. of the nitrogen oxides, and β is a constant depending on the temp. and rate of flow of air. H. N. Warren found traces of selenious acid in a sample of commercial nitric acid. This impurity was probably derived from the sulphuric acid. F. A. F. Crawford examined the organic impurities in nitric acid; G. Lockemann, arsenic.

The purification and concentration of the acid can be effected by fractional distillation in a current of inert gas, or ozonized oxygen whereby 98 per cent. HNO_3 can be obtained; and, by the low temp. redistillation of the conc. acid with its own vol. of conc. sulphuric acid, H. E. Roscoe obtained an acid of 99·5–99·8 per cent. HNO_3. The concentration of the acid by the fractional distillation of the acid with or without the addition of sulphuric acid was discussed by J. Pelouze, J. Dalton, J. Tünnermann, H. J. M. Creighton and co-workers, M. Kaltenbach, F. Förster and co-workers, E. Galle, C. D. Carpenter and J. Babor, E. Mitscherlich, G. Lunge and H. Rey, R. Weber, J. L. Gay Lussac, J. L. Proust, A. Smith, N. A. E. Millon, D. P. Konowaloff, and J. Giersbach and A. Kessler. The acid can be concentrated by freezing. According to F. W. Küster and S. Münch, when nitric acid containing 98·5 per cent. of HNO_3 is partially frozen, and the liquid removed, almost pure nitric acid is obtained. By continued fractionation, products were obtained of constant f.p., that is, the temp. at which successive fractions began to crystallize were constant. As solidification, however, proceeded, the temp. fell appreciably, and this indicated that an impurity was present which could not be removed by fractional crystallization. The acid obtained in this manner contained 99·4±0·1 per cent. of HNO_3. Absolute nitric acid exists only in the form of snow-white crystals at a temp. below −41°. Nitric acid crystals melt to a yellow liquid, which is a soln. of nitrogen pentoxide and water in nitric acid. Whilst solid nitrogen pentoxide is colourless, the liquid has not yet been obtained colourless. This liquid, in presence of dry air, becomes colourless, the pentoxide being removed and the water remaining. The liquid obtained after removal of the pentoxide contained 98·67 per cent. of HNO_3. When dry air was passed into an acid containing 99·4 per cent. of HNO_3, the yellow colour of the acid disappeared exactly at the point when the percentage of HNO_3 was 98·67. J. Giersbach and A. Kessler obtained 100 per cent. nitric acid by mixing nitrogen pentoxide with the calculated quantity of water, but this acid is partly dissociated $2HNO_3 \rightleftharpoons N_2O_5+H_2O$.

Instead of decomposing the nitrate with sulphuric acid, the early workers employed vitriol, alum, clay, or white arsenic as indicated in the preceding section. T. Ramon de Luna[4] employed magnesium sulphate; R. Wagner, aluminium hydroxide, and precipitated silica; and F. Kuhlmann, manganese chloride, sulphate, or dioxide. W. Garroway treated a mixture of an alkaline earth and the alkali nitrate with steam; G. Lunge and M. Lyte likewise treated a mixture of the alkali nitrate and ferric oxide. The process was described in detail by J. L. F. Vogel. J. D. Darling and C. L. Forrest electrolyzed the molten nitrate for the alkali metal, and passed the resulting gases into water.

F. Förster and co-workers [5] found that the concentration of nitric acid above 68 to 69 per cent. HNO_3, by treatment of dil. nitric acid with nitrogen peroxide, water, and oxygen, may be effected if the time of treatment is extended, the oxygen used only in slight excess, and the gas velocity reduced. Even so, only 80 per cent. nitric acid is produced. A very high conc. results by interaction of the weak nitric acid soln. with sufficient excess of liquid nitrogen peroxide, followed by slight agitation with oxygen. When the equilibrium $2NO_2 \rightleftharpoons N_2O_4$ is reached in the treatment of nitrous gases with water, nitric peroxide dissolves, and thereby initiates the interaction $N_2O_4+H_2O \rightleftharpoons HNO_3+HNO_2$, the nitrous acid being then decomposed into nitric acid and nitric oxide, and oxidized.

Nitric acid is manufactured at the present day by one of three processes: (i) By the direct oxidation of nitrogen in the electric arc as indicated in connection with the fixation of nitrogen; (ii) By oxidation of ammonia as indicated in connection with that compound; and (iii) By the decomposition of sodium nitrate with sulphuric acid. Some chemical changes involved in the third reaction have just been discussed. The plant employed consists of (i) the distilling apparatus; (ii) the condensing system; (iii) the receiving vessel; (iv) the bleaching system; and (v) the absorption apparatus.

The retorts formerly employed were made of glass or iron; they are now made of cast iron. The older retorts were cylindrical and were supported horizontally in the flue of the fire; the more modern retorts are of the pot-type, and are supported vertically in the flue. There are several modifications of the pot retort—*e.g.* by O. Guttmann,[6] F. Valentiner, J. Prentice, etc. That of J. Prentice has a loose bottom which can be cemented in as required. F. Bottomley recommended retorts of fused silica. The condensing apparatus formerly employed consisted of a battery of Woufile's bottles cooled by air; but both air and water are now usually employed. There are several different systems of condensation—*e.g.* those of O. Guttmann, E. Hart, A. Hough, J. V. Skoglund, etc. The receiving apparatus for the condensed acid can be made of well-vitrified stoneware, glass, fused silica, and acid-resisting alloys. Formerly acid was decolorized by blowing a current of air through the warm product. In J. V. Skoglund's bleaching system, the hot condensed acid is allowed to reflux so as to meet the hot gases from the retort which raise its temp. and drive out the nitrogen peroxide, or all but about one per cent. of nitric acid. From 6 to 10 per cent. of the nitrogen content of the original nitrate passes the condenser and receiver. This is recovered by passing the gases through a series of absorption towers packed with acid-proof material, and down which trickles dil. nitric acid. The gas with the most nitrous fumes comes in contact with the most conc. acid, while the gas almost freed from nitrous fumes comes in contact with the most dil. acid. C. L. Burdick and E. S. Freed found that the reactions in the absorption towers involve the reversible reaction: $3NO_2+H_2O \rightleftharpoons 2HNO_3+NO$; and the reaction: $2NO+O_2=2NO_2$ which goes to an end, but is comparatively slow. The slowness of the reaction and the necessarily limited capacity of the towers prevent complete recovery—a 95 per cent. conversion being considered good practice.

There are many modifications—*e.g.* in F. Valentiner's process in which the decomposition of the nitrate is carried out under reduced press., and accordingly at a reduced temp., so as to avoid thermal decomposition of the nitric acid. This process was modified by H. Fischer, and A. Hough. According to W. Mason, the best results are obtained with the press. reduced from 25 to 15 mm. of mercury. The formation of nitrous acid, which is especially to be avoided in this process, is unconnected with the use of an iron pot but is caused by over-heating; with careful firing, even with sulphuric acid of sp. gr. 1·75, the nitrous acid content may be as low as 0·2 per cent. An undesirable acceleration of the distillation accompanied by frothing often occurs, when about 30 per cent. of the nitric acid distillation has occurred, is due to the loss of water from the acid sulphate. A yield of 97–99 per cent. nitric acid is obtained by this method. There are also continuous systems of manufacturing nitric acid by M. Prentice, C. Uebel, etc. Manufacturing details of these and other technical processes are described in A. Cottrell's *The Manufacture of Nitric Acid and Nitrates* (London, 1923). There are also numerous articles in the technical journals.[7]

§ 43. The Composition of Nitric Acid and its Hydrates

According to V. H. Veley and J. J. Manley,[1] and F. W. Küster and S. Münch, absolute nitric acid exists only in snow-white crystals stable below —41°; on melting it partly decomposes into water and nitrogen pentoxide which dissolves in the melted acid to form a yellow soln. When a current of dry air is passed through the liquid, the liberated nitrogen pentoxide escapes, and a colourless acid containing 98·67 per cent. of HNO_3 results. This acid can be volatilized unchanged. E. Aston and W. Ramsay said that the 99·8 per cent. acid has a pale yellow colour, and fumes strongly when exposed to air. The commercial nitric acids contain different proportions of water, and vary in colour from a pale straw-yellow to an orange-brown owing to the presence of the lower nitrogen oxides in soln.

The red fuming liquid known as **fuming nitric acid** is a soln. containing a variable quantity of nitrogen peroxide in conc. nitric acid. It is produced by introducing nitrous acid, nitric oxide, or nitrogen trioxide or peroxide, into conc. nitric acid. E. Mitscherlich said that monohydrated nitric acid can dissolve half its weight of nitrogen peroxide. The fuming acid is made by distilling a mixture of sodium or potassium nitrate with half its weight of sulphuric acid, with fuming sulphuric acid, or with potassium hydrosulphate. In any case the reaction: $KHSO_4+KNO_3=K_2SO_4+HNO_3$, occurs at so high a temp. that the nitric acid is decomposed, forming nitrogen peroxide, which dissolves in the distillate; with the conc. sulphuric acid, some nitrogen pentoxide is formed, and this also dissolves in the distillate. C. Brunner, and E. Schaller recommended making the fuming acid by adding either sulphur or starch to the mixture of alkali nitrate and sulphuric acid in the retort. L. Vanino made the fuming acid by adding paraformaldehyde to conc. nitric acid. Many other organic substances can be used.

The fuming acid was very early recognized to be a soln. of nitrogen trioxide and peroxide in nitric acid. L. Marchlewsky said some nitric oxide is present, but showed that N_2O_4 and NO_2 are the dominant solutes. D. Gernez, and L. Marchlewsky argued that a labile compound of nitric acid and nitrogen peroxide is present because (i) a very marked contraction occurs when these two constituents are mixed together—Table XXXI shows the results of G. Lunge and L. Marchlewsky's observations on the effect of nitrogen peroxide on the density of nitric acid; and (ii) a soln. of nitrogen peroxide in chloroform, benzene, or carbon disulphide shows the nitrogen peroxide spectrum, while the soln. in conc. nitric acid

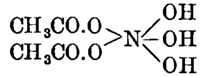
does not. C. Montemartini argued against chemical combination because nitrogen peroxide can be extracted from the fuming acid by carbon disulphide. The maximum density of mixtures of nitrogen peroxide and nitric acid was found by G. Lunge and L. Marchlewsky to be a maximum with 42·5 per cent. of the peroxide. This corresponds with **nitroxyl nitric acid,** $2HNO_3.N_2O_4$, or $HNO_3.NO_2$. W. R. Bousfield obtained singular points in the sp. vol. curve corresponding with $4HNO_3.N_2O_4$, and $3HNO_3.2N_2O_4$. In their study of the reciprocal solubility of nitric acid and nitrogen proxide, P. Pascal and M. Garner found this complex acid to be stable below −48·5° and above this temp. to dissociate giving off the peroxide. They also found that sulphuric acid is not appreciably soluble in nitrogen peroxide, but when added to anhydrous nitric acid or the acid containing a little water, it does not appreciably alter the solubility of the peroxide in the acid providing the mixture does not contain more than 30 per cent. of sulphuric acid, the water content being the principal factor of solubility.

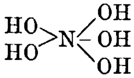
Red fuming nitric acid is highly corrosive. According to S. Feldhaus, if water be slowly added to the acid, the colour changes from dark red to brown and yellowish-green, and, with ice-cold water, a dil. soln. is blue. When warmed, the soln. gives off nitric oxide. No gas is evolved if the acid be added to water slowly enough to prevent a rise of temp. L. Marchlewsky and co-workers said that the blue soln. contains only nitrous acid, the green soln. nitrous acid and nitrogen peroxide. When the red, fuming acid gives off nitrogen peroxide and a colourless hydrate remains, its sp. gr. is 1·5, and L. Carius found that it oxidizes organic compounds to carbon dioxide any sulphur present being converted to sulphuric acid, and any phosphorus into phosphoric acid; he therefore recommended it for use as an oxidizing agent in organic analysis. Fuming nitric acid is a more powerful oxidizing agent than nitric acid alone; it inflames phosphine, hydrogen selenide, hydrogen iodide, straw, saw-dust, and other organic substances. These reactions were discussed by L. Archbutt, R. Haas, A. W. Hofmann, K. Kraut, G. Lechartier, and K. Lund. Some of its general properties are those of nitric acid, others of nitrogen peroxide.

Many investigations on the physical properties of soln. of nitric acid showed the existence of discontinuities which have been interpreted to mean that definite hydrates are formed. This was noted by E. A. Smith[2] in 1848. E. A. Bourgoin, E. Mitscherlich, A. Bineau, M. Berthelot, H. Erdmann, W. N. Hartley, T. Graham, J. Kolb, and J. Wislicenus also suggested that nitric acid forms definite hydrates. V. H. Veley and J. J. Manley, and S. U. Pickering observed discontinuities in the f.p. curve corresponding with the existence of a monohydrate and a trihydrate; M. Berthelot, J. Thomsen, and S. U. Pickering observed corresponding sharp breaks in the heat of soln.; C. Chéneveau, in the viscosity curves; W. N. Hartley, in the absorption spectra; H. Crompton, and V. H. Veley and J. J. Manley, in the electrical conductivity or resistance curves; and V. H. Veley and J. J. Manley in the curve of refractive indices. The curves showed singularities corresponding with hydrates with 14, 7, 4, 3, 1½, and 1 H_2O. H. Erdmann claimed to have isolated by freezing at low temp. hydrates with 2, 1½, 1, and ½ H_2O. If dry air be passed through nitric acid at −15°, water evaporates and *orthonitric acid*, $HNO_3.2H_2O$, or $N(OH)_5$, remains. This hydrate is stable at −15°, and furnishes long needles which melt at −35°, and the liquid boils at 40°–40·5°, and 13 mm. press. By treating nitric acid (sp. gr. 1·4) with acetic anhydride, $(CH_3CO)_2O$, the fraction which boils at 127·7° (730 mm.) has a sp. gr. 1·197 (15°). Its empirical formula is $C_4H_9NO_7$ and its general properties, mol. wt., and mode of preparation show that it is a mixed anhydride—**diacetylorthonitric acid**—with the constitutional formula:



$$\begin{array}{l}CH_3CO.O\\CH_3CO.O\end{array}{>}N\begin{array}{l}/OH\\-OH\\\backslash OH\end{array}$$

Diacetylorthonitric acid, $(CH_3COO)_2N(OH)_3$.



$$\begin{array}{l}HO\\HO\end{array}{>}N\begin{array}{l}/OH\\-OH\\\backslash OH\end{array}$$

Orthonitric acid, $N(OH)_5$.

$$Ca{<}\begin{array}{l}O.N(OH)_4\\O.N(OH)_4\end{array}$$

Calcium nitrate, $Ca(NO_3)_2.4H_2O$.

While orthonitric acid itself is unstable, this compound is comparatively stable, and it can be distilled without decomposition. Crystallized calcium nitrate, $Ca(NO_3)_2.4H_2O$, can be considered to be the calcium salt of orthonitric acid. The constitution of nitric acid was discussed by A. Hantzsch. H. Erdmann said that he had obtained prismatic crystals of *pyromesonitric acid,* $2HNO_3.3H_2O$, or $H_8N_2O_9$, or $(HO)_4N.O.N(OH)_4$, which freezes at —39° ; rhombic plates of *mesonitric acid,* $HNO_3.H_2O$, or H_3NO_4, or $O : N(OH)_3$, which freezes at —34° ; and stellar aggregates of *pyrometanitric acid,* $2HNO_3.H_2O$, or $H_4N_2O_7$, or $(OH)_2NO.N.O.NO(OH)_2$, which freezes at —65·2°, and boils at 21·5° and 24 mm. press. The corresponding *metanitric acid* would be represented by HNO_3, or $(HO)NO_2$, ordinary nitric acid. There is but little satisfactory evidence of the polybasicity of these acids, although G. Oddo showed the higher oxygenated compounds of nitrogen may have a tendency to form complexes by polymerization, because the acid salt $KNO_3.HNO_3$ may be regarded as a monopotassium salt of *dinitric acid ;* and $KNO_3.2HNO_3$, as the monopotassium salt of *trinitric acid :*

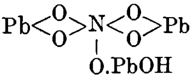
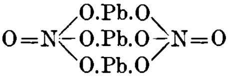
Trinitric acid, $H_3N_3O_9$.

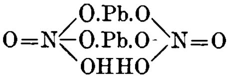
A number of basic lead salts have been considered as salts of some of these acids. Thus, J. Loewe referred the salt $6PbO.N_2O_5.H_2O$ to orthonitric acid, and $3PbO.N_2O_5$ to metanitric acid ; and J. J. Berzelius, and M. E. Chevreul also referred the salt $2PbO.N_2O_5.H_2O$ to metanitric acid :



$6PbO.N_2O_5.H_2O$.



$3PbO.N_2O_5$.



$2PbO.N_2O_5.H_2O$.

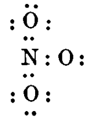
H. L. Wells, and H. Klinger's basic nitrates of lead, cadmium, zinc, and mercury were shown by G. Watson to fall in line with this hypothesis ; but F. Meissner could not support it, and F. W. Kuster and R. Kremann showed that the f.p. curve of binary mixtures of nitric acid and water invalidates H. Erdmann's conclusions—*vide infra.*

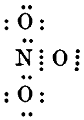
In 1786, H. Cavendish measured the f.p. of mixtures of nitric acid and water, and he showed that when the liquid is frozen, it exhibits two kinds of congelation. What he called *spiritous congelation* occurs when the more conc. acid is frozen, and with a more dil. acid *aqueous congelation.* Translated into modern language, in the one case nitric acid first freezes out of soln., and in the other case ice. He also obtained what he called a *point of easiest freezing* at —1·5°. This point nearly a century later was called the eutectic temp. J. Dalton obtained a buttery mass by cooling the acid to —54°, and M. Berthelot froze the conc. acid to a solid at —47°. F. W. Küster and R. Kremann examined the f.p. of binary mixtures: $HNO_3–H_2O$, in some detail. The results are summarized in Fig. 87. The ice-curve falls down from zero to the first eutectic with 32·7 per cent. of HNO_3 at —43·0° when the two solid phases are ice and **trihydrated nitric acid,** $NHO_3.3H_2O$. The curve rises from this eutectic to a maximum at —18·5° and 53·80 per cent. of HNO_3, corresponding with the m.p. of the trihydrate. There is then a fall to a second eutectic at —42·0° with 70·50 per cent. of HNO_3. The two solid phases are the trihydrate, and **monohydrated nitric acid,** $HNO_3.H_2O$. The curve then rises to a second maximum at —38·0° and 77·75 per cent. HNO_3 corresponding with the m.p. of the monohydrate. The curve then falls to a third eutectic at —66·3° and 89·95 per cent. HNO_3. The two solid phases are the monohydrate and nitric acid, The curve then rises to —41·2, the m.p. of 100 per cent. HNO_3. These two hydrates were first isolated by S. U. Pickering, who gave —18° for the m.p. of the trihydrate, and —36·8 for that of the monohydrate. V. H. Veley and J. J. Manley gave respectively —18·2° and —45°. Irregularities with 96–100 per cent. HNO_3, are connected with anhydride formation. H. Crompton found that the second differential of the electrical conductivity curves agreed with the assumption that the two hydrates, $HNO_3.4H_2O$, and $HNO_3.15H_2O$, are formed in accord with the breaks in the first differential of D. I. Mendeléeff's sp. gr. curves—*vide* sulphuric acid. Observations were also made by C. D. Carpenter and A. Lehrman.

Analyses of nitric acid by A. L. Lavoisier, H. Cavendish, J. J. Berzelius, H. Davy, and H. St. C. Deville agree with the empirical formula HNO_3. The calculated value for the **vapour density** is 31·5. L. Playfair and J. A. Wanklyn obtained 2·375 for the vap. density at 40·5°, and 2·258 at 68·5°, but A. Calm showed that the vapour density of the acid cannot be determined because of dissociation. Nitric acid is nearly always regarded as being constituted with quinquevalent nitrogen, but I. I. Kanonnikoff inferred that the indices of refraction of a number of nitrates agreed better with tervalent nitrogen. These two hypotheses are symbolized:

$$HO{-}N\leqslant^{O}_{O} \qquad\qquad HO{-}N<^{O}_{O}.$$

J. W. Brühl's observations on the refractive indices agreed with the formula $HO.O.N{=}O$; but R. Löwenherz's values for ethyl, propyl, isobutyl, and amyl nitrates agree better with the quinquevalent nitrogen atom. H. E. Armstrong and F. P. Worley made some observations on the constitution of nitric acid—*vide* sulphuric acid. H. Burgarth, H. Remy, and H. Henstock discussed the electronic structure; and from observations on the absorption spectra of sodium and potassium nitrates in different solvents, G. Scheibe inferred that the nitrate ion is dipolar, and that the electronic structure is such that the first of the following forms exists in equilibrium with small proportion of the second:





G. Oddo and G. Anelli found that in what are usually regard as associating solvents—nitrobenzene, and in ethylene bromide—the cryoscopic data give values for the mol. wt. which are only slightly larger than is required for HNO_3. An analogous result was obtained by F. M. Raoult with acetic acid, and by E. Mameli with chloroacetic acid. N. Tschernay concluded from his observations on the coeff. of thermal expansion of soln. of the nitrates that nitric acid exists in soln. with doubled molecules $(HNO_3)_2$, or $H_2N_2O_6$; and E. Aston and W. Ramsay found the mol. wt. is nearly 126, the theoretical value for $H_2N_2O_6$, 63, corresponding with a mixture of $H_2N_2O_6$-mols. with a small proportion of HNO_3-mols. W. N. Hartley also inferred from his observations on the absorption spectra that the molecules in aq. soln. are complex $(HNO_3)_n$, and in some cases form the equivalent of mesonitric acid, H_3NO_4. He believed that the hypothesis is supported by the observations of W. H. Perkin, S. U. Pickering, and V. H. Veley and J. J. Manley; and said that the anhydrous acid is probably bi-molecular, $H_2N_2O_6$; and with acids between 78 and 100 per cent. HNO_3 there is a mixture of mesonitric acid, H_3NO_4, and the bi-molecular acid, $H_2N_2O_6$. The former is supposed to be active, the latter inert.

According to A. Hantzsch, while in aq. soln., nitric acid behaves as if it were constituted $HO.NO_2$, in alcoholic soln., the hydrogen can be split off by electrolytic dissociation. The optical properties also indicate that under these conditions the constitution may alter to $NO_3.H$. He calls the latter a *pseudo-acid*, meaning an acid which is homopolar with respect to hydrogen, but whose hydrogen atoms do not exercise an acid function, which, in the case of oxy-acids, are linked with oxygen in the form of hydroxyl. When water is added, the pseudo-acid becomes a true acid by a change in its constitution and optical properties. D. D. Karve found that the heats of soln. of nitric acid in alcohol and ether support the hypothesis. A. Hantzsch and L. Wolf assume that soln. of nitric acid contain equilibrium mixtures of the pseudo-acid, $HO.NO_2$, and of the true acid, $H.NO_3$, which is assumed to be present as hydroxonium nitrate, $(H.OH_2)(NO_3)$. The absorption spectrum and the electrical conductivity of nitric acid led to the inference that yet a third kind of molecule is present. Soln. of nitric acid in absolute sulphuric acid contain a largely ionized electrolyte which is more transparent than an equally conc. ethereal or aq. soln. of nitrate acid. Since soln. of acetic acid in absolute sulphuric acid, producing an acetylium cation, behave similarly, it is inferred that a **nitronium** cation is formed by dissolving nitric acid in absolute sulphuric acid, and the soln. contains **nitronium pyrosulphate,** $\{NO(OH)_2\}(HSO_4)$, and $\{N(OH)_2\}(HSO_4)_2$—*vide infra.* This hypothesis is confirmed by the isolation from soln. of perchloric acid in anhydrous nitric acid of **nitronium perchlorate,** $\{N(OH)_3\}(ClO_4)$, or of **nitronium oxyperchlorate,** $\{NO(OH)_2\}ClO_4$, by crystallization from perchloric acid and nitric acid respectively. R. Weber also isolated nitronium pyrosulphate, $\{NO(OH)_2\}HS_2O_7$, or $\{N(OH)_3\}S_2O_7$, in 1871—*vide infra.* The so-called nitrating acid—a mixture of conc. sulphuric and nitric acid—is assumed to contain **nitronium hydrosulphate,** $\{N(OH)_3\}(HSO_4)_2$, and not nitrogen pentoxide as suggested by A. Saposchnikoff. It is inferred that homogeneous nitric acid contains nitronium nitrate, $\{N(OH)_3\}(NO_3)_2$; and anhydrous nitric acid is considered to be a soln. of conducting nitronium nitrate in non-conducting pseudo-nitric acid—98·6 per cent. acid at 0° has 80 per cent. of pseudo-acid and 20 per cent. nitronium nitrate. The absorption spectra of aq. soln. show that nitronium nitrate is completely hydrolyzed by the addition of one mol. proportion of water, since from this point the absorption curves can be additively constructed from those of the pseudo-acid in ether and the true-acid in water. The conversion of the pseudo-acid into the true-acid (or its hydroxonium salt) is practically complete after the addition of 8 mols of water, whereas the dissociation at this point does not amount to 40 per cent. The last traces of the pseudo-acid have disappeared after addition of 50 mols of water, and the soln. then contains only hydroxonium salt which is not completely ionized, in the sense of the ionization theory, in 0·01*N*-soln. In the most dil. soln., the sole absorbent material is the nitrate ion; orthonitric acid and nitrogen pentahydrate do not exist (the so-called diacetylorthonitric acid, $N(OH)_3(OAc)_2$, is a molecular compound of the pseudo-acid, $[(CH_3.CO_2H)_2HO.NO_2]$).

The reactions between the three strongest oxyacids, perchloric, sulphuric, and nitric, give particularly strong evidence in favour of the chemical theory of acids according to which the strength (acidity) can be measured only chemically by their tendency towards salt formation, and not physically by their ability to furnish hydrogen-ions. According to the ionization theory, perchloric acid is the strongest acid, followed by nitric and then by sulphuric acids. Actually, homogeneous perchloric is incomparably stronger than nitric acid; and sulphuric acid, which is feebly ionized in aq. soln., is in the homogeneous condition stronger than nitric acid, since it causes the production of nitronium sulphate. In aq. soln., the great differences towards salt formation of the three acids are almost annihilated, since water as a basic anhydride. particularly in excess, and hence in dil. soln., converts them almost completely into hydroxonium salts.

§ 44. The Physical Properties of Nitric Acid

The most conc. acid at ordinary temp. can be obtained as a colourless, transparent liquid. J. L. Proust[1] gave 1·62 for the highest **specific gravity** attainable, but this is a much greater value than others have been able to obtain—*e.g.* E. Mitscherlich, and R. Kirwan gave 1·54 at 20°; N. A. E. Millon, 1·55 at 15°; J. Pelouze, 1·52 at 15°; J. Kolb, 1·559 at 0°; and L. J. Thénard, 1·513. V. H. Veley and J. J. Manley found the sp. gr. of the most conc. acid to be 1·54212 at 4°; 1·52234 at 14·2°; and 1·50394 at 24·2°. F. Kohlrausch found the sp. gr. of the normal acid to be 1·0318 at 18°, and E. H. Loomis, 1·0324. Observations have been reported by E. Ruppin, R. Rehyer, G. B. Squire, C. Schultz-Sellack, T. Graham, D. I. Mendeléeff, O. Grotrian, H. Hager, G. W. Muncke, P. T. Meissner, H. Jahn and E. Schüler, W. H. Perkin, W. C. Röntgen and J. Schneider, A. V. Saposchnikoff, N. Tschernay, R. Wegner, and V. S. M. van der Willigen. Collections of data on the sp. gr. of aq. soln. of nitric acid of different concentrations have been made by C. F. Richter, A. Ure, H. Pützer, H. Goebel, F. Winteler, J. Kolb, etc. The results of G. Lunge and H. Rey are indicated in Tables XXXII and XXXIII. They refer to the contents of pure HNO_3; if nitrous acid or nitrogen peroxide be present, there will be less HNO_3 at the same sp. gr.—*vide* Table XXX. The correction for temp. is such that the amount indicated is to be added for every degree below 15°, and sub-

Specific Gravity Corrections.

Sp. gr. .	1·000–1·020	1·020–1·040	1·040–1·070	1·070–1·100	1·100–1·130	1·130–1·160
± .	0·0001	0·0002	0·0003	0·0004	0·0005	0·0006
Sp. gr. .	1·160–1·200	1·200–1·245	1·245–1·280	1·280–1·310	1·310–1·350	1·350–1·365
± .	0·0007	0·0008	0·0009	0·0010	0·0011	0·0012
Sp. gr. .	1·365–1·400	1·400–1·435	1·435–1·490	1·490–1·500	1·500–1·520	—
± .	0·0013	0·0014	0·0015	0·0016	0·0017	—

tracted for every degree above that temp. This correction is applicable only when the temp. are near 15°. The results were confirmed by V. H. Veley and J. J. Manley, and W. R. Bousfield, and afford further evidence of the existence of hydrates in soln. Irregularities with 96–100 per cent. HNO_3 are connected with anhydrous formation. H. C. Jones measured the sp. gr. of dil. soln. and found:

	0·025*N*-	0·05*N*-	0·10*N*-	0·25*N*-	0·50*N*-	*N*-	2*N*-
Sp. gr. .	1·00093	1·00180	1·00350	1·00848	1·01686	1·03360	1·0670

From this and the lowering of the f.p. he inferred that the formation of hydrates does not begin until the soln. is over 0·75*N*. When nitric acid and water are mixed, there is a **contraction**, and J. Kolb found the maximum contraction occurs with a mixture corresponding with $2HNO_3.3H_2O$. On the other hand, F. W. Küster and R. Kremann found that although the vol. changes continuously, there are two deviations. Thus, expressing the vol. change, δv, in thousandths of the vol. at 0°, they found between —15° and 0°:

HNO_3	25	45	50	54	60	70	77·7	80	89·4 per cent.
δv .	6·8	10·6	11·9	11·9	13·2	14·6	13·2	14·2	14·9

The one break occurs with about 54 per cent. HNO_3, and corresponds with $HNO_3.3H_2O$; while the other break occurs with about 77·77 per cent. HNO_3, and corresponds with $HNO_3.H_2O$. These deviations probably represent the formation of the mono- and tri-hydrates. J. N. Rakshit studied this subject. P. Wright found that the temp. of **maximum density** of water is lowered 0·8° in $\frac{1}{16}N$-HNO_3 ; 1·6° in $\frac{1}{8}N$-soln. ; and 3·1° in $\frac{1}{4}N$-soln. V. H. Veley and J. J. Manley found that for acids containing 78 to 99·97 per cent. of HNO_3, the contraction $\times 10^5$ is $4660-205\delta\omega$ at 4° ; $4590-208\delta\omega$ at 14·2° ; and $4623-19\delta\omega$ at 24·2°, where $\delta\omega$ represents the percentage difference of HNO_3. M. Berthelot expressed the **molecular volume** of soln. of nitric acid containing N- mols of water per mol of HNO_3, by mol. vol. $=18N+29+39(N+3{\cdot}2)^{-1}$. W. Grunert found that the sp. gr. of mixtures of nitric acid and potassium nitrate at 20 increased proportionally with the concentration over the whole range examined. S. Sugden discussed the mol. vol. of nitric acid.

The effect of temp. on the sp. gr., or the **thermal expansion** of dil. aq. soln. of nitric acid, has been measured by C. Forch, and W. Ostwald ; and of conc. soln., by F. W. Küster and R. Kremann, who found breaks in the otherwise continuous curve corresponding with $HNO_3.3H_2O$ when 54·00 per cent. HNO_3 is present, and with $HNO_3.H_2O$, when 77·77 per cent. nitric acid is present. V. H. Veley and J. J. Manley measured the coeff. of cubical expansion, α, of nitric acid and found :

	4° to 14·2°				14·2° to 24·2°			
HNO_3	25·5	51·2	75·6	100·0	25·5	51·2	75·6	100·0 per cent.
α .	0·000550	0·000942	0·000088	0·001274	0·000585	0·000907	0·001076	0·001240

G. Forch's results for $\delta v=(v-1)$ are

	5°	10°	15°	20°	30°	40°
0·5N-HNO_3 . .	0·00039	0·00108	0·00203	0·00323	0·00628	0·01011
0·999N-HNO_3 . .	0·00084	0·00190	0·00317	0·00466	0·00817	0·01239
1·998N-HNO_3 . .	0·00153	0·00321	0·00503	0·00699	0·01131	0·01612

Observations were also made by V. H. Veley and J. J. Manley, while W. R. Bousfield found for the sp. gr. of soln. with $\frac{1}{32}N$-HNO_3 to N-HNO_3 :

	N-	$\frac{1}{2}N$-	$\frac{1}{4}N$-	$\frac{1}{8}N$-	$\frac{1}{16}N$-	$\frac{1}{32}N$-
4° . .	1·035801	1·018011	1·009031	1·004533	1·002271	1·001130
11° . .	1·034339	1·017082	1·008386	1·004040	1·001852	1·000748
18° . .	1·032439	1·015616	1·007160	1·002931	1·000802	1·999731
25° . .	1·030163	1·014707	1·005445	1·001309	1·999235	0·998192

The sp. gr. of mixtures of sulphuric and nitric acids was measured by E. Roberts, and P. Pascal and M. Garnier—for some of A. V. Saposchnikoff's results, *vide infra*, electrical conductivity. According to A. Marshall the following represents the sp. gr. of the mixtures at 18°/18° when the sp. gr. of the sulphuric acid is 1·8437, and of nitric acid, 1·5009 :

	0·52	4·67	9·10	22·51	39·49	57·78	72·89	98·19
Sp. gr. .	1·8456	1·8586	1·8605	1·8215	1·7601	1·6879	1·6227	1·5080

D. Colladon and C. Sturm[2] found the coeff. of **compressibility** of nitric acid at 0° between 1 and 32 atm. press. to be 0·000032 ; and W. C. Röntgen and J. Schneider obtained respectively 0·958 and 0·981 for the relative compressibility (water unity) of soln. of nitric acid respectively containing 1500 and 700 mols. of HNO_3 per gram of water. S. Pagliani and E. Oddone found the **viscosity** coeff., η, of nitric acid to be :

HNO_3 .	100	72·85	67·82	64·30	61·56	58·10	53·90 per cent.
η at 0° .	0·02275	0·03276	0·03422	0·03560	0·03459	0·03295	0·02945
η at 10° .	0·01770	0·02456	0·02579	0·02676	0·02604	0·02470	0·02324

If that of water be unity, R. Reyher found the viscosity of N-HNO_3 to be 1·0266 at 25° ; $\frac{1}{2}N$-HNO_3, 1·0115 ; $\frac{1}{4}N$-HNO_3, 1·0052 ; and $\frac{7}{8}N$-HNO_3, 1·0027. T. Graham made some observations on this subject; and F. W. Küster and R. Kremann found water unity at 0°:

HNO_3	98·5	82·0	70·0	65·0	50·0	30·0	10·0
η at 15°	0·548	1·036	1·277	1·300	1·144	0·822	0·655
η at −15°	0·833	2·240	3·268	3·304	2·369	2·635	—

W. R. Bousfield gave for the viscosity coeff. between 4° and 25°:

	4°	11°	18°	25°
N-	0·015487	0·012807	0·010731	0·009176
$\frac{1}{2}N$-	0·015513	0·012684	0·010590	0·009011
$\frac{1}{4}N$-	0·015552	0·012655	0·010546	0·008696
$\frac{1}{8}N$-	0·015586	0·012651	0·010519	0·008943
$\frac{1}{16}N$-	0·015605	0·012663	0·010525	0·008927
$\frac{1}{32}N$-	0·015630	0·012672	0·010528	0·008920
Water	0·015666	0·012672	0·010514	0·008901

These results calculated for water are plotted in Fig. 91. The explanation of the maxima in the curves depends on the complex structure of the water molecule (1. 9, 7). L. J. Simon also studied the viscosity of nitric acid. W. Grunert found that the viscosities of mixtures of nitric acid and potassium nitrate at 20°, increase over the whole range of concentration examined. E. C. Bingham and S. B. Stone measured the fluidity of mixtures of soln. of nitric and sulphuric acids at 10°, 20°, and 40°.

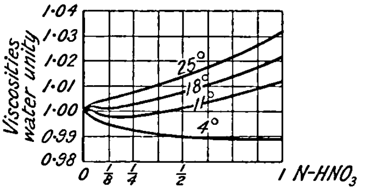

FIG. 91.—Viscosity of Nitric Acid of Various Concentrations at Different Temperatures.

O. Jahnke found the **surface tension,** σ dynes per cm., and the **specific cohesion,** a^2 sq. mm., of nitric acid with p per cent. of HNO_3, at 20°, to be:

p	7·25	9·00	22·00	37·00	50·00	70·00
σ	73·10	72·70	71·48	68·10	65·43	59·36
a^2	14·34	14·07	12·82	11·23	10·13	8·66

E. Aston and W. Ramsay found for nitric acid of sp. gr. 1·5304, σ=41·30 at 11·6°; sp. gr. 1·4696, σ=35·95 at 46·2°; and of sp. gr. 3·806, σ=31·46 at 78·2° (by extrapolation). This gives the molar **surface energy** $\sigma(Mv)^{\frac{2}{3}}$, 492·3, 440·4, and 395·6 ergs, and the results show that liquid nitric acid probably consists of a mixture of mols of HNO_3 and $(HNO_3)_2$. The evidence favours the view that negative curvature is due to some form of dissociation, whilst positive curvature is brought about by solvation. The conc. of the mixture showing the maximum deviation from the linear fluidity-vol. conc. curve is independent of the temp., provided that only one solvate is formed, and in such favourable cases it is believed that this conc. may be utilized for finding the composition of the solvate.

The velocity of **diffusion** of nitric acid in water was studied by S. Arrhenius, J. H. Long, J. J. Coleman, G. Umoff, and J. Stefan. The results of J. D. R. Scheffer at 9°, and of J. Trovert at 19·5°, for the coeff. of diffusion, k, in sq. cm. per day, and with the conc., C mols per litre, are as follow:

C	0·04	0·44	3·56	0·02	0·90	3·90
k	1·73	1·78	1·94	2·12	2·26	2·46

while L. W. Oholm gave for 20°, $2N$-, k=2·150; $1·5N$-, k=2·141; N-, k=2·164; $0·5N$-, k=2·227; $0·1N$-, k=2·246; and for $0·05N$-, k=2·266. Y. Terada measured the speed of dialysis.

About 1777, C. W. Scheele[3] found that when the vapour of nitric acid is passed through a white-hot tube, it decomposes into nitrogen and oxygen; but if the tube is not heated to a very high temp., only oxygen and nitrogen peroxide are formed. P. Braham and J. W. Gatehouse, and H. Böttger said that when nitric acid is heated all the nitrogen oxides as well as nitrogen and oxygen are produced. L. Carius found that nitric acid is entirely decomposed at 256° in accord with the equation $4HNO_3=4NO_2+2H_2O+O_2$; and measuring the progress of the decomposition by the vap. density, D, at different temp. (air unity), he found:

	86°	100°	130°	160°	190°	220°	250°	256°	265°	312°	
D .	2·05	2·02	1·92	1·79	1·59	1·42	1·29	1·25	1·24	1·23	
a .	9·53	11·77	18·78	28·96	49·34	72·07	93·03	100·00	—	—	per cent.
v .	9·43	10·41	16·62	26·22	43·69	63·77	82·30	88·47	—	—	c.c.

The penultimate line represents the calculated percentage decomposition, a; and the last line, the vol. of oxygen, v c.c., obtained per gram of nitric acid. M. Berthelot showed that nitric acid sealed in evacuated tubes and kept in the dark remains unaltered for several weeks at ordinary temp., but at 100°, the nitric acid decomposes into nitrogen peroxide, oxygen, and water. The decomposition is incomplete, and is limited by the water produced, for, under similar conditions, nitric acid of sp. gr. 1·333 suffers no change at 100°. The decomposition can scarcely be regarded as reversible, since the oxygen will combine very slowly with any nitrous acid that may be formed by the action of the nitric peroxide on the water. The decomposition of nitric acid into nitric peroxide, oxygen, and water at 100° would absorb about —6·5 Cals. per mol. of acid. The decomposition of nitric anhydride absorbs much less, hence the instability of this compound. On the other hand, the heat of formation of hydrated nitric acid is much higher than that of the anhydrous acid, hence the greater the stability of the former.

J. C. G. de Marignac [4] found the **specific heat** of soln. with 58·3, 12·3, and 3·4 per cent. HNO_3 to be respectively 0·6651, 0·8752, and 0·9618 between 21° and 52°; and J. Thomsen, for soln. with 26, 15, and 3·4 per cent. HNO_3, respectively 0·768, 0·849, and 0·963 at 18°. T. Thomson, and T. W. Richards and A. W. Rowe also measured the sp. ht. of nitric acid. N. de Kolossowsky discussed the sp. ht. of soln. of the acid. P. Pascal and M. Garnier obtained results for nitric acid, and for mixtures with nitrogen peroxide and with sulphuric acid. They gave for the mean sp. ht. of nitric acid at 20°:

HNO_3 .	10·00	25·27	40·00	45·87	60·52	70·00	81·80	90·33	92·15	98·15	per cent.
N_2O_4 .	—	—	—	—	—	0·70	1·54	2·30	4·22	1·85	„
Sp. ht. .	0·900	0·787	0·669	0·662	0·637	0·610	0·575	0·530	0·500	0·475	

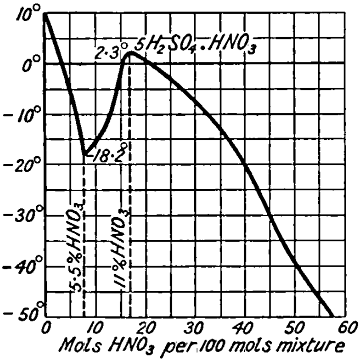

FIG. 92.—Freezing-point Curve of Binary Mixtures: HNO_3–H_2SO_4.

J. Dalton gave —19° for the **melting point** of nitric acid of sp. gr. 1·30; and F. W. Küster and S. Münch for absolute nitric acid —41°. A. Hantzsch and L. Wolf gave —42·3° for the m.p. of absolute nitric acid. This subject has been already discussed in connection with the hydrates of nitric acid, Fig. 92. E. H. Loomis,[5] H. C. Jones, and H. C. Jones and F. H. Getman measured the **lowering of the freezing point** of water by nitric acid, and found that when a litre of soln. contains n mols of HNO_3, the lowering of the f.p., $\delta\theta$, and the calculated percentage ionization, a, for dil. soln. are as follow:

n .	0·001054	0·003158	0·007378	0·1153	0·05103	0·1059
$\delta\theta$.	0·0040°	0·0119°	0·0276°	0·4300°	0·1892°	0·3735°
a .	100	99·4	97·9	97·3	95·8	86·6 per cent.

W. C. Holmes measured the f.p. of mixtures of sulphuric acid with up to 50 per cent. of nitric acid. If no water be present so that the total acidity is 100 per cent. there is a minimum at —18·2° when 5·4 per cent. HNO_3 is present; and a maximum at 2·3° with 10·8 per cent. HNO_3. This corresponds with **nitratopentasulphuric**

acid, $HNO_3.5H_2SO_4$. If the total acidity be 95 per cent., the f.p. falls to —41° with 2·35 per cent. HNO_3; rises to a maximum at —11° with 9·75 per cent. HNO_3; and falls to —41·3° with 49·09 per cent. HNO_3; when the total acidity is 103 per cent., there is a minimum at —12·3° with 8·15 per cent. HNO_3, and a maximum at 10·5° with 15·52 per cent. HNO_3. In both cases, the results are complicated by water and sulphur trioxide respectively.

A. V. Saposchnikoff [6] measured the **vapour pressure** of soln. of nitric acid, at 15°, and his results are as follow:

Sp. gr. . .	1·400	1·453	1·462	1·487	1·497	1·510
HNO_3 . .	65·30	78·10	82·10	88·65	92·93	98·00 per cent.
Pressure .	1·90	9·40	16·64	29·70	42·60	46·20 mm.
N_2 in vapour .	19·32	22·52	22·65	23·05	23·50	23·75 per cent.

Since nitric acid contains 22·22 per cent. of nitrogen, some nitrogen oxides must also be present in the vapour from the conc. acid; and water vapour, from the dil. acid. H. J. M. Creighton and J. H. Githens gave for the vap. press., p mm., at different temp:

HNO_3 .	0	20	30	40	50	60	70	80	90	100 per cent.
p at 75° .	289	260	230	195	155	135	115	170	295	524
p at 85° .	434	290	350	300	250	225	195	250	440	725
p at 95° .	634	554	497	435	375	330	300	375	625	—
p at 100° .	760	663	585	510	450	405	370	450	745	—

The curves thus show a minimum vap. press., Fig. 93, and there is also a corresponding maximum in the b.p. curves. A. Klemenc and A. Nagel found for the partial press., p mm., of water and HNO_3 over aq. soln. of nitric acid at 12·5°, and 30°:

	HNO_3	0	N-	$2N$-	$5N$-	$10N$-	$15N$-	$20N$-	$24N$-
12·5°	p_{HNO}	—	—	0·030	0·0181	0·526	1·19	10·80	25·69
	p_{H_2O}	10·87	10·44	9·99	8·19	4·88	1·22	—	—
30°	p_{HNO_3}	—	—	0·0070	0·0482	0·641	3·28	—	—
	p_{H_2O}	31·77	30·72	29·42	24·07	13·88	2·95	—	—

C. L. Burdick and E. S. Freed also made analogous observations for acid with 24·1 to 69·9 per cent. HNO_3 at 25°, 50°, and 75°. G. B. Taylor tabulated the available data. The vap. press. of mixtures of nitric and sulphuric acids rises and falls with increasing proportions of nitric acid. P. Pascal studied the variations in the conc. of the nitric acid in the vapours emitted on distillation. A. V. Saposchnikoff's results are shown in Fig. 94. The maximum for nitric acid of sp. gr. 1·40 occurs at 23·5 mm. with 45 per cent. HNO_3; for nitric acid of sp. gr. 1·48, at 34 mm. with

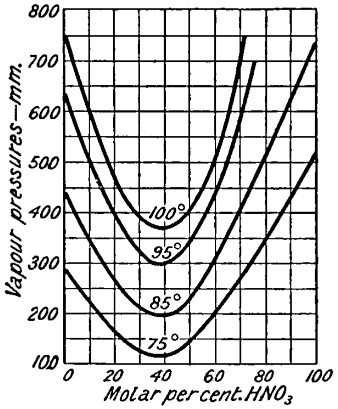

FIG. 93.—Vapour Pressure Curves of Nitric Acid.

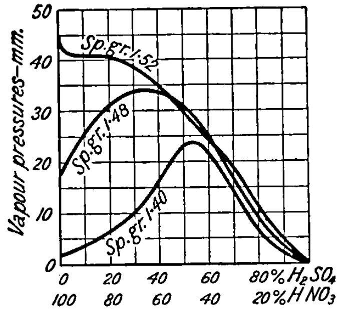

FIG. 94.—Vapour Pressures of Mixtures of Nitric and Sulphuric Acids.

67 per cent. HNO_3; and with an acid of sp. gr. 1·52, the value falls to from 46 mm. to 41 mm. with about 92 per cent. HNO_3 and remains constant to about 80 per cent. HNO_3, when it falls steadily as indicated in the diagram, Fig. 94. E. Oeman found the constant boiling acid contains 68 per cent. HNO_3; and the distillation curve shows that at conc. over 92 per cent. HNO_3, dissociation does not occur in accord with the electrical conductivity measurements. W. C. Sproesser and G. B. Taylor measured the vap. press. of 20–80 per cent. acids between 0° and 80°. With acid above 90 per cent. HNO_3, decomposition occurred at all temp. above 0°.

H. E. Roscoe said that the **boiling point** of the most conc. acid is 86° at 760 mm. press., but decomposition occurs before this temp. is attained; and H. Erdmann gave 21·5° at 24 mm. press. The influence of press. on the b.p. given by H. J. M. Creighton and J. H. Githens for an acid with 99·7 per cent. HNO_3 is as follows:

Press.	47	60	110	203	290	360	500	675 mm.
B.p.	22·1°	26·2°	35·6°	49·0°	57·1°	63·4°	72·7°	82·5°

Their results for the boiling points of aq. soln. of nitric acid of different conc. and at different press. are given in Table XXXIV. J. Dalton pointed out that when conc. or dil. soln. of nitric acid are boiled at atm. press., the b.p. gradually rises to 120·5°, and the composition of the distillate then does not change. The fact was subsequently confirmed by E. Mitscherlich, N. A. E. Millon, A. Smith, A. Bineau, and H. W. F. Wackenroder. The soln. of constant b.p. was found by H. E. Roscoe to contain 68 per cent. of HNO_3, and to have a sp. gr. of 1·414 at 15·5°. If this soln. be distilled under an increased or decreased press., the composition of the constant boiling soln. has a different concentration for each change of press. In illustration, H. J. M. Creighton and J. H. Githens found the maximum b.p. is 121·70° and 760 mm. when 68·18 per cent. HNO_3 is present; 99·9° at 360 mm. when 67·15 per cent. HNO_3 is present; and 74·2° at 110 mm. when 66·8 per cent. HNO_3 is present. Hence, argued H. E. Roscoe, the soln. with 60 per cent. of HNO_3 does not contain a definite hydrate; if it did, the composition would remain constant through a definite range of press. and temp. The b.p. curves of nitric acid for 760 mm. and 360 mm. are shown in Fig. 97. C. D. Carpenter and J. Babor distilled dil. nitric acid without a fractionating column, and found that with successive portions

Table XXXIV.—Boiling Points of Nitric Acid of Different Concentrations and at Different Pressures.

Per cent. HNO_3	Molecular per cent. HNO_3	Boiling point.				Vapour pressure mm.

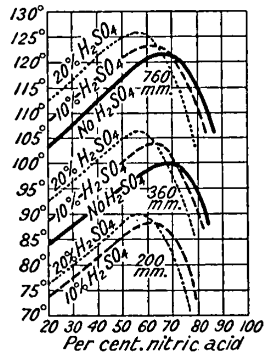

Fig. 95.—Boiling Points of Solutions of Nitric Acid with and without Sulphuric Acid.

of the distillate there was a loss of 3 per cent. of the nitric acid in concentrating from 10 per cent. to 20 per cent. HNO_3, 9·3 per cent. between 20 and 30 per cent. HNO_3, and 20·9 per cent. between 30 and 40 per cent. HNO_3. The curve representing the relation between the vol. of the residual soln. and the conc. of nitric acid contained therein is a regular hyperbola, terminating at a point corresponding to the constant b.p. mixture. Concentration under the conditions described is therefore not economically possible.

The effect of sulphuric acid on the b.p. was measured by H. J. M. Creighton and H. G. Smith, and the results are indicated in Fig. 95. P. Pascal represented the b.p. of the ternary system: HNO_3–H_2SO_4–H_2O, as a surface over the triangular diagram; this subject was also examined by M. Kaltenbach. H. J. M. Creighton and H. G. Smith showed that the presence of potassium hydrosulphate in the nitric acid raises the b.p. of the mixture, but this is not attended by any appreciable change in the composition of the mixture of maximum b.p., but additions of sulphuric acid to aq. nitric acid cause a decrease in the HNO_3 content of the mixture of maximum b.p., and this the more the greater the amount of H_2SO_4 present. Thus, at 760 mm. press. the maximum b.p. occurs at 68·18 per cent. HNO_3 with no sulphuric acid; with 64·5 per cent. HNO_3 and 10 per cent. H_2SO_4; and with 59·2 per cent. HNO_3 and 20 per cent. H_2SO_4. Hence, with 68 per cent. aq. soln. of nitric and 20 per cent. sulphuric acids, a conc. acid distils over until acid of maximum b.p. is obtained. This shows why 68–69 per cent. HNO_3 soln. of nitric acid can be conc. to over 90 per cent. HNO_3 by distillation with conc. sulphuric acid; potassium hydrosulphate is of little use in this direction. The effect of reducing the press. is to make the mixture of maximum b.p. still less conc., and thus favour the concentration of the more conc. acid. The distillation of these mixtures was further studied by P. Pascal and M. Garnier, E. Galle, J. Baumann, L. Ramberg, and E. Berl and O. Samtleben. E. Oeman said that no dissociation occurs in the distillation of acid of conc. over 92 per cent.

The **heat of formation** given by J. Thomsen[7] is (H,N,3O)=41·51 Cals.; (H,NO,2O) =63·085 Cals.; (NO_2,O,H)=43·515 Cals.; and $\frac{1}{2}(N_2O_4,O,H_2O)$=18·67 Cals. M. Berthelot gave (H,N,3O)=34·0 Cals. for the gas, 41·6 Cals. for the liquid, 42·2 Cals. for the solid, and 48·8 Cals. for the soln. M. Berthelot gave 7·18 Cals. for the **heat of solution,** and J. Thomsen, 7·49 Cals. The former also gave the following data marked B, and J. Thomsen those marked T, for the heat of dilution of a mol of HNO_3, with *n* mols of water, at 10°:

n	0·5	1·0	1·5	2·0	3·0	4·0	5·0
Cals. B	2·03	3·34	4·16	4·86	5·76	6·39	6·76
Cals. T	2·005	3·285	4·16	—	5·71	—	6·665
n	6	8	10	20	40	100	200
Cals. *B*	6·98	7·22	7·27	7·36	7·27	7·21	7·18
Cals. *T*	—	—	7·318	7·458	7·436	7·439	7·493 (320)

He also found 7580 cals. for the heat of soln. of a mol of HNO_3 in 320 mols of water; for $HNO_3.H_2O$, 4280 cals.; for $HNO_3.2H_2O$, 2740 cals.; and for $HNO_3.3H_2O$, 1830 cals. Observations were also made by G. Rousseau and G. Tite, S. U. Pickering, T. W. Richards and A. W. Rowe, and J. Petersen. M. Berthelot gave for the **heat of fusion** of HNO_3, 9·54 Cals. per gram, or 601 Cals. per mol; and for the **heat of vaporization,** 115·1 Cals. per gram, or 7250 Cals. per mol. For the **heat of neutralization** of HNO_3 with an eq. of sodium hydroxide, M. Berthelot gave 13·68 Cals.; potassium hydroxide, 13·77 Cals.; ammonium hydroxide, 12·32–12·6 Cals.; thallium hydroxide, 13·69 Cals.; calcium hydroxide, 13·9 Cals.; strontium hydroxide, 13·9 Cals.; barium hydroxide, 13·9–14·13 Cals.; magnesium hydroxide, 13·76 Cals.; zinc hydroxide, 9·8–9·915 Cals.; cadmium hydroxide, 10·16 Cals.; manganese hydroxide, 11·475 Cals.; ferrous hydroxide, 10·475 Cals.; cobaltous hydroxide, 10·55 Cals.; nickelous hydroxide, 10·55 Cals.; cupric hydroxide, 7·445 Cals.; cupric oxide, 7·625 Cals.; silver oxide, 5·2–5·44 Cals.; mercuric oxide, 3·105–3·65 Cals. (R. Varet); mercurous oxide, 2·895–9·1 Cals. (R. Varet); lead oxide, 8·385–8·885 Cals.; and uranyl hydroxide, H_2UO_4, 4·2 Cals. (J. Aloy). P. Dutoit and E. Grobet measured the rise of temp. during the progressive neutralization of various bases with nitric acid with the idea of detecting the formation of basic salts, etc. J. H. Mathews and A. F. O. German gave for $2N$-, $1N$-, $\frac{1}{2}N$- and $\frac{1}{4}N$-NaOH, respectively 13·636, 13·614, 13·647, and 13·548 Cals.; and A. Wörmann

	6°			18°			32°		
	$\frac{1}{4}N$-	$\frac{3}{16}N$-	$\frac{1}{8}N$-	$\frac{1}{4}N$-	$\frac{1}{8}N$-	$\frac{1}{20}N$-	$\frac{1}{4}N$-	$\frac{1}{8}N$-	$\frac{1}{20}N$-HNO_3
KOH	14·472	14·402	14·405	13·912	13·838	13·864	13·103	—	13·087 Cals.

Observations on this subject were also made by T. W. Richards and A. W. Rowe, T. Andrews, and J. Thomsen. D. D. Karve studied the heats of soln. in alcohol, and ether. The heat developed by oxidizing reactions with nitric acid was discussed by M. Berthelot in 1880. J. W. McDavid studied the heat developed on mixing soln. of nitric and sulphuric acids, and his results, expressed in gram-calories per gram of product—when the mixed acid is produced from 100 per cent. nitric acid, 100 per cent. sulphuric acid, and water—are shown in Fig. 96. C. L. Burdick and E. S. Freed calculated the free energy of nitric acid vapour at 10°, 50°, and 75° to be respectively, −16,750 cals., −16,240 cals., and −14,720 cals.; or, at $T°$ K., $-25510+31T$; and for soln. of nitric acid:

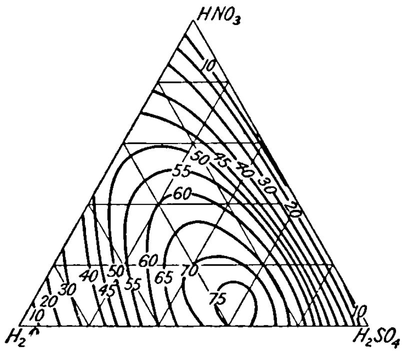

FIG. 96.—Heat developed on Mixing Nitric and Sulphuric Acids and Water.

HNO_3		5	10	20	30	40	50	60	70 per cent. wt.
Free Energy	25°	−24250	−23560	−22820	−22190	−21570	−20900	−20190	−19350
	50°	−23040	−22270	−21410	−20640	−20040	−19370	−18700	−18000
	75°	−21700	−20770	−19820	−19070	−18440	−17780	−17110	−16500

The **index of refraction** μ, of nitric acid was measured by J. H. Gladstone,[8] and J. H. Gladstone and W. Hibbert found that the value is changed only a little by dilution. J. W. Brühl found for the D-line with nitric acid of sp. gr. 1·50999 at 20°/4°, $\mu=1·39584$, and with an acid of sp. gr. 1·50875, $\mu=1·36870$; the corresponding mol. **dispersion** was 0·338 and 0·340. V. H. Veley and J. J. Manley found for sodium light at 14·2°:

HNO_3	2·19	11·88	70·04	71·57	89·88	95·66	98·67	99·87 per cent.
μ	1·336208	1·349371	1·406094	1·406046	1·401419	1·398148	1·396908	1·397167

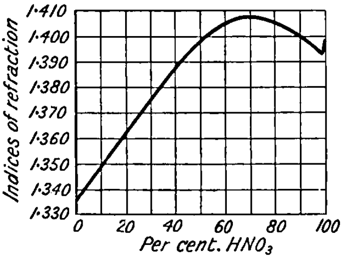

FIG. 97.—Refractive Indices of Nitric Acid.

There is a slow increase as the conc. of the acid increases up to about 70 per cent. HNO_3 when a maximum is attained—Fig. 96; the values then decrease slowly to about 91 per cent. HNO_3, and thereafter more quickly to 98·67 per cent. HNO_3 when there is a slight increase. The value for the anhydrous acid is nearly the same as that for an acid with 50 per cent. HNO_3. J. H. Gladstone gave 17·24 for the **refraction equivalent** of nitric acid. J. A. Wasastjerna made observations on this subject. J. C. Ghosh and S. C. Bisvas measured the extinction coeff. in the ultra-violet. C. V. Raman found that the light scattered by dust-free nitric acid is nearly always unpolarized; and he said that W. L. Bragg's observations on the scattering of light by nitric acid support the hypothesis that the nitric acid molecule and the NO_3-ion are anisotropic. S. Venkateswaran, C. V. Raman, and C. W. Sweitzer studied the scattering of light by nitric acid. W. H. Perkin measured the **magnetic rotatory power** at 15°, and found the specific rotation, the molecular rotation, and the molecular rotation less that of water, to be :

HNO_3 . . .	99·45	56·44	32·36	26·81	22·54 per cent.
Specific rotation .	0·5292	0·8042	0·9066	0·9238	0·9350
Molecular rotation .	1·226	3·678	8·163	10·360	12·783
Mol. rot. less water .	1·207	0·977	0·852	0·805	0·753

C. Féry examined the effect of the progressive addition of sodium hydroxide to a soln. of nitric acid on the index of refraction, and found the maximum deviation corresponded with the ratio $NaOH : HNO_3$. R. Wachsmuth made some measurements of this constant. W. N. Hartley observed the **absorption spectra** of nitric acid and found that with 89·60 per cent. HNO_3, the spectrum is continuous to 2644 with a weak extension at 3685, and between 2718 and 2743 ; with 72·57 per cent. acid, the spectrum is continuous to 3079 with a weak extension between 3105 and 3150 ; and with acids between 69·80 and 2031 per cent. HNO_3, the spectrum is continuous to 3079. The acid of sp. gr. 1·432 in thickness 2 mm. transmits a longer spectrum than the same acid diluted to 36 times its vol. in thickness 100 mm. The marked changes in the spectra with acids of sp. gr. approximating 1·432 are 1·490, led to the assumption that there is some chemical action going on between the water and the acid, when the conc. change. K. Schaefer and co-workers found that soln. of the nitrates exhibit selective absorption, while the alkyl nitrates cut off only the ultra-violet end of the spectrum. Dil. nitric acid has a spectrum like that of the salts, but with a conc. above $2N$-HNO_3, the ester type appears, and with the conc. acid, there is only continuous absorption. The absorption spectrum of nitric acid vapours is very like that of 98·7 per cent. HNO_3. Hence, the NO_3-group in the vapour is very similar to that in the ester, and the conc. acid. The absorption limit of $0{\cdot}2N$-HNO_3 is displaced towards the ultra-violet by 20 per cent. of sulphuric acid, and at the same time, the absorption curve is flattened ; this effect increases with increasing conc. of sulphuric acid. Sulphuric acid displaces the equilibrium between the two types of the nitrate spectrum. Observations were also made by G. Massol and A. Faucon, W. J. Pope, R. A. Morton and R. W. Riding, and by E. Siegler-Soru. E. C. C. Baly and co-workers found that in alcoholic soln. the ester type of absorption occurs, and in aq. soln. increasing dilution brings out the nitrate bands more clearly, corresponding with W. N. Hartley's suggestion that the band is due to ionized nitrate. C. Schaefer and M. Schubert found that the ultra-red reflection spectra of a number of nitrates show λ^{-1} three maxima, at approximately $7{\cdot}5\mu$, $12{\cdot}5\mu$, and $15{\cdot}0\mu$; in addition, mercurous nitrate shows a fourth maximum at $10{\cdot}08\mu$ with ordinary light. The three maxima, observed with the biaxial nitrates, with ordinary light, are made up of three components corresponding respectively with the vibrations parallel to the axes of the three indices of refraction. The characteristic vibrations, as in the case of the carbonates and sulphates, depend very slightly on the metal, and are due to internal vibrations of the NO_3-group, which are practically the same in all the nitrates examined.

According to F. Kohlrausch and O. Grotrian,[9] the **electrical conductivity** of nitric acid increases as the conc. increases up to 30–33 per cent. HNO_3 and thereafter decreases. Measurements were also made by H. Crompton, E. Bouty, F. W. Küster and R. Kremann, R. Lenz, etc. According to V. H. Veley and J. J. Manley, the specific conductivity of nitric acid in $K \times 10^8$ mercury units at 15° is :

HNO_3 .	1·30	3·12	20·11	30·42	51·78	78·96	94·32	98·50	99·34 per cent.
$K \times 10^8$	632·06	1440·6	6363·8	7008·2	5554·2	1945·1	207·8	167·81	387·34

The more detailed results, plotted in Fig. 98, show that the conductivity rapidly increases with concentration up to a maximum at about 30 per cent. HNO_3, and then there is a decrease until a minimum is reached with 96·12 per cent. HNO_3. F. W. Küster and R. Kremann detected two irregularities in the conductivity curve of soln. containing 25 and 50 per cent. of HNO_3 corresponding respectively with the tri- and monohydrates; and a third irregularity with between 96–100 per cent. HNO_3, at which the concentration irregularities occur with sp. gr. and f.p. curves, and is concerned with the formation of the anhydride. A. Hantzsch and L. Wolf could detect no minimum in the conductivity of soln. of nitric acid. The minimum value for the conductivity of 99·5 per cent. HNO_3 is 89×10^{-4} at 0°, whereas an almost absolute acid gave 94×10^{-5} at $-40°$. Observations on dil. soln. were made by W. Ostwald, S. Arrhenius, E. H. Loomis, H. C. Jones and F. H. Getman, etc. According to F. Kohlrausch and O. Grotrian, the eq. conductivity, λ, for soln. with a mol of HNO_3 in v litres of water at 18° is:

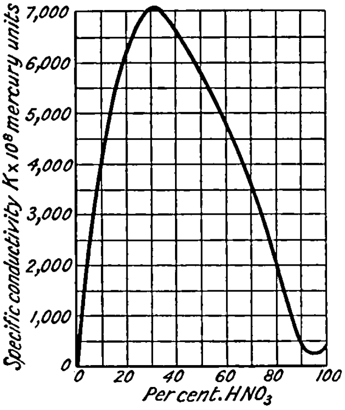

FIG. 98.—Specific Electrical Conductivity of Nitric Acid at 15°.

v	0·1	0·2	0·5	1	2	5	20	100	500	1000
λ	65·4	156	258	310	324	340	357	368	375	(375)

S. Arrhenius gave for the conductivity, λ, at $\theta°$, $\lambda = \lambda_0 e^{-0{\cdot}0014\theta}(1 + 0{\cdot}0157\theta)$; there is a maximum value for the conductivity at 167°, *i.e.* when $(1 + 0{\cdot}0157\theta)0{\cdot}0014 = 0{\cdot}0014$. Working with soln. containing M milliformula-weight per litre at 4°, A. A. Noyes found the effect of temp. on the conductivity of the soln. to be:

		18°	25°	50°	75°	100°	128°	156°	218°	306°
M	0·5	374·0	417·0	563·9	697·2	815·0	930·9	1029·0	—	—
	2·0	371·2	413·7	558·8	689·7	786·0	919·0	1012·0	1166	1158
	10·0	365·0	406·0	548·0	676·0	782·7	893·0	978·0	—	—
	12·5	363·9	405·0	546·2	673·4	750·1	887·0	972·0	—	—
	50·0	353·7	393·3	528·6	649·4	751·2	847·4	921·4	—	—
	80·0	349·0	388·0	521·0	637·0	735·0	827·0	873·0	926	454
	100·0	346·4	385·0	515·9	632·5	729·9	820·0	885·7	—	—

E. Bouty found that nitrates dissolved in conc. nitric acid raise the conductivity in proportion to the amount dissolved. A. Klemenc and R. Schöller measured the conductivity of mixtures of nitrous and nitric acids, but obtained no definite evidence of the existence of $H_2N_3O_8$. Observations on the temp. coeff. were made by F. Kohlrausch and O. Grotrian, C. Déguisne, and J. and G. E. Gibson. According to S. Arrhenius, the temp. coeff. between 18° and 52°, is:

v	2	10	100	1000	∞
Temp. coeff. . . .	0·0143	0·0147	0·0152	0·0154	0·0157

V. H. Veley and J. J. Manley said that nitric acid at conc. above 94 per cent. HNO_3 behaves like a metallic conductor in having a negative temp. coeff. H. C. Jones found for the mol. conductivity, μ, and percentage **degree of ionization,** α, for soln. with a mol of the salt in v litres at 0°.

v	0·5	1·0	2	4	10	20	40	60
μ	177·15	203·72	216·63	222·82	226·24	233·88	234·89	238·07
α	74·71	85·93	91·38	93·99	95·43	98·65	99·08	100·00

It is inferred that in dil. soln. there is no tendency to form hydrates; and from the f.p. data, it is concluded that hydration does not begin until the soln. is 0·75N-. For soln. with M mols of HNO_3 per litre, he calculated that H mols of water were in combination with a mol of the salt at the given conc. of a litre of the soln., at that conc., contained 1000 grms. of water.

M	0·6	0·8	1·0	12·0	3·0	4·0	5·0	6·0
H	2·07	3·41	3·76	5·06	5·18	6·02	5·83	5·09

H. Crompton found that the second differential coeff. of the electrical conductivity and the composition of soln. agree with the presence of the hydrates $HNO_3.4H_2O$, and $HNO_3.15H_2O$—*vide* sulphuric acid. S. Arrhenius gave —1362 cals. for the **heat of ionization** with $0{\cdot}1N$-HNO_3 at 35°, for $v=10$; and J. Petersen, —2800 cals. for $u=1{\cdot}5$ to 6·0. W. Bein obtained 0·172 for the **transport number** of the anion of nitric acid in $0{\cdot}05N$-soln. at 25°; H. Jahn and D. Bukschnewsky, 0·170 at 18° with $0{\cdot}00N$- to $0{\cdot}25N$-soln.; and A. A. Noyes and Y. Kato, 0·156 at 20° with $0{\cdot}06N$-soln., and 0·160 in $0{\cdot}007N$- to $0{\cdot}02N$-soln. The NO_3-ion is one of the most electronegative of ions, and its velocity at 18° under a potential gradient of one volt. per cm. is $6{\cdot}18\times10^{-4}$ cm. per second. P. Walden measured the ionic velocities in acetone soln.; and he calculated the diameter of the NO_3'-ion to be $2{\cdot}57\times10^{-8}$ cm. R. T. Lattey discussed the application of the dilution law. V. H. Veley and J. J. Manley concluded from their observations on the electrical conductivity that there is no simple substance of the composition represented by the formula HNO_3; *the substance represented by the formula* HNO_3 *is an ideal because it is really a mixture of* HNO_3, N_2O_5, *and* H_2O. For the affinity constants, *vide* sulphuric acid.

M. Faraday found that a very conc. soln. of nitric acid is a good conductor and, on electrolysis, develops oxygen at the anode, while in the vicinity of the cathode, the liquid is coloured first yellow and then red. If the acid be diluted with more than its own vol. of water, hydrogen is also given off at the cathode, and this the more, the less the concentration of the acid. "The acid which gave no gas at the cathode with a weak voltaic battery did evolve gas with a stronger; and that battery which evolved no gas there with a strong acid, did cause evolution with an acid more dilute." The amount of oxygen liberated by conc. and dil. acids corresponds with the readings of the coulombmeter, and likewise also the acid if it has a sp. gr. below 1·24. C. F. Schönbein, and E. A. Bourgoin found that with a very dil. acid some nitrogen, nitrous acid, and ammonia are formed at the cathode, and E. A. Bourgoin later observed the formation of nitrous oxide and hydroxylamine. Analogous observations were made by T. Bloxam, C. Luckow, G. Vortmann, P. A. Favre, and A. Brester. The nature of the products obtained by the electro-reduction of nitric acid naturally depends on the temp., concentration of soln., degree of acidity, nature of electrode, current strength, and potential. W. Zorn obtained only hyponitrites (*q.v.*) when using a mercury cathode; and K. Ulsch, ammonia, with a copper cathode. E. Müller and co-workers obtained nitric oxide at the cathode during the electrolysis of 40 per cent. nitric acid containing 1 per cent. of nitrous gases in soln. According to H. J. M. Creighton, when a soln. of nitric acid is electrolyzed in a cell in which the anode and cathode are separated by a porous diaphragm, conc. of the acid occurs through electrolytic decomposition of water, and at the same time the conc. of the acid in the anolyte is increased at the expense of that in the catholyte on account of the different migration velocities of the hydrogen and nitrate ions. The acid in the catholyte is further reduced by reduction to nitrogen oxides, hydroxylamine, or ammonia, according to the nature of the cathode metal. Experiments were made in which 70–71 per cent. nitric acid was electrolyzed in a diaphragm cell using platinum electrodes, and provision was made for returning the gaseous nitrogen oxides formed in the anode chamber back to the catholyte chamber. With a current of 6 to 8 ampères and an e.m.f. of 3·0 to 6·5 volts, it was found possible thus to increase the conc. of acid in the anode chamber to 99·65 per cent. HNO_3.

J. Tafel found that while nitric acid is reduced only to hydroxylamine (*q.v.*) by mercury or well-amalgamated electrodes, a copper cathode reduces it to ammonia and at the same time has no action on hydroxylamine. A. Brochet and J. Petit studied the electro-reduction of nitric acid by an alternating current. T. H. Jeffery described the electrolysis of nitric acid with a gold anode, and obtained from the anode liquor crystals of aurinitric acid, $HAu(NO_3)_4.3H_2O$. R. Ihle's observations on the **oxidation-potential** of nitric acid have been discussed in connection with nitrous acid (*q.v.*). He found that if the conc. of the nitric acid be expressed by

C per cent. by vol.; and the e.m.f. of the cell Pt | HNO_3 | $ZnSO_4$ | Zn, by *E* volts, the potential of HNO_3 : Pt becomes:

C . .	95·54	76·94	57·70	35·04	15·27	6·30
E . .	2·045	1·999	1·960	1·890	1·746	1·706
Potential .	1·28	1·23	1·19	1·12	0·98	0·94

The calculations are uncertain because of the unknown nature and conc. of the products of the reaction. The presence of nitrous acid lowers the oxidation potential which increases the rate of oxidation. A. Klemenc and R. Schöller measured the conductivity of mixtures of nitrous and nitric acids; and A. V. Saposchnikoff, of mixtures of sulphuric and nitric acids at 25° and found for the sp. conductivity *K*, and sp. gr. *D*:

HNO_3 .	100	90·31	70·69	40·67	12·54	10·68	7·80	0 per cent.
D .	1·5100	1·5670	1·6608	1·7898	1·8807	1·8810	1·8734	1·8380
K .	0·04797	0·05175	0·06592	0·07145	0·09052	0·09547	0·10130	0·01458

H. F. Vieweg found that air bubbled through nitric acid of less conc. than 0·0003*N* acquires a negative charge, and if of greater conc. a positive charge (0·1*N*-$NaNO_3$ unity). H. Wild studied the electrocapillary curves of nitric acid in different menstrua. S. Wosnessensky measured the contact potential of soln. of nitric acid in water and in isoamyl alcohol; and E. Baur also used several other organic liquids in place of this alcohol. W. Wild measured the electrocapillary action of nitric acid in liquid ammonia soln.

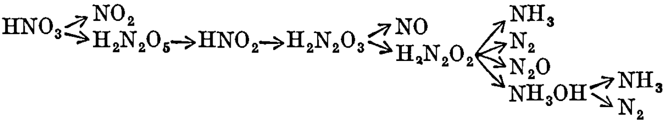
§ 45. The Chemical Properties of Nitric Acid

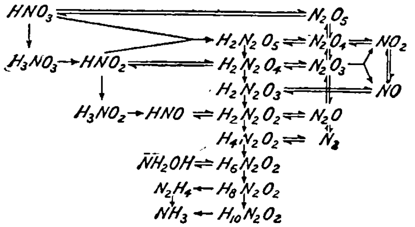
Nitric acid has a peculiar, pungent, and not very powerful smell. It is very corrosive and produces painful wounds on the skin.[1] The burn produced by sulphuric acid is greyish-brown, that produced by nitric acid is bright yellow, and that produced by the mixed acids is reddish-brown with a faint yellow tinge, most distinguishable at the margin of the burn. With more severe burns, there is congestion, and bullæ are quickly formed. As pointed out by J. R. Glauber and R. Boyle, nitric acid gives a bright yellow coloration with hair, wool, wood, etc. Its action on organic matter is rapid. It acts by forming nitric esters or nitro-substitution products. F. C. Calvert said that nitric acid diluted 1 : 1,000 prevents the development of neither fungi nor protoplasmic life.

The electrical conductivity, the lowering of the f.p., the rate of hydrolysis of methyl acetate, and the inversion of cane-sugar, by W. Ostwald[2] have shown it to be one of the most powerful of the monobasic acids. It is therefore very active chemically and it usually behaves as an oxidizing agent, and is itself reduced. S. Genclin described a demonstration experiment to show the reduction of nitric acid to nitrous acid by zinc. The nature of the reduction products depends on the conditions. As previously indicated, there may be produced nitrous acid, nitrogen peroxide, nitric oxide, nitrous oxide, nitrogen, ammonia, hyponitrous acid, and hydroxylamine—and possibly *nitrohydroxylaminic acid*, $H_2N_2O_3$. W. Ostwald has expressed these remarkable results in the language of the ionic hypothesis, by assuming that the simple acid, $(HO)NO_2$, can ionize $HNO_3 \rightleftharpoons NO_2^{\cdot} + OH'$; the hydrate, $(HO)_3NO \rightleftharpoons NO_2H^{\cdot\cdot} + 2OH' \rightleftharpoons NO + 3OH'$; and the hydrate, $(HO)_5N \rightleftharpoons NOH^{\cdot\cdot\cdot\cdot} + 4OH' \rightleftharpoons N^{\cdot\cdot\cdot\cdot\cdot} + 5OH'$. The electrification of the positive ions is supposed to be discharged by the reducing agent. J. J. Acworth and H. E. Armstrong hold that the direct reduction products of nitric acid are nitrous acid, hyponitrous acid, hydroxylamine and ammonia, while nitrogen peroxide, nitric oxide, nitrous oxide, and nitrogen are produced by secondary reactions; thus, for nitrogen peroxide, $HNO_3 + HNO_2 = 2NO_2 + H_2O$; for nitric oxide,

$3HNO_2=2NO+HNO_3+H_2O$; for nitrous oxide, $H_2N_2O_2=N_2O+H_2O$, and $HNO_2+NH_2OH=N_2O+2H_2O$; and for nitrogen, $H_2N_2O_2+2NH_2OH=2N_2+4H_2O$, and $HNO_2+NH_3=N_2+2H_2O$. The special conditions required to secure that one of these products predominates, have been discussed in connection with the particular compounds. L. H. Milligan postulates the existence of G. Oddo's nitrosic or *nitrosonitric acid*, $H_2N_2O_5$—*vide supra*—and assumes the transient formation of A. Angeli's nitrohydroxylamic acid, $H_2N_2O_3$—*vide infra.* He symbolizes the reduction of nitric acid:



V. Schvonen's conclusions are indicated in connection with hydroxylamine. The play of reductions and oxidations, and of hydrations and dehydrations when nitric acid is in contact with the different metals, is thus symbolized by E. J. Joss, where the lines directed vertically downwards represent reductions; and horizontal lines, the gain or loss of water mols.; and the reductions due to hydrogen are assumed to involve hydrogenations by the addition of one or more mols. of hydrogen to a mol. of the compound to be reduced:



The action of heat on the vapour and the decomposition of the soln. during distillation have already been discussed. P. Braham and J. W. Gatehouse said that pure nitric acid is not decomposed during ebullition, but if a trace of nitrous acid be present, decomposition occurs. The vapour of nitric acid is decomposed when passed through a red-hot tube, forming oxygen and nitrogen peroxide, but at a higher temp., E. Mitscherlich showed that nitrogen and oxygen are formed. H. Böttger devised an apparatus for demonstrating the reaction. A. Hantzsch and L. Wolf found that absolute nitric acid is stable at —40°; the 99·5 per cent. acid is unstable at 0°; but the 98·4 per cent. acid can be kept some days at moderate temp. In 1777, C. W. Scheele recorded that nitric acid of sp. gr. not less than 1·4 is decomposed by sunlight whereby the liquid becomes yellow, and oxygen is evolved. J. L. Gay Lussac, J. Fiedler, and W. H. A. Peake confirmed this fact. According to M. Berthelot, the reaction: $4HNO_3=2N_2O_4+2H_2O+O_2$, which takes place when nitric acid is exposed to light is endothermal; and it does not take place in dil. soln. A soln. of sp. gr. 1·365 corresponding with 60 per cent. acid underwent no appreciable change during several weeks' exposure. W. C. Reynolds and W. H. Taylor obtained evidence of a slow decomposition even with 10 per cent. acid. C. F. Schönbein observed that nitric acid of sp. gr. 1·35 in darkness is decomposed at 0° if in presence of platinum black. V. H. Veley and J. J. Manley suggested that the decomposition in sunlight is rather a decomposition of the vapour than of the liquid. P. Braham and J. W. Gatehouse reported:

> Pure nitric acid placed in a full bulb, sealed, and exposed several days to sunlight, remained colourless, and without evolution of gas; but the same acid exposed to sunlight in a sealed tube only partially full was powerfully decomposed, yielding over 1 per cent. of

nitrous acid and a considerable amount of gas. This action in sealed tubes is not continuous; for when the nitrous acid formed attains to about 2 per cent. of the quantity of nitric acid present, all decomposition ceases. This dissociation by sunlight is due to the violet end of the spectrum, the red end having no effect whatever.

This result was confirmed by W. C. Reynolds and W. H. Taylor, who showed that no decomposition occurs if the vapour be screened from light. They also found that M. Berthelot's statement that the reaction is not wholly reversible is inaccurate. The reaction is reversible because the products of the decomposition slowly recombine in the dark. M. Berthelot was probably misled by the slowness of the reverse reaction. The reaction is represented: $4HNO_3 \rightleftharpoons 2H_2O + 2N_2O_4 + O_2$, but it is probable that the decomposition takes place in stages involving first the production of nitrous acid and oxygen, and the nitrous and nitric acid then produce water and nitrogen peroxide. Samples of acid with 70 and 90 per cent. HNO_3 remained colourless if stored many weeks in sealed tubes in darkness, but the 100 per cent. acid remained colourless for a few weeks, while in 12 months, the acid was bright yellow and the tube had developed an oxygen press. of 9·7 atm. With the pure acid, in darkness, there is an induction period occupying about a month, the reaction then proceeds slowly, and after many months, reaches a state of equilibrium. The difference between absolute nitric acid and conc. soln. of that acid may be due to the presence of a trace of nitrogen pentoxide in the vapour, since A. V. Saposchnikoff, and V. H. Veley and J. J. Manley have shown that a measurable amount of the pentoxide is present in the vapour over nitric acid with an excess of sulphuric acid. On the other hand, mixtures of equal vols. of purified nitric and sulphuric acids have been kept nine months in darkness without change of colour or the liberation of any oxygen. M. Berthelot found that radium rays decompose the acid in the same way as sunlight does.

A. F. de Fourcroy said that **hydrogen** does not affect nitric acid at ordinary temp., but when hydrogen mixed with the vapour of the acid is transmitted through a red-hot tube, there are detonations attended by the formation of nitrogen. M. Berthelot also showed that at ordinary temp. and at 100°, free hydrogen does not decompose the acid. F. Kuhlmann found that a mixture of hydrogen and nitric acid vapour forms ammonia when passed through a red-hot tube containing spongy platinum. The so-called nascent hydrogen, however, will reduce the acid, forming products which vary with the conc. of the acid—*vide* ammonia, and other lower oxides formed by the reduction of nitric acid. If the acid is very dilute, E. A. Bourgoin, and J. H. Gladstone and A. Tribe found that it is not much affected by nascent hydrogen. J. H. Gladstone and A. Tribe, and M. N. and S. C. Banerjee found that the conc. acid is rapidly reduced by hydrogen occluded by platinum or palladium; while T. E. Thorpe, and J. H. Gladstone and A. Tribe found that nitrates are reduced to ammonia by the copper-zinc couple, and that reduction is electrolytic, for it takes place at the surface of the copper. According to C. F. Schönbein, nitric acid which can be distilled without the formation of nitrogen peroxide, gives ruddy fumes of that gas when heated in the presence of platinum black, and as indicated above this agent favours the decomposition of the acid in darkness. According to W. R. E. Hodgkinson and F. K. S. Lowndes, when a small hydrogen flame—from platinum tube 9 to 10 cms. long, with a jet about 1 mm. bore —is lowered into a half-litre flask, containing conc. nitric acid, and the press. so arranged that the flame just touches the acid, the jet becomes heated to whiteness, and a fine coloured conical flame extends from the neck of the flask to the liquid surface, and white fumes of ammonium nitrate or nitrite escape. If the white-hot point of the tube be immersed under the acid, red fumes escape as well. The hydrogen continues to burn under the acid until it becomes considerably diluted. P. T. Austen said that hydrogen burns with an intense white flame in the vapour of nitric acid. H. Gall and W. Manchot said that the catalytic reduction of nitric acid in aq. soln. in the presence of spongy platinum yields ammonia and nitrous acid. If **water** be gradually added to the fuming acid, the reddish-brown colour changes to green, then blue, and finally it becomes colourless; if, on the other hand, the fuming acid be added to water, these colours are obtained in their reverse order. L. Marchlewsky considers that the concentrated reddish-brown acid contains nitrogen peroxide, which on the addition of water decomposes into nitrous and nitric acids, that the green colour is due to the presence of both nitrogen peroxide NO_2, and nitrogen trioxide; and that the blue acid contains the trioxide (*vide supra*).

According to H. Moissan,[3] if **fluorine** be passed into nitric acid, each bubble of gas is attended by the decomposition of acid accompanied by a flame. A. Connell found that if **iodine** be gently heated with conc. nitric acid, iodic acid is produced with the liberation of nitrogen peroxide. L. H. Angus and H. M. Dawson found that the effect of nitrates on the solubility of iodine in water can be represented by $S=S_0e^{-0{\cdot}0533C}$, where S_0 denotes the solubility of iodine in water alone in millimols per 1000 grms.; S, the solubility in a salt soln. containing C mols of salt per 1000 grms. of water. For the effect of nitrates on the solubility of iodine in $1{\cdot}3N$-HNO_3 in place of water, $S=S_0e^{-0{\cdot}0577C}$; and in $2{\cdot}7N$-HNO_3, $S=S_0e^{-0{\cdot}0593C}$. A. W. Hofmann confirmed this observation—*vide* iodic acid (2. 19, 11). For the action of **hydrochloric acid** on nitric acid, *vide infra*, aqua regia. G. Gore, and O. Ruff and K. Stäuber investigated the action of nitric acid on **hydrofluoric acid**, but obtained no nitrosyl fluoride (*q.v.*). P. T. Austen said that **hydrogen chloride** does not react with the vapour of nitric acid. C. F. Schönbein found that **hydrogen bromide** decomposes conc. nitric acid at 0°, forming bromine, nitrogen peroxide, and water, and if the soln. be diluted with an excess of water, the original substances are reproduced. P. T. Austen said that hydrogen bromide is only slightly decomposed by the vapour of nitric acid. A. W. Hofmann described the action of nitric acid on **hydrogen iodide** whereby nitric oxide, iodine, and water are formed; with the fuming acid, each bubble of hydrogen iodide produces a red flame with the separation of iodine; P. T. Austen also found that hydrogen iodide reacts with the vapour of nitric acid liberating iodine. A. Eckstädt found that in dil. soln. **hydriodic acid** reduces nitric acid to nitrous acid. R. Luther and N. Schiloff represented the reaction with nitric acid, zinc, and hydriodic acid, $HNO_3+Zn=ZnO+HNO_2$, and $2HNO_2+2HI=I_2+2NO+2H_2O$, as an induced or a coupled reaction, where nitric acid is the actor, zinc the inductor, and hydriodic acid the acceptor. The coupled reactions are linked by an intermediate stage of the actor, which, in the second stage, and so far as it itself is concerned, reacts in a similar manner with the acceptor. In the electrolysis of an acid soln. of a nitrate, the current acts as the inductor, $HNO_3+E=HNO_2$, and the process was therefore called *electrolytic induction*.

Nitric acid transforms **sulphur** into sulphuric acid, and this the more readily the more finely divided the element. According to R. Bunsen,[4] finely-divided sulphur as it separates from the metal sulphides by treatment with acids, may be easily and completely oxidized by the action of conc. nitric acid on a water-bath; with boiling nitric acid of sp. gr. 1·42, the particles of sulphur melt, and coalesce into drops, which are oxidized but slowly. J. J. Berzelius found that **selenium** is converted into the dioxide when warmed with nitric acid; and D. Klein and J. Morel showed that finely-divided **tellurium** is attacked by nitric acid of sp. gr. 1·25, at −11°, when the soln. is diluted with water, tellurous anhydride is deposited, or, at a low temp., tellurous acid, and a basic tellurous nitrate in soln. A. Vogel, and N. A. E. Millon found that nitric acid freed from nitrogen peroxide is not decomposed by **hydrogen sulphide** at ordinary temp. Similarly, R. Kemper passed hydrogen sulphide into nitric acid of sp. gr. 1·18 without decomposition; if the acid contains a trace of nitrogen peroxide, acquired by standing in air, there is a reaction at 25°, and sulphur, sulphuric acid, nitric oxide, nitrogen, and ammonia are formed J. F. W. Johnston, and C. Leconte also noticed that ordinary dil. nitric acid is reduced by hydrogen sulphide, forming sulphur, ammonium sulphate, nitric oxide, and free sulphuric acid. If the conc. acid be poured into a jar of hydrogen sulphide, a blue flame develops at the mouth of the jar in a few seconds, and there is a slight noise. Red fumes appear, and the hydrogen and part of the sulphur are oxidized, and some sulphur separates in the free state. P. T. Austen also observed that hydrogen sulphide burns with a yellow flame in the vapour of nitric acid, forming clouds of nitrosulphonic acid. J. Kessel observed that the reaction with fuming nitric acid is sometimes accompanied by an explosion. A. W. Hofmann observed that fuming nitric acid reacts with incandescence with hydrogen sulphide, and with **hydrogen selenide.** According to S. L. Dana, if dil. nitric acid be repeatedly saturated with **sulphur dioxide,** sulphuric acid is formed. According to R. Weber, nitric acid is not reduced by sulphur dioxide so readily as is nitrous acid. If one vol. of nitric acid, sp. gr. 1·4, be boiled with 5 vols. of **sulphurous acid,** nitrous and nitric oxides are formed ; if less water be used, much nitric oxide is given off before the liquid boils. The reduction of nitric acid occurs more readily in the presence of sulphuric acid. If nitric acid be sufficiently dilute not to be attacked by sulphur dioxide, it is attacked if sulphuric acid be present. The reaction occurs in different ways dependent on the conc. of the acid. Thus, if sulphur dioxide be passed into a mixture of sulphuric acid with 10 per cent. of conc. nitric acid, and the mixture be allowed to stand for 24 hrs., crystals of nitroxyl sulphonic acid are formed. If the crystals are dissolved, and more sulphur dioxide be introduced, the soln. acquires a dark violet colour, which is retained in an atm. of sulphur dioxide. The soln. contains a mixture of nitrous and sulphurous acids. When a mixture of nitric acid and sulphuric acid of sp. gr. at least 1·34, is treated with sulphur dioxide, nitric oxide is formed. If 30 c.c. of sulphuric acid of sp. gr. 1·396 be mixed with 5 to 6 c.c. of nitric acid of sp. gr. 1·25, and treated with sulphur dioxide, in the cold, nitric oxide is given off as the soln. becomes green. With more conc. sulphuric acid, say sp. gr. 1·44 to 1·496, the mixture becomes blue ; with sulphuric acid of sp. gr. 1·53, grass-green to yellowish-green ; and with the acid of sp. gr. 1·63, yellow or colourless. F. Sestini observed that if liquid sulphur dioxide be treated with the hydrate of nitric acid, red vapours and crystals of nitroxylsulphonic acid are formed, which disappear with an excess of sulphur dioxide. The liquid then becomes violet. D. Klein and J. Morel found that hot nitric acid of sp. gr. 1·35 dissolves **tellurium dioxide,** forming a soln. of basic tellurium nitrate. The dehydrating influence of **sulphuric acid** on nitric acid, and the physical properties of the mixed acids, have already been discussed.

P. T. Austen [5] found that **ammonia** burns with a yellow flame if it issues from a fine jet into the vapour of nitric acid, and is ignited ; he also found that the vapour of nitric acid does not support the combustion of **nitrous oxide,** but dense fumes of ammonium nitrate may be formed. Nitric acid absorbs **nitric oxide** more copiously, the more conc. the acid, and the lower the temp. J. Priestley observed that when the conc. acid absorbs nitric oxide, its colour becomes first yellow, then orange, then olive-green, light green, and lastly, greenish-blue. The vol. of the acid increases during the absorption, and red fumes of nitrogen peroxide are formed. According to L. J. Thénard, nitric acid of sp. gr. 1·115 absorbs but little nitric oxide at ordinary temp., and remains colourless ; an acid of sp. gr. 1·32 becomes green ; and acid of sp. gr. 1·41, orange ; and one of sp. gr. 1·5, becomes dark red, and evolves nitrogen peroxide when heated. J. Fritzsche found that dil. nitric acid (1 : 5), say $HNO_3 : 2H_2O$, at 0° forms a blue liquid when treated with nitric oxide, and the liquid furnishes nitrous acid when distilled, if a more conc. acid be used, the liquid is yellow and it contains nitrogen peroxide. V. H. Veley showed that the reaction $2NO + HNO_3 + H_2O \rightleftharpoons 3HNO_2$ is reversible ; and A. V. Saposchnikoff investigated the reaction in some detail—*vide supra,* nitrous acid, and *vide infra,* nitratosulphuric acid. For the action of **nitrogen peroxide,** *vide supra.* A. A. Kasaneeff studied the effect of the acid on the solubility of some nitrates.

According to C. Wittstock,[6] when nitric acid, of sp. gr. 1·2, is warmed with **phosphorus,** nitrous and nitric oxides and a small quantity of free nitrogen are evolved, while phosphorus and phosphoric acids are formed. L. Gmelin said that no nitrous oxide is here produced ; and G. Watson, a colourless gas either nitrogen or in most cases nitrous oxide is produced. L. A. Buchner said that no ammonia is formed during this reaction; but J. Personne found that ammonia is always produced when phosphorus is treated with conc. or dil. (1 : 2) nitric acid. E. J. Maumené obtained a similar result; and C. Montemartini showed that with an excess of 17·3, 28·3, and 68 per cent. nitric acid, at 13° to 14°, the dissolution of one gram of phosphorus causes the production of 0·0739, 0·0824, and 0·0095 grm. of ammonia respectively. C. F. Schönbein observed that conc. nitric acid effervesces violently with phosphorus at ordinary temp., and the action increases in violence until it reaches the ignition temp. of the phosphorus, which then burns in the acid vapours with great splendour. According to L. V. Brugnatelli, paper moistened with nitric acid and laid on a flat piece of phosphorus detonates when struck by a hammer. A. Schrötter said that red phosphorus is more easily oxidized by nitric acid than yellow phosphorus; and J. Böeseken observed the formation of about equal parts of phosphoric and hypophosphoric acids when red phosphorus is boiled with nitric acid of sp. gr. 1·25. A. Siemens found that phosphorus pentoxide is produced when a soln. of yellow phosphorus in benzene is treated with dil. nitric acid, and the solvent volatilized; with red phosphorus, the reaction is more complex. P. T. Austen said that phosphorus inflames in the vapour of nitric acid, and burns with an intense white light. T. Graham found that **phosphine** is violently decomposed by conc. nitric acid; and, added A. W. Hofmann, when a glass rod dipped in fuming nitric acid is held over the water from which phosphine, which is not spontaneously inflammable, is bubbling, each bubble of gas coming in contact with the phosphine causes inflammation. Warm fuming nitric acid dropped in a cylinder of the same gas produces a detonation. H. Davy found that **phosphorous acid** is oxidized by nitric acid to phosphoric acid. H. Rose said that **phosphoric oxide** dissolves in dil. nitric acid more rapidly than phosphorus itself, while J. Pelouze found that conc. nitric acid inflames phosphoric oxide.

N. A. E. Millon[7] found that nitric acid, if free from nitrous acid, does not act on **arsenic** or **antimony** at 20°—only the most conc. acid acts slightly on antimony without effervescence. According to J. L. Proust, when conc. nitric acid is poured on melted **bismuth,** the metal becomes incandescent. N. A. E. Millon showed that bismuth retains its metallic lustre at 20° in dihydrated nitric acid free from nitrous acid; and that bismuth is rapidly dissolved in acid with 4 to 4·5 mols of water, but is not attacked by an acid of sp. gr. 1·108. In the latter case the reaction is started by raising the temp., or by passing in a current of nitric oxide, but it can be again arrested by cooling or by the addition of ferrous sulphate—*vide* arsenic, antimony, and bismuth. C. W. G. Nylander found that with **arsenic trioxide,** and warm nitric acid of sp. gr. 1·38, nitrogen peroxide is evolved; and, added N. Bunge, if the acid is less conc. nitric oxide is formed. C. W. Hasenbach said that nitrogen peroxide alone is formed with an acid of sp. gr. 1·5; and with an acid of sp. gr. 1·38 to 1·40, a dark green mixture of nitrous acid and nitrogen peroxide is produced. Observations on this subject were made by A. Geuther, O. N. Witt, and G. Lunge—*vide supra,* nitrogen trioxide. A. Klemenc and R. Schöller studied the reaction $H_3AsO_3+HNO_3 \rightleftharpoons H_3AsO_4+HNO_2$. They assume that the oxidation occurs through the formation of what they called *E*-nitric acid, $H_2N_3O_3$—*vide infra*—and that there is the cycle of changes $H_3AsO_3+H_2N_3O_8 \rightleftharpoons H_2AsO_4+H_3N_3O_7$; and $H_2N_3O_7+HNO_3 \rightleftharpoons H_2N_3O_8+HNO_2$. The latter reaction is strongly catalyzed by mercury ions. A. Klemenc and F. Pollak found that 10^{-9} mol of mercuric nitrate per litre slows down the velocity of oxidation—*vide* arsenic acid, and arsenic sulphide. H. Wurtz found that **arsenic trichloride** is converted into arsenic acid by nitric acid, while **antimony trichloride** is converted incompletely and with difficulty into antimonic acid—the reaction was studied by S. Schlesinger.

L. Carius,[8] A. Scott, R. J. Friswell, W. Luzi, and others have studied the action of nitric acid on **carbon** and graphite—*vide* **5**. 39, 11. L. R. Parks and P. C. Bartlett studied the adsorption of nitric acid by charcoal; and N. Schiloff and S. Pewsner the adsorption force between charcoal and nitric acid. M. J. M. Creighton and

W. H. Ogden found that in the explosive disintegration of carbon anodes in nitric acid, the gas evolved is mainly air ; the fragments are sometimes covered with minute yellow crystals ; and it is suggested that the disintegration is caused by the formation and decomposition of graphitic acid. Ignited charcoal burns vividly in contact with conc. nitric acid, but the diamond is not oxidized by boiling nitric acid. C. F. Schönbein said that powdered carbon decomposes conc. nitric acid in the cold with the evolution of carbon dioxide and nitrogen peroxide. Glowing carbon was found by P. T. Austen to burn in the vapour of nitric acid, and F. C. G. Müller found the products of combustion of charcoal in nitric acid vapour over 1000° were 52·2–57·2 per cent. CO_2 ; 13·3–14·7, CO ; 3·4–4·6, H_2 ; 24·9–26·7, N_2 ; and some ammonia. M. Dubinin studied the adsorption of nitric acid by charcoal. K. J. P. Orton and P. V. McKie found that **acetylene** is readily absorbed by nitric acid, and with fuming nitric acid carbon dioxide and trinitro methane are produced. The reaction is accelerated by the presence of mercury salts. A. Baschieri, and G. Testoni and L. Mascarelli obtained a number of complex substances. P. V. McKie represented the course of the reaction : $CH:CH \rightarrow CH(OH):CH(NO_2) \rightarrow CH(OH)_2.CH(NO_2)_2 \rightarrow CH(NO_2).CHO \rightarrow CH(NO_2)_2.COOH \rightarrow CH_2(NO_2)_2 \rightarrow C(NO_2)_2:N.OH \rightarrow CH(NO_2)_3$. P. V. McKie observed a similar reaction with **ethylene,** and she obtained β-nitroethyl alcohol among the intermediate products. The course of the reaction is assumed to be: $CH_2:CH_2 \rightarrow CH_2(OH):CH_2(NO_2) \rightarrow CH_2(NO_2).CHO \rightarrow CH_2(NO_2).COOH \rightarrow CH_3.NO_2 \rightarrow CH(NO_2):N.OH \rightarrow CH_2(NO_2)_2 \rightarrow C(NO_2)_2:NOH \rightarrow CH(NO_3)_3$. Nitric acid reacts with numerous **organic compounds,** forming nitro-derivatives; and with **alcohols,** it produces esters. R. Scheidewind removed nitric acid from soln. in certain analytical work by adding alcohol from time to time to the boiling soln. N. Schiloff and co-workers studied the partition of nitric acid between alcohol and water. Nitric acid is quite soluble in **ether,** so that the acid can be extracted from its aq. soln. by this solvent. C. Tanret, P. N. Pavloff, A. Klemenc and R. Schöller, and P. Bogdan measured the partition coeff. of nitric acid between water and ether at 25°. They found that the nitration of organic substances in water and ether soln. proceeds only in the presence of oxides of nitrogen with the nitrogen having a lower valency than five, and is accompanied by oxidation so that the action is autocatalytic. The velocity of nitration varies with the two-thirds power of the conc. of the nitric acid. It is suggested that what they call *E*-nitric acid, $H_2N_3O_8$ is formed $2HNO_3+NO_2 \rightleftharpoons H_2N_3O_8$, as an intermediate compound—*vide supra et infra*, arsenious acid, and the metals. Expressing the concentration of the soln. in mols per litre, P. Bogdan found :

Aq. phase .	0·02462	0·02760	0·04749	0·09005	0·2644	0·4811	0·578	50·9145
Ether phase .	0·0$_3$249	0·0$_3$290	0·0$_3$641	0·0$_2$181	0·0$_2$894	0·0278	0·0378	0·0855

He also observed that the solubility of water in ether is influenced by the presence of nitric acid in dil. soln. The mol. elevation of the b.p. of ether produced by nitric acid is not independent of the conc. The conductivities of soln. of nitric acid in water saturated with ether show that the degrees of ionization calculated from them are in agreement with the dilution law, and the calculated ionization constant, at 25°, is 1·39. Assuming that mass law is true for the ionization of nitric acid in the ether soln., the coeff. of partition of the non-ionized part of the nitric acid is water : ether=3·9. According to A. Quartaroli, the reaction between anhydrous **formic acid** and nitrates is really a process of autocatalysis in which nitrogen trioxide is the positive catalyst. Until a trace of this substance has been formed, the velocity of the reaction is very small, but the nitrogen trioxide cannot accumulate in quantity, because it also reacts with formic acid. In agreement with this view it is found that oxidizing agents, transforming the nitrogen trioxide into nitric acid, act as negative catalysts. Traces of potassium chlorate, hydrogen dioxide, potassium permanganate, or carbamide hinder the reaction or prevent it entirely, so that there results the paradox that oxidizing agents may prevent oxidation. Nitrates are reduced by quickly warming them with formic acid : $2KNO_3+6HCOOH=4CO_2+5H_2O+2HCOOK+N_2O$, the reaction is quantitative and can be used for quantitative determinations ; the reaction is also a convenient method of preparing nitrous oxide free from other nitrogen oxides provided the heating be rapid until the first bubbles appear. If the initial warming be slow, the soln. becomes blue and red fumes appear. **Formaldehyde** can be used in the preparation of fuming nitric acid. When paraformaldehyde is added to nitric acid, nitric oxide, NO, is evolved even in the cold. By gently heating and conducting the escaping gases with nitric acid, the fuming acid is obtained. F. O. Rice emphasized the parallel behaviour in the nitration of **phenol** by nitric acid, and the action of metals on that acid. With dil. nitric acid, 25 per cent. of the acid may be reduced to nitrous oxide and nitrogen during the nitration of phenol ; and by keeping the temp. below 100°, much of the reduction of the acid to lower oxides can be avoided. K. H. Meyer and co-workers, and A. Klemenc and E. Ekl studied the action of nitric acid on phenol and on aryl-compounds. The action of nitric acid on metals in likened by N. R. Dhar to the action of the acid on organic compounds like sugar, starch, etc. Here, as shown by A. Naumann, the reaction, as in the conversion of sugar to oxalic acid, is accelerated by vanadium pentoxide, as well as by sodium nitrate, and manganese salts, whereas molybdic acid and silver salts retard the action. O. Warburg studied the reduction of nitric acid in the cells of the *Chlorella vulgaris*, in light and in darkness ; and S. G. Mokruschin, the adsorption of the acid by filter paper. C. M. Faber and co-workers studied the adsorption of nitric acid by colloidal **silica** (*q.v.*) ; and N. R. Dhar, the induced reaction involving the effect of nitric acid on the reduction of mercuric chloride by oxalic acid. For the reducing action of **titanous salts,** *vide infra.*

In 1663, R. Boyle [9] noticed that many **metals** remain inert towards conc. nitric acid, but are readily attacked by the dil. acid. This observation was confirmed in 1685 by J. Bohn, by J. Woodhouse in 1799, and by J. Keir in 1790. According to J. L. Proust, during the attack of the metals by nitric acid, oxygen is transferred to the metal with the evolution of heat. The action is slow at first, but becomes accelerated, and sometimes ends in actual combustion or incandescence such as occurs when conc. nitric acid is poured on heated iron filings, or on melted bismuth, tin, or zinc. N. A. E. Millon's memoir : *Recherches sur l'acide nitrique*, is one of the most important—*vide* **3.** 21, 6—he demonstrated that nitric acid of whatever concentration does not attack many metals ; the reaction occurs only when a trace of free nitrous acid is present. This important result was confirmed by V. H. Veley, W. J. Russell, S. W. Young and E. M. Hogg, etc. V. H. Veley inferred from his observations that (i) the primary change is that between the metals and nitrous acid ; (ii) no gas is evolved at first from the surface of the metal ; (iii) the amount of nitrous acid increases up to a constant and maximum proportion ; and (iv) those conditions which increase the amount of metal dissolved per unit time, are equally those conditions which increase this constant proportion of nitrous acid. If then a trace of nitrous acid becomes once formed, and if, also, the quantity of nitric acid is present in very considerable excess, it would appear that these results may be explained as follows : (i) the metal dissolves in nitrous acid to form the metallic nitrite and nitric oxide ; (ii) the nitrite formed is decomposed by the excess of nitric acid to reproduce the nitrous acid ; and (iii) the nitric oxide formed in (i) is not evolved as such, but reduces the nitric acid or the nitrate to produce a further quantity of nitrous acid. These changes may be presented thus, taking copper for example: (i) $Cu+4HNO_2=Cu(NO_2)_2+2H_2O+2NO$; (ii) $Cu(NO_2)_2+2HNO_3=Cu(NO_3)_2+2HNO_2$; (iii) $2NO+HNO_3+H_2O=3HNO_2$. G. J. Burch and V. H. Veley found that when the metals, copper, silver, bismuth, and mercury are introduced into purified nitric acid of varying degrees of concentration, and a couple made with platinum, the electromotive force of such a cell increases considerably until it reaches a constant and (in most cases) a maximum value. This rise of electromotive force is attributed to the production of nitrous acid by the decomposition of the nitric acid, and the final value is considered to be due to the former acid only, while the initial value is due for the most part to the latter acid, though it is affected to a remarkable degree by the amount of impurity of nitrous acid either initially present or produced by minute and unavoidable uncleanliness of the metallic strips and the containing vessel. If nitrous acid has been previously added to the nitric acid, then the maximum electromotive force is reached at once. If the conditions, namely, increase of temp., impurity, and of concentration of acid, are such as could favour a more rapid production of nitrous acid, then the rise of electromotive force is concomitantly more rapid. Conversely, if the conditions are unfavourable to the production of nitrous acid, the rise of electromotive force is less rapid. If any substance, such as urea, be added, which would tend to destroy the nitrous acid as fast as it may be formed, then the rise of electromotive force is extremely slow, being dependent upon the number of molecular impacts of nitrous acid upon the surface of the metal. Thus the results obtained by the electrometer and by the chemical balance are in every way confirmatory, the one of the other. R. Ihle did not agree with these conclusions. If the rate of increase in the e.m.f. depends solely on the number of nitrous acid mols. formed from the nitric acid, the maximum e.m.f. finally attained should be greater the greater the conc. of the nitrous acid in the nitric acid. The opposite of this is true, and to get over the difficulty, G. J. Burch and V. H. Veley assumed that the ready-formed nitric acid is not so active as nitrous acid in the process of formation and decomposition. W. D. Bancroft added that the assumption that the metal dissolves to nitrite has no weight because the addition of nitrous acid to Grove's cell, or Smee's cell—1. 16, 5—increases the depolarizing action of the nitric acid, but no metal dissolves in the nitric acid soln. and consequently there is no formation of nitrite. According to R. Ihle:

> If one dilutes the conc. nitric acid in the Grove cell gradually and measures the e.m.f. of the cell at the same time, one finds that the e.m.f. remains nearly constant until the conc. of the nitric acid drops to about 38 per cent. At slightly lower conc. the cell shows, though at first only for a very short time, a changed and much smaller e.m.f. than the 1·8 volt characteristic of the Grove cell; it corresponds rather to the 0·7 volt of the Smee cell. If one dilutes the nitric acid more and more, the time during which the cell stays at the lower potential increases until at a nitric acid content of 27–28 per cent. the element keeps the low e.m.f. of the Smee cell permanently. Just as one can make dil. nitric acid active as a depolarizer by means of nitrous acid, so one can also remove the depolarizing power of conc. nitric acid containing more than 38 per cent. HNO_3, by removing continuously the small amount of nitrous acid which is always present in so strong nitric acid by means of urea or potassium permanganate and can thereby convert a Grove cell into a Smee cell. With very conc. acid containing 50–60 per cent. HNO_3, the conversion is only temporary because more nitrous acid forms soon. From this it follows that nitrous acid is the real depolarizer in the Grove cell and not nitric acid as is usually assumed, or at any rate, that it is only in presence of nitrous acid that the oxygen of the nitric acid reacts with hydrogen set free electrolytically at the platinum. The question arises as to how this action takes place, and it seems probable that we are dealing with a case of catalysis. Nitrous acid plays the part of a catalyzer here just as it does in other cases, such as the action of nitric acid on metals studied by V. H. Veley.

The conc. of the nitrous acid does not increase when a soln. of nitric acid is electrolyzed, even in cases where there is no evolution of gas. If nitric acid were the depolarizer it should be almost entirely removed before the nitrous acid is attacked. In order to explain the removal of nitrous acid, W. D. Bancroft inferred that there is a reversible reaction in which there is a state of dynamic equilibrium, $HNO_3+HNO_2 \rightleftharpoons N_2O_4(\text{or } 2NO_2)+H_2O$, so that nitric acid is continually changing to nitrogen peroxide, and being formed therefrom. During the moments of change, the nitric acid, the nitrogen atom, or some radical containing nitrogen and oxygen must be in a different state from what it would be if no nitrous acid were present and if this reaction were not taking place. The particular intermediate stage involved in this reaction presumably permits more rapid reaction with nascent hydrogen. E. J. Joss inferred that the activation of the nitric acid depends on the formation of nitrosic acid (*q.v*) as an intermediate product in the state of dynamic equilibrium:

$HNO_3+HNO_2 \rightleftharpoons H_2N_2O_5 \rightleftharpoons 2NO_2+H_2O$. Nitrous acid is not the actual depolarizer, but it acts as a catalytic agent making the nitric acid active; the real depolarizer in the action of nitric acid on metals is nitrosic, not nitrous, acid.

Details of the various observations of the action of nitric acid on the metals are discussed in connection with the individual elements. The more important memoirs are those of V. H. Veley, C. Montemartini, E. Divers, H. E. Armstrong and J. J. Acworth, E. J. Joss, W. D. Bancroft, G. O. Higley and co-workers, and J. L. Schönn. B. C. Banerji and N. R. Dhar studied the action of nitric acid on metals in the presence of different salts. Ferrous salts acted as catalysts by producing nitrous acid in a reaction with nitric acid; ferric salts also acted as catalysts by being reduced to ferrous salts by the metal. Oxidizing agents like potassium permanganate and chlorate act as negative catalysts by hindering the formation of nitrous acid. The dissolution of a 1 : 1 nickel-copper alloy is periodic because a period of activity is followed by one of no activity, and that again by one of activity, and so on, continuously alternating in sequence. This *pulsating action* was discussed by M. Faraday, C. F. Schönbein, A. Mousson, L. Gmelin, etc.

The earliest view of the reaction between nitric acid and the metals assumed that the metals are first oxidized by the acid—*the oxidation theory.* Thus, L. Gmelin said that the portion of the nitric acid which oxidizes the metal is sometimes converted into nitrogen peroxide, sometimes into nitric oxide, or into nitrous oxide, or nitrogen gas; and, if the metal at the same time decomposes water, the hydrogen of the water combining with the nitrogen of the acid forms ammonia. As N. A. E. Millon has shown, the oxidation of the metal usually occurs only when nitrous acid is present; because, although nitrous acid contains less oxygen than nitric acid, it parts with that element more readily because its affinity for water is less than that of nitric acid. J. F. Norris, and J. L. Howe favour the oxidation theory. The theory was advocated by N. R. Dhar, who compared that action of nitric acid on metals with that of the persulphates on the metals. This theory is virtually *the phlogiston hypothesis* of C. W. Scheele translated into the language of the antiphlogistic theory.

Another hypothesis—*the hydrogen theory*—assumes that a nitrate of the metal and nascent hydrogen are first formed. The nascent hydrogen is then supposed to reduce the nitric acid to nitrous acid, etc. J. J. Acworth expresses the idea in this form: The action of the metal consists simply in the displacement of the hydrogen of the acid and the formation of the corresponding nitrate in the manner expressed by the equation: $M+2HNO_3=M(NO_3)_2+2H$. In no circumstances, however, is the hydrogen thus displaced evolved as such. It at once acts on the free acid present, or on the metal nitrate which has been formed, reducing it more or less completely to nitrous acid, hyponitrous acid, hydroxylamine, and ammonia; while the nitrogen peroxide, nitric oxide, nitrous oxide, and nitrogen are formed by secondary reactions. This view of the reaction agrees with that of W. D. Bancroft.

The products formed by the action of metals, and metal salts on nitric acid involve reduction, or hydrogenation, dehydration, and hydration processes as previously indicated—also *cf.* the individual elements. C. L. Bloxam found that with sodium *hydrogen* is evolved. The formation of *nitrogen peroxide* was observed by J. J. Acworth, H. E. Armstrong and J. J. Acworth, P. C. Freer and G. O. Higley, C. Montemartini, etc., by the action of many metals—*e.g.* copper, zinc, cadmium, mercury, antimony, bismuth, molybdenum, iron, cobalt, and nickel; and L. H. Milligan and G. R. Gillette, by the action of stannous chloride on nitric acid. The nitrous acid or nitrite is probably formed by direct reduction, and by the action of hydroxylamine. The nitrous acid reacts with nitric acid to form nitrogen peroxide: $HNO_3+HNO_2=2NO_2+H_2O$. As indicated above, E. J. Joss assumed that nitrosic acid, $H_2N_2O_5$ (*q.v.*), represents an intermediate stage in the process: $HNO_3+HNO_2 \rightleftharpoons H_2N_2O_5 \rightleftharpoons 2NO_2+H_2O$. C. Kippenberger, A. van Bijlert, J. Tafel, P. C. Ray, and C. Montemartini observed the production of *nitrites*—or *nitrogen trioxide*—in the reduction of nitric acid by magnesium, zinc, cadmium, mercury, aluminium, lead, antimony, bismuth, molybdenum, manganese, cobalt, and nickel. J. J. Acworth, H. E. Armstrong and J. J. Acworth, P. C. Freer and G. O. Higley, C. Montemartini, A. van Bijlert, A. Pleischl, N. A. E. Millon, F. Kuhlmann, etc., observed *nitric oxide* to be formed by the reducing action of copper, silver, zinc, cadmium, tin, antimony, bismuth, molybdenum, iron, cobalt, and nickel; and L. H. Milligan and G. R. Gillette, by the action of ferrous and stannous chlorides on nitric acid. The nitric oxide is derived from the nitrous acid: $3HNO_2=2NO+H_2O+HNO_3$; and from the ephemeral nitrohydroxylamic acid: $H_2N_2O_3=2NO+H_2O$. J. J. Acworth, H. E. Armstrong and J. J. Acworth, C. Montemartini, etc., observed *nitrous oxide* among the products of the action of copper, zinc, cadmium, cobalt, and nickel on nitric acid. J. J. Acworth observed no nitrous oxide with silver. L. H. Milligan and G. R. Gillette obtained nitrous oxide by the action of stannous chloride. Nitrous oxide is formed by the dehydration of hyponitrous acid: $H_2N_2O_2=H_2O+N_2O$, or by the interaction of nitrous acid and hydroxylamine: $HNO_2+NH_2OH=N_2O+2H_2O$; or $2HNO_3+4NH_2OH=3N_2O+7H_2O$. C. Montemartini found *hyponitrites* among the products of the action of zinc, cadmium, cobalt, and nickel on nitric acid. Hyponitrous acid is formed by direct reduction; J. J. Acworth, H. E. Armstrong and J. J. Acworth, H. St. C. Deville, A. von Bijlert, A. Pleischl, C. Montemartini, etc., obtained *nitrogen* among the products of the action of copper, silver, zinc, cadmium, tin, cobalt, and nickel on nitric acid. L. H. Milligan and G. R. Gillette also observed that some nitrogen is formed when nitric acid is reduced by stannic chloride. It is probable that the nitrogen is not formed by the interaction of nitrous acid and ammonia, since nitrogen is produced when there is nothing to show that any ammonia is formed. As observed by G. Oesterheld, it may be formed by the interaction of hyponitrous acid and hydroxylamine: $H_2N_2O_2+2NH_2OH=2N_2+4H_2O$; and, according to M. Berthelot and J. Ogier, A. Hantzsch and L. Kaufmann, and P. C. Ray and A. C. Ganguli, by the reaction: $5H_2N_2O_2=4H_2O+2HNO_3+4N_2$. E. Divers, C. Montemartini, and C. Kippenberger found that *hydroxylamine* is a product of the action of nitric acid on magnesium, zinc, cadmium, aluminium, tin, and manganese—C. Montemartini, and A. van Bijlert observed none with zinc, and J. Tafel, none with copper, or mercury. J. A. Wilkinson showed that if the conc. of the mercury ions be kept low, then hydroxylamine is formed. E. J. Maumené, O. von Dumreicher, and L. H. Milligan and G. R. Gillette observed hydroxylamine to be a product of the action of stannous chloride on nitric acid; and L. H. Milligan and G. R. Gillette, of titanous chloride. Hydroxylamine is probably produced by direct reduction; so also with *ammonia:* $HNO_3\rightarrow HNO_2\rightarrow H_2N_2O_2\rightarrow NH_2OH\rightarrow NH_3$. T. E. Thorpe, and J. H. Gladstone and A. Tribe observed that the copper-zinc couple will reduce nitrates to ammonia; and E. Divers divided the metals into two classes: (i) those like copper, silver, mercury, and bismuth which formed neither ammonia nor hydroxylamine; and (ii) those which produce hydroxylamine or ammonia. Ammonia was observed with magnesium, zinc, cadmium, aluminium, tin, lead, iron, and sodium amalgam. P. C. Freer and G. O. Higley also observed ammonia with iron; W. Smith, with aluminium; C. Montemartini, with lead; A. Pleischl, with tin; F. Kuhlmann, with zinc; and J. W. Turrentine, and E. J. Joss, with nitrates and copper in the presence of sulphuric acid. J. Tafel obtained no ammonia with mercury or copper; and G. O. Higley found none in the products of the reaction with lead and nitric acid, but E. Divers obtained ammonia, and E. J. Joss said that the reason ammonia is not always obtained, is because the secondary reaction by which an intermediate product decomposes to give nitrous oxide, is catalyzed by lead ions, until it predominates over the direct reduction. J. B. Kinnear obtained a quantitative reduction of nitrates to ammonia by sulphuric acid and zinc. This shows that the reduction potentials of zinc and lead suffice to reduce nitric acid to the ammonia stage. C. Kippenberger observed that dil. soln. of nitrates are reduced to ammonia by magnesium, aluminium, and manganese; J. Personne, and E. J. Maumené, by phosphorus, arsenic, and antimony; and C. Montemartini, by cadmium, cobalt, and nickel. L. H. Milligan and G. R. Gillette found that while stannous chloride can reduce nitric acid to ammonia, the apparently stronger reducing agent carries the reduction to hydroxylamine. The reaction was also examined by E. Divers and T. Haga, S. Schlesinger, and E. Pugh.

A. de la Rive held that the dissolution of a metal in connection with an acid depends on the formation of local elements between an impurity in the metal and the acid, say Cu | HNO_3 | M. H. E. Armstrong amplified the suggestion, and developed *the electrolytic theory* of chemical action. He said that two substances will react only in presence of certain impurities (catalytic agents). Interaction does not take place between pure substances. He assumes that "when the complex formed by the association of the interacting substances meets with the necessary third component, a conducting system is established, and that as soon as this is formed a change sets in. . . ." According to this hypothesis, "a circuit of change must comprise three distinct terms or components." One of these must be a conductor of electricity which is capable of forming with the reacting substance a system analogous with a closed voltaic circuit. As W. D. Bancroft expressed it:

> The most striking characteristic of an electrolytic action is that it occurs in two places—at the anode and at the cathode. This peculiarity can be made less marked by bringing the electrodes nearer and nearer together. When the distance between them vanishes, we have a chemical reaction in the ordinary sense of the word and not an electrochemical reaction. Any chemical reaction, therefore, which can be made to take place electrolytically, must consist of an anode and a cathode process. Considering the matter in this light, we see that there is a possibility of the anode and cathode processes interfering and of one perhaps masking the other.

T. Ericson-Aurén and W. Palmaer found that the addition of anything which raises the e.m.f. of the combination—the addition of certain metal salts, depolarizers, etc., and variations in the nature of the negative element—increases the rate of dissolution, and conversely. This subject has been discussed in connection with copper—**3**. 21, 6. W. D. Bancroft said that the general results show that the action of nitric acid on metals can be profitably considered as a case of electrolytic corrosion, the anode reaction being the formation of a nitrate. The nature of the metal shows itself in three ways: (i) in the reducing power as measured by the over-voltage; (ii) in the catalytic action of the metal; and (iii) in the catalytic action of the salt of the metal. The electrolytic reduction of nitric acid has been discussed in connection with hydroxylamine. The hydrogen and electrolytic theories can be translated into the language of the *ionic hypothesis;* thus, according to W. Ostwald—*vide supra*—the reduction of nitric acid is supposed to start from the ionization of the acid, so that the direct reduction products are nitrogen peroxide, nitrous acid, nitric oxide, hyponitrous acid, and either nitrogen or hydroxylamine and ammonia, with nitrous oxide as a secondary dehydration product of hyponitrous acid—*vide supra* for the relation of these products to nitric acid.

L. S. Bagter, in explaining the action of nitric acid on copper, assumed that nitrous acid is the depolarizer. He concluded that the process involved (i) the oxidation of the hydrogen film on the copper by the nitrous acid, which itself is reduced to hyponitrous acid, the copper passing into soln. to replace the hydrogen removed; and (ii) the oxidation of the hyponitrous acid to nitrous acid by nitric acid, which itself is reduced to nitrous acid. A. Klemenc assumed that in the nitration of organic substances—*vide supra*—what was called *E*-nitric acid, $H_2N_3O_8$, is formed, and the theory can be also applied to the action of nitric acid on the metals. Thus, P. C. Ray's observation that mercurous nitrite is formed by the action of nitric acid on mercury is explained by assuming that a state of equilibrium, $2HgNO_3+NO_2 \rightleftharpoons Hg_2N_3O_8$, is formed in the diffusion layer near the surface of the metal, and that the mercury *E*-nitrate diffuses away and is decomposed: $2Hg_2N_3O_8+H_2O=HgNO_2+3HgNO_3+2HNO_3$. The conc. of the *E*-acid in the diffusion layer reaches a maximum at a distance from the metal of five-sixths of the thickness of the diffusion layer. M. Drapier's observation that the velocity of soln.

of a copper cylinder in nitric acid is considerably lessened by rotating the cylinder is explained by assuming that *E*-acid is lost on the soln. side of the diffusion layer during rotation.

According to J. G. Thompson, aluminium and its alloys are superior in their resistance to 100 per cent. nitric acid to all the iron-alloys tried excepting high-silicon cast-iron; these alloys, however, are severely corroded by acid of less than 68 per cent. HNO_3. Molybdenum steel, or steel containing 5·5 per cent. chromium, was little better than plain steel, but steels with 10·8 to 15·7 per cent. chromium, better resisted attack by the stronger acid; while steels with over 16 per cent. chromium showed no signs of attack by nitric acid below 68 per cent. concentration. The presence of nickel reduces the beneficial action of chromium. Of all the alloys tested, a high-silicon cast-iron—14·55 per cent. Si, and 0·59 per cent. C—was the most resistant. It was unattacked by acid of any concentration. A similar cast-iron with 12·24 per cent. Si, and 1·17 per cent. of C, was not so good.

H. Braconnot showed that an alcoholic soln. of nitric acid is often less active than the aq. soln. He said that the alcoholic soln. acts feebly on bismuth, zinc, and copper because of the low solubility of the nitrates of these metals in alcohol; and that it does not attack mercury because of the insolubility of the nitrate in alcohol. P. Pascal discussed the action of mixtures of sulphuric and nitric acids on aluminium, steel, and lead. The addition of sulphuric or nitric acid to a manganic salt or manganese dioxide, in the presence of hydrofluoric, phosphoric, or arsenic acid, may convert the whole of the manganese into the corresponding manganic salt. J. Jannek and J. Meyer found that conc. nitric acid distilled with **platinum** apparatus contains impurities not found when vessels of fused-quartz are employed. G. P. Baxter and F. L. Grover said that if clean, well-seasoned platinum is used, the results are as good as with quartz provided the acid is free from traces of hydrochloric acid.

The lower oxides of many metals and their salts are oxidized by either cold or hot nitric acid—*e.g.* **cuprous oxide, mercurous oxide, stannous oxide, and ferrous oxide,** and their salts. According to A. von Bijlert,[10] **ferrous sulphate** in the presence of free sulphuric acid is quantitatively oxidized to ferric oxide; but in the absence of sulphuric acid, about one-third of the ferrous salt is oxidized to ferric nitrate: $6FeSO_4+8HNO_3=2Fe_2(SO_4)_3+2Fe(NO_3)_3+2NO+4H_2O$; with dil. nitric acid—230 grms. HNO_3 per litre—there is no action at 0°, a slow action at 25°, and a rapid action at 30°. L. H. Milligan and G. R. Gillette concluded that when an excess of nitric acid, of 15–20 per cent. strength, is reduced at 20° by ferrous salt soln., the reaction first passes through an induction period, and the soln. becomes dark red-brown indicative of the formation of the $Fe^{\cdot\cdot}.NO$ complex which is rapidly decomposed—nitric oxide is the principal product, but considerable nitrogen peroxide is also formed. When small amounts of nitric acid are added to an excess of boiling ferrous salt soln., nitric oxide only is produced. O. Baudisch and P. Mayer found that the reduction of nitrates by ferrous hydroxide in neutral and alkaline soln. is quantitative. The reduction of nitric acid by **stannous chloride** has been discussed in connection with hydroxylamine. M. Coblens and J. K. Bernstein found that nitric acid furnishes nitric oxide when treated with stannous chloride containing a drop of ferrous sulphate; and when an excess of sodium hyposulphite acts on nitric acid. L. H. Milligan and G. R. Gillette concluded that

> When an excess of nitric acid of 10–50 per cent. strength is treated in the cold with stannous salt soln., hydroxylamine salts are the *primary* end-product of the reaction, but when the conditions of temp. and conc. are such that the nitric acid and the hydroxylamine salts react, then nitrous oxide is the chief product together with small amounts of nitric oxide, nitrogen and traces of nitrogen peroxide. No ammonium salts are formed. When stannous salts are used in excess over the nitric acid, the reaction takes place with hydroxylamine and ammonium salts as the products either in hot or cold soln., but the reaction is very slow in the latter case. When an excess of nitric acid is treated with titanous salt soln., the reaction takes place very rapidly with the formation of nitric oxide as the chief

product together with a considerable amount of nitrous oxide, a smaller amount of nitrogen, and traces of nitrogen peroxide and also of hydroxylamine salts. No ammonium salts are formed. The reaction appears to progress in practically the same way no matter whether the nitric acid or the titanous salt is in excess, neither hydroxylamine nor ammonium salts being formed in the latter case. Titanous salts are stronger reducing agents than corresponding stannous salts, and yet the chief product by the former acting on an excess nitric acid is nitric oxide; whereas the chief product from the latter is hydroxylamine, which is a "more reduced" compound, but is produced by the weaker reagent. This shows that catalytic effects play an important part, and evidence indicates that the "ous" salt of titanium is the catalyzer for the decomposition of nitrohydroxylamic acid and production of nitric oxide.

Many **metal chlorides** when heated with an excess of nitric acid are converted into the nitrates. Thus, J. L. Smith found that the transformation occurs with potassium or sodium chloride in the presence of 7 to 8 parts of nitric acid; J. S. Stas said that at 40°–50°, potassium, sodium, or lithium chloride require respectively 3, 4, and 5·5 parts of nitric acid. J. L. Smith said that ammonium chloride and nitric acid yield nitrous oxide. H. Wurtz found that auric, cadmium, cerium, lanthanum, didymium, ferric, and platinic chlorides are decomposed by nitric acid incompletely and with difficulty. S. Schlesinger said that the two copper chlorides, mercurous, zinc, and lead chlorides, are decomposed, but, added H. Wurtz, with difficulty and incompletely; while mercuric and silver chlorides are not attacked. F. Rose found cobalt amminochlorides are readily converted into the nitrate.

Nitric acid is usually monobasic, forming a series of salts, the **nitrates.** The basic salts have been discussed by A. Ditte,[11] E. Groschuff, and others—see, for example, the basic lead nitrates. The nitrates are usually made by the action of the acid on the metal, hydroxide, oxide, carbonate, etc. According to H. Braconnot, the conc. acid does not decompose dehydrated sodium, barium, calcium, or lead carbonate, even when boiling, because the nitrates of these bases are insoluble in the conc. acid, and a surface film of nitrate protects the remainder of the carbonate from the acid. Potassium carbonate is decomposed by the conc. acid because the nitrate is soluble in the conc. acid. J. Pelouze said that an alcoholic soln. of nitric acid does not act on potassium carbonate, but it acts slowly on sodium, barium, and magnesium carbonates, and rapidly on calcium and strontium carbonates; because, added H. Braconnot, calcium and strontium nitrates are readily dissolved by alcohol, whereas potassium nitrate is but sparingly soluble in that menstruum. Potassium hydroxide resists attack by a soln. of nitric acid in ether unless the mixture is boiled or shaken. A. A. Kazantzeff discussed the influence of nitric acid on the solubilities of the nitrates.

The great number of hydrates of the metallic nitrates in which the number of water mols. is some multiple of 3—say 3, 6, 9, 12—has been the subject of remark, and has led observers to assume that these hydrates are to be regarded as addition products of the base with one of the hypothetical nitric acids—orthonitric acid, H_5NO_5, mesonitric acid, H_3NO_4, and ordinary or meta-nitric acid, HNO_3, and also nitric anhydride, N_2O_5. H. E. Armstrong has argued that the acid and base first unite additively, and that the salt is formed by an intra-molecular change in the addition-product so produced. In confirmation, there are many hydrates of salts whose composition can be exactly derived from the direct addition of acid and base; *e.g.* $CaSO_4.2H_2O$; $BaCl_2.2H_2O$; $HgNO_3.H_2O$, etc. According to J. H. Kastle, 75 per cent. of the nitrates described in literature can be included in one or other of the following five classes:

(1) The anhydrous nitrates are addition products of nitric anhydride and the metallic oxide, $Cs_2O+N_2O_5=2CsNO_3$, *e.g.* the nitrates of the five alkali metals, silver, barium, strontium, magnesium, thallium, gallium, and lead; and the double nitrates of gold or silver with the alkali metals: *e.g.* $KAu(NO_3)_4,KAg(NO_3)_2$.

(2) The nitrate is an addition product of ordinary nitric acid, and the metallic base: $Hg(OH)+HNO_3=HgNO_3.H_2O$. Thorium nitrate, $Th(NO_3)_4.4H_2O$, is another example.

(3) Many nitrates of the bi- and ter-valent metals are addition products of mesonitric acid: $Cd(OH)_2+2H_3NO_4=CdNO_3.4H_2O$, and calcium and strontium nitrates, $Ca(NO_3)_2.4H\ O$ and $Sr(NO_3)_2.4H_2O$, are further examples. With the tervalent metals,

$Fe(OH)_3+3H_3NO_4=Fe(NO_3)_3.6H_2O$; and the corresponding nitrates of didymium, thallium, cerium, erbium, lanthanum, samarium, and yttrium are examples. A series of double nitrates of cerium with cobalt, magnesium, manganese, nickel, or zinc, of the type : $2Ce(NO_3)_3.3MgNO_3.24H_2O$; and a series with lanthanum nitrate and magnesium, manganese, or zinc nitrate of the type : $2La(NO_3)_3.3Zn(NO_3)_2.24H_2O$, belong to the same class.

(4) Another series may be derived by the addition of orthonitric acid, H_5NO_5, to the bivalent metal base, with the bivalent metals: $Co(OH)_2+2H_5NO_5=Co(NO_3)_2.6H_2O$, and the corresponding nitrates of nickel, iron, manganese, magnesium, zinc, and calcium. Examples with the tervalent metals are: $Al(OH)_3+3H_5NO_5=Al(NO_3)_3.9H_2O$, and the corresponding nitrates of chromium, and iron, as well as the double nitrates of nickel and didymium, $2Di(NO_3)_3.3Ni(NO_3)_2.36H_2O$. Thallium nitrate is an example with a quadrivalent metal: $Th(OH)_4+4H_5NO_5=Th(NO_3)_4.12H_2O$.

(5) A few nitrates can be referred to a pyrometanitric acid, $H_4N_2O_7$. Thus, $Cu(OH)_2+H_4N_2O_7=Cu(NO_3)_2.3H_2O$; and similarly also with germanium, and manganese nitrates.

J. H. Kastle argued that the hypothesis contains " at least an element of truth." When the hypothesis is adapted to an imaginary $H_{13}N_3O_{14}$, regarded as $3H_5NO_5$ less H_2O, in order to explain the octohydrate of thallium nitrate, $Th(NO_3)_3.8H_2O$, the argument becomes less probable. J. Loewe, and M. E. Chevreul referred some of the basic lead nitrates—*e.g.* $PbHNO_4,Pb_3(NO_4)_2$—to an hypothetical orthonitric acid, while J. H. Kastle suggested the possibility of the hydrated nitrates being salts of more complex acids *e.g.*—$Fe(NO_3)_3.9H_2O$ is $H_{18}FeN_3O_{18}$; and when part of the hydrogen is replaced by a metal, the so-called basic salts are formed.

§ 46. The Halogen Compounds of Nitrogen

H. N. Warren [1] electrolyzed a conc. soln. of ammonium fluoride, and observed that oily drops collected about the cathode; he suggested that **nitrogen fluoride,** analogous to nitrogen chloride, was formed. The oily drops exploded more violently than nitrogen chloride. O. Ruff and E. Geisel said that there is something wrong with H. N. Warren's statement because hydrogen is evolved at the cathode, and at the anode, a mixture of oxygen and nitrogen, quite free from fluorine, is given off. The anode liquor, however, contains something which liberates iodine from potassium iodide. Nitrogen fluoride is not formed by the action of fluorine on ammonium fluoride, nor by treating nitrogen chloride with silver fluoride; nor was H. Moissan able to make it by the action of fluorine on nitrogen in the cold, or by the action of the electric discharge on a mixture of nitrogen and fluorine.

About 1811, P. L. Dulong prepared *une nouvelle substance detonnante* by the action of chlorine gas on a soln. of an ammonium salt at 8°. This proved to be the violent explosive **nitrogen chloride,** NCl_3. He continued work on this compound after it had caused him the loss of three fingers and one eye. The preparation and handling of this compound require the greatest care. Every vessel employed must be washed by alkali-lye in order to free it from grease; even grease from the fingers may cause an explosion. The substance is very liable to spontaneous explosion, and thick gloves, and a face shield are indispensable. This question has been discussed by V. Meyer, and L. Gattermann. The substance may be formed in some

---

reactions made with a totally different object—*e.g.* E. Dreyfuss mentioned its formation during the preparation of sulphamide; and F. Repiton, in some analytical work, obtained a violent explosion which he attributed to the unforeseen formation of this compound.

In preparing nitrogen by the action of chlorine upon aqueous ammonia, if the current of chlorine be continued after all the ammonia has been converted into ammonium chloride, the unmanageable explosive—nitrogen chloride—may be produced: $NH_4Cl+3Cl_2=4HCl+NCl_3$. Chlorine gas decomposes ammonia gas, or an aq. soln. of ammonia setting free nitrogen and hydrogen chloride, which unites with any unchanged ammonia, forming ammonium chloride: $8NH_3+3Cl_2=6NH_4Cl+N_2$. According to R. Porret and co-workers, a similar result obtains if the chlorine acts on a salt of ammonium and a weak acid; but if a salt of a strong acid be exposed to the chlorine gas—*e.g.* chloride, sulphate, phosphate, nitrate, or oxalate—the ammonia is to a certain extent protected from the action of the chlorine, and some of the explosive oil is formed, thus, $NH_4Cl+3Cl_2=4HCl+NCl_3$. This also occurs when chlorine in excess acts on aq. ammonia. W. A. Noyes and A. C. Lyon consider that the normal reaction between chlorine and ammonia should be symbolized: $12NH_3+6Cl_2 \rightarrow N_2+NCl_3+9NH_4Cl$, but only when the ammonia and chlorine are present in these proportions. If an excess of ammonia be present, it reacts with the nitrogen chloride giving free nitrogen: $NCl_3+4NH_3 \rightarrow 3NH_4Cl+N_2$, and ammonium hypochlorite: $NCl_3+2NH_3+3H_2O \rightleftharpoons 3NH_4OCl$; on the other hand, if a relatively small proportion of ammonia be present, the ammonium chloride formed in the reaction absorbs nitrogen, and the volume of nitrogen evolved will be less than that indicated by the normal equation—one-sixth the volume of the chlorine. W. A. Noyes and A. B. Haw said that in preparing the trichloride by this process a considerable proportion always decomposes into chlorine and nitrogen, either directly or by interaction between the trichloride and ammonia. The ratio of the number of mols. of chlorine to the number of mols. of ammonia may be varied between wide limits without affecting appreciably the ratio between the number of mols. of ammonia and the number of mols. of ammonium chloride. This ratio is 4 to 3. The chlorine reacts primarily with the ammonia, but only to a trifling extent, or not at all, with the solid ammonium chloride which is formed. According to C. T. Dowell and W. C. Bray, the reaction between chlorine and ammonia in strongly acidic soln. is typified by $NH_4Cl+4Cl_2=NCl_3+4HCl$; in strongly basic soln., by $8NH_3+3Cl_2=N_2+6NH_4Cl$; and in the presence of hypochlorous acid, by $NH_3+HOCl=H_2O+NH_2Cl$. They consider that the equation given by W. A. Noyes and A. C. Lyon is the resultant of a series of consecutive reactions the first of which is the formation of chloroamide · $NH_3+Cl_2=HCl+NH_2Cl$. L. Gattermann said that the product of the action of chlorine on ammonium chloride is a mixture of different chlorinated ammonias, and the composition depends on the conditions of the experiment. If the washed product be treated with chlorine, nitrogen trichloride is produced. W. A. Noyes said that ammonium sulphate is better than the chloride for preparing nitrogen trichloride.

R. Porret and co-workers said that 32° or upwards is more favourable for the production of nitrogen chloride than ordinary temp.; and that below 0°, none is produced. The presence of ammonium sulphide, sulphur, or powdered charcoal prevents the formation of nitrogen chloride; and this compound is not formed if the chlorine be mixed with one-third its vol. of air or carbon dioxide, or with an equal vol. of hydrogen. They prepared it by inverting a jar of chlorine over a dish containing a soln. of ammonium chloride at 32°. The oil forms a film on the sides of the vessel, and over the liquid, and finally sinks to the bottom in the form of oily drops. G. S. Sérullas inverted a jar of chlorine over a dish containing a warm soln. of ammonium chloride, and added more soln. to the dish as the liquid rose in the jar. When the chlorine was all absorbed, the jar was cautiously removed so as to prevent the oil attaching itself to the surface, and forming a film which volatilizes rapidly in air. A continuous current of luke-warm water was then passed into the dish containing the oil until the runnings were free from chlorides. J. J. Berzelius made nitrogen chloride by passing chlorine into a jar filled with a soln. of ammonium chloride, and inverted over a dish containing the same soln.

A. J. Balard noted that nitrogen chloride is formed when hypochlorous acid is in contact with ammonium chloride or sulphate, or aq. ammonia. W. Hentschel prepared nitrogen chloride by mixing a 5 per cent. soln. of sodium hydroxide sat. with chlorine, and a 10 per cent. soln. of ammonium chloride. The oil so formed was dissolved in benzene, chloroform, or carbon disulphide. The reaction is symbolized: $2NH_4Cl+7NaOCl=6NaCl+NaNO_3+4H_2O+NCl_3$. An excess of the hypochlorite produces chlorine which is dissolved by the nitrogen chloride. He also made the chloride by the action of a soln. of bleaching powder on ammonium chloride. If the soln. be alkaline, nitrogen chloride is not formed. H. Rai recommended the following procedure:

About 10 c.c. of a freshly prepared, filtered, conc. soln. of bleaching powder in a large test-tube are cooled in ice to about 0°, and an equal vol. of cold, sat. ammonium chloride soln. is added. When the vigorous reaction has subsided, after ten minutes, the nitrogen chloride is exploded by the addition of turpentine. The chloride on the surface explodes instantly, that at the bottom more violently after some time, the interval between the two explosions depending on the height of the liquid column, the amount of turpentine added, the nature of the surface explosion, and the amount of nitrogen chloride present. All apparatus must be absolutely free from grease and direct sunlight should be entirely excluded.

E. Dreyfuss, H. Rai, G. Lunge and R. Schoch, C. F. Schönbein, J. Thiele, H. Ditz, and T. Salzer studied the action of bleaching powder on a soln. of ammonium chloride. J. Kolb represented the reaction: $2NH_3+3CaOCl_2=3CaCl_2+3H_2O+N_2$. W. A. Noyes said that the treatment of an ammonium salt with hypochlorous acid gives a trichloride pure and free from chloro-amines. Nitrogen trichloride may be separated from a soln., in which it is prepared, by a current of air, drying the air and vap. of trichloride by passing through conc. sulphuric acid, and condensing the trichloride in a U-tube surrounded by a freezing mixture. J. Guinchant obtained nitrogen chloride by the action of hypochlorites on urea. According to R. Böttger, and H. Kolbe, drops of nitrogen chloride are formed on the anode during the electrolysis of conc. soln. of ammonium chloride. H. Hofer used a soln. of ammonium chloride sat. at 35°, and warmed to 40° by a current of 10–12 amps. and 7–8 volts. F. Mareck obtained a brown deposit on the cathode during the electrolysis of a cold sat. soln. of ammonium chloride. The nature of the deposit was not established.

The composition of the explosive product was represented by H. Davy as NCl_4; R. Porret and co-workers, by $NHCl_3$; N. A. E. Millon, as NH_2Cl; by J. H. Gladstone, as N_2HCl_5; and by A. Bineau, H. St. C. Deville and P. Hautefeuille, L. Gattermann, W. Hentzschel, P. L. Dulong, and D. L. Chapman and L. Vodden, NCl_3. The great explosiveness of the compound is referred by L. H. Friedburg to the internal strain induced by the chlorine atoms. T. T. Selivanoff said that nitrogen chloride is an amidoanhydride of hypochlorous acid, because this acid and not hydrochloric acid is developed when nitrogen chloride is hydrolyzed by water; and this hypothesis also explains why the chloride is so easily reduced with the formation of ammonia and chlorine by the action of hydrochloric acid. W. A. Noyes found that when nitrogen trichloride is titrated with a soln. of arsenious acid, one mol of trichloride is eq. to 6 gram-atoms of available chlorine, indicating that the nitrogen is negative and the chlorine positive, and that it hydrolyzes as a reversible reaction: $N'''Cl_3^{\cdot\cdot\cdot}+3H^{\cdot}O''H^{\cdot}=N'''H_3^{\cdot\cdot\cdot}+3H^{\cdot}O''Cl^{\cdot}$. He inferred that in the reaction between ammonia and chlorine, when nitrogen trichloride is formed, some chlorine molecules may be split up into Cl' and $Cl^{\cdot}$; and some of the nitrogen atoms may be temporarily positive and others negative. Hence, two nitrogen trichlorides are conceivable; in one—*nitro-nitrogen trichloride*—the nitrogen would be positive and the chlorine negative, and in the other—*ammono-*

nitrogen trichloride, presumably ordinary nitrogen chloride—the nitrogen is negative and the chlorine positive. W. A. Noyes believed that evidence of the existence of the nitro-nitrogen trichloride was obtained by passing a mixture of nitrosyl chloride and phosphorus pentachloride through a heated porcelain tube. Attempts to prepare nitro-nitrogen trichloride or nitrogen trichloride by passing mixtures of nitrogen and chlorine through a flaming arc were entirely unsuccessful. Passing the same gases through a powerful ozonizer had the same result and no action at all occurred with Strutt's active nitrogen. The results, although negative, confirm the hypothesis that electrons are held jointly by two atoms rather than the view that electrons are transferred from one atom to another when atoms combine. H. Henstock discussed the electronic structure.

H. Davy said that nitrogen chloride is a yellow, thick, oily liquid whose sp. gr. is 1·653; R. Porret and co-workers gave 1·6. I. I. Saslavsky discussed the mol. vol. H. Davy said that nitrogen chloride does not freeze at —40°. R. Porret and co-workers found that the chloride evaporates rapidly in air and can be distilled below 71°. The heat of formation worked out by H. St. C. Deville and P. Hautefeuille is —38·478 Cals. per eq.; and with the detonation at constant vol., a temp. of 2128° is attained, and a press. of 5361 atm.; with the detonation in air, at 760 mm., the temp. is 1698°. J. Thomsen was not satisfied with the above determination of the heat of formation. W. A. Noyes and W. F. Tuley found the heat of formation of nitrogen trichloride, in soln. in carbon tetrachloride, from gaseous nitrogen and chlorine, to be —54·7 Cals. R. Porret and co-workers said that the oily liquid does not conduct electricity.

The oil has a pungent odour which makes the eyes smart; and its action on the lungs is less powerful than that of chlorine. The physiological action was examined by W. Hentzschel. Nitrogen chloride explodes with great violence in many circumstances. There is a bright flash, a loud report, and the containing vessel may be shattered to bits. L. Gattermann said that a flash of direct sunlight, or magnesium light, may produce the explosion. He observed no explosion when the chloride was heated to 90°, but at 95° a sudden and violent explosion occurs. The destructive force seems to be downwards; this subject has been discussed by H. N. Warren, V. Meyer, and R. Wagner. Mere contact with many substances causes an explosion. W. Hentzschel found that nitrogen chloride dissolved in various organic solvents is decomposed by light usually with the formation of chlorination products. With carbon tetrachloride the reaction is simple: $2NCl_3 \rightarrow N_2+3Cl_2$; and E. J. Bowen measured the rates of decomposition in terms of the light energy absorbed, and concluded that more than one mol. is decomposed per quantum of energy absorbed.

According to R. Porret and co-workers, nitrogen chloride can be evaporated in **hydrogen, oxygen,** or atm. **air** without decomposition. A. Jouglet said that the chloride explodes in contact with **ozone.** When kept under cold **water,** H. Davy and G. S. Sérullas found that nitrogen chloride is decomposed within 24 hrs. with the formation of nitrogen and chlorine gases, and nitric and hydrochloric acids. T. T. Selivanoff suggested that in aq. soln. nitrogen trichloride is hydrolyzed $NCl_3+3H_2O \rightleftharpoons NH_3+3HOCl$; and in confirmation, D. L. Chapman and L. Vodden found that conc. **hydrochloric acid** reacts with a conc. soln. of nitrogen trichloride in carbon tetrachloride, forming chlorine and ammonium chloride: $NCl_3+3H_2O \rightleftharpoons NH_3+3HOCl$; $HOCl+HCl \rightleftharpoons Cl_2+H_2O$; and $NH_3+HCl \rightleftharpoons NH_4Cl$. Assuming the electronic theory of valency, N. V. Sidgwick said that when nitrogen trichloride reacts with water producing hypochlorous acid, its unshared pair of electrons are offered to the hydrogen of the water producing $Cl.N(Cl_2)-H.O.H$, which then decomposes. H. Davy also found that conc. hydrochloric acid gradually converts the oil into ammonium chloride with the evolution of chlorine gas: $NCl_3+4HCl = NH_4Cl+3Cl_2$. W. A. Noyes said that the formation of ammonium chloride from nitrogen trichloride and dry hydrogen chloride is not a hydrolysis when it occurs in the absence of water, and probably it is not a hydrolysis in the presence of water.

Rather does it consist primarily in the formation of *trichloroammonium chloride*, $(NCl^{\cdot}_3H)Cl'$, followed by the loss of an atom of positive chlorine with an atom of negative chlorine. The formation of nitrogen trichloride by the action of chlorine on a soln. of an ammonium salt appears to be the reverse of this reaction. T. T. Selivanoff found that dil. hydrochloric acid reacts with nitrogen chloride, forming hypochlorous acid, which is decomposed as fast as it is formed, and chlorine is evolved. C. T. Dowell and W. C. Bray showed that nitrogen trichloride, in carbon tetrachloride soln., reacts with a dil. soln. of **ammonium chloride,** and more rapidly with a conc. soln. $NH_4Cl+NCl_3=N_2+4HCl$. T. T. Selivanoff found that nitrogen trichloride decomposes in contact with **iodine,** and a dil. soln. of iodine yields iodic acid. C. T. Dowell and W. C. Bray found that a soln. of iodine reacts with nitrogen chloride in carbon tetrachloride soln. liberating nitrogen and forming iodine chloride —the addition of water results in the precipitation of iodic acid. If **potassium iodide** is used, 18 per cent. of the nitrogen is liberated as such, and the addition of sulphuric acid did not affect the result. According to N. A. E. Millon, an aq. soln. of **potassium bromide** forms nitrogen bromide or iodide, and potassium chloride. T. T. Selivanoff said that iodine is liberated from potassium iodide. G. S. Sérullas said that **sulphur** is without chemical action on nitrogen chloride, but is quietly dissolved. According to P. L. Dulong, sulphur decomposes nitrogen chloride, producing a substance which rapidly dissolves in water, forming a soln. of hydrochloric and sulphuric acids. G. S. Sérullas noted that contact with **selenium** produces an explosion; with an aq. soln. of **hydrogen sulphide,** milk of sulphur is deposited, a little nitrogen is evolved, and a soln. of ammonium chloride and hydrochloric acid formed. C. T. Dowell and W. C. Bray found that hydrogen sulphide reacts with nitrogen chloride in carbon tetrachloride soln., liberating 5·5 per cent. of the nitrogen and reducing the remainder to ammonia. R. Porret and co-workers found that contact with **hydrogen sulphide or persulphide** produces an explosion. N. A. E. Millon found that an aq. soln. of potassium sulphide produces a greenish-yellow powder which floats on the liquid. R. Porret and co-workers observed no action with **mercuric sulphide.** J. H. Gladstone showed that with **sulphurous acid,** nitrogen, ammonia, and hydrochloric acid are formed. C. T. Dowell and W. C. Bray found that of all the reducing agents tried, **sodium sulphite** was the only one which converted the whole of the nitrogen into ammonia when it acts on a carbon tetrachloride soln. of nitrogen trichloride: $3Na_2SO_3+NCl_3+3H_2O=3Na_2SO_4+2HCl+NH_4Cl$. H. Davy said that in contact with dil. **sulphuric acid,** nitrogen and oxygen are evolved. According to T. T. Selivanoff, dil. sulphuric acid forms a soln. containing hypochlorous acid, and the reaction is reversible. The iodide dissolves in **sulphur chloride.** R. Porret vaporized the chloride in **nitrogen** without any perceptible change. With conc. aq. **ammonia,** an explosion occurs, but H. Davy found that with a dil. soln., nitrogen is evolved and nitric acid formed. S. M. Tanatar obtained hydrazoic acid by the action of nitrogen chloride on **hydrazine.** C. T. Dowell and W. C. Bray found that with a carbon tetrachloride soln. of nitrogen chloride, both hydrazine and **hydroxylamine** give off nitrogen. R. Porret observed an explosion occurs when nitrogen chloride is brought in contact with **nitric oxide**; and H. Davy noted that with conc. **nitric acid,** nitrogen gas is evolved. G. S. Sérullas found that with a soln. of **silver nitrate,** nitrogen, nitric acid, and silver chloride are formed. G. S. Sérullas observed that contact with **phosphorus** causes nitrogen chloride to explode, and R. Porret and co-workers noted that soln. of phosphorus in carbon disulphide, **phosphine,** and **calcium phosphide** produce rather less violent explosions, and the decomposition by a soln. of phosphorus in ether is gradual. H. Davy said that nitrogen chloride is dissolved by **phosphorus trichloride**; and R. Porret and co-workers observed no reaction with dil. **phosphorous acid.** G. S. Sérullas found that nitrogen chloride explodes in contact with powdered **arsenic**; while R. Porret and co-workers said that arsenic is separated from **arsine** by the action of nitrogen chloride. G. S. Sérullas observed that with **arsenious acid,** ammonia is formed. C. T. Dowell and W. C. Bray found that a soln. of nitrogen chloride in carbon tetrachloride reacts with arsenious acid, liberating 7·7 per cent. of nitrogen, in the elemental form. Reducing the conc. of the soln. increases the yield of nitrogen, and with up to $0{\cdot}5N$-H_2SO_4, the yield of free nitrogen is augmented. The reduction of sodium arsenite soln. was also examined by W. Hentzschel, W. A. Noyes and A. C. Lyon, and D. L. Chapman and L. Vodden—*vide supra*. R. Porret could detect no reaction between native **antimony sulphide** and nitrogen chloride.

R. Porret and co-workers observed no reaction between **carbon** as charcoal on nitrogen chloride, and the chloride can be vaporized in an atm. of **ethylene** without undergoing chemical change. W. Hentzschel said that the chloride is dissolved by **benzene, chloroform, carbon tetrachloride,** and **carbon disulphide.** These soln. are sulphur-yellow, and refract light strongly; they are rapidly decomposed in light, but in diffuse daylight, or in darkness, they can be kept unchanged for weeks. The decomposition of an ethereal soln. is vigorous in sunlight, and some nitrogen is reduced to ammonia. The benzene soln. gives nitrogen and hexachloroethane when exposed to sunlight. The carbon tetrachloride soln. becomes yellow through the soln. of liberated chlorine, the chloroform soln. furnishes chlorine, hydrogen and ammonium chlorides, and hexachloroethane, but no carbon tetrachloride. The carbon disulphide soln. forms some sulphur chloride. R. Porret and co-workers said that the yellow soln. of nitrogen chloride in carbon disulphide does not explode with phosphorus or the fatty oils, but quietly sets fire to an excess of these substances; and, added G. S. Sérullas, the soln. is slowly decomposed under water into nitrogen, ammonia, hydrochloric acid, and sulphuric acid. The addition of phosphorus to the soln. causes a violent ebullition. N. A. E. Millon found that an explosion is produced when nitrogen chloride is brought in contact with **potassium cyanide**—solid or conc. soln.—a moderately dil. soln. producing potassium chloride and amidogen cyanide, while a dil. soln. disengages nitrogen gas only. Solid or an aq. soln. of **potassium thiocyanate** produces with nitrogen chloride an orange-yellow buttery mass, which dissolves in an excess of soln. R. Porret and co-workers observed no reaction with **potassium ferrocyanide.** T. T. Selivanoff found that nitrogen chloride is decomposed by a soln. of succinimide, forming chlorosuccinimide; the same product is obtained by the action of hypochlorous acid in place of nitrogen chloride. This and the other reactions of nitrogen chloride led T. T. Selivanoff to assume that nitrogen chloride is a derivation of hypochlorous acid—*vide infra*, nitrogen iodide. R. Porret and co-workers, C. T. Dowell and W. C. Bray found that a carbon tetrachloride soln. of nitrogen trichloride converts quinol into hexachloroquinol; and carbamide in acid soln. is not acted on, but in neutral soln. there is a slow evolution of nitrogen. They also observed that nitrogen chloride explodes in contact with various **organic substances.**

Thus, R. Porret and co-workers found that lead paint, margarates and oleates of manganese, copper, silver, and mercury; petroleum; amber oil, and amber; turpentine, camphorated olive oil; palm oil; train oil, olive oil; linseed oil; myrrh; and caoutchouc cause rapid decomposition. The decomposition is more or less gradual with margarates and oleates of barium, strontium, calcium, magnesium, potassium, aluminium, tin, and cobalt; ordinary resin, and ox-gall resin, and soln. of resin or shellac in alcohol. No decomposing action was observed with jet; shellac; frankincense; scammony; aloes; ethyl sulphate and nitrite; sugar; manna; gum; starch; indigo; gum kino; catechu; dried white-of-egg; benzoic acid; gum ammoniac; wax; spermaceti; stearine; butter; lard; or alcohol. Combination attended by a more or less partial decomposition occurs with asphalt, elaterite, copal, mastic, guaiacum, euphorbium, asafœtida, camphor, sulphuretted camphor, oil of musk, stearic and oleic acids, etc. W. Hentzschel found that aniline and nitrogen chloride in benzene soln. furnish trichloroaniline; methylaniline, trichloromethylaniline; and dimethylaniline, a chlorine derivative of tetraphenyl hydrazine. W. Strecker observed no reaction between benzene soln. of nitrogen chloride and magnesium ethyl iodide or magnesium phenyl bromide. G. H. Coleman and co-workers studied the addition products formed by the acetylene hydrocarbons with nitrogen trichloride dissolved in carbon tetrachloride.

P. L. Dulong, and H. Davy found that nitrogen chloride in contact with **copper** or **mercury** under water sets free nitrogen and forms a **metal** chloride; R. Porret and co-workers could detect no action on **tin** or **zinc.** G. S. Sérullas found that **lead, cobalt, copper, and silver oxides** decompose nitrogen chloride, forming chlorides and nitrates. A dil. soln. of **potassium hydroxide** forms the alkali chloride and nitrate with the evolution of nitrogen; R. Porret and co-workers found that an explosion occurs when nitrogen chloride is brought in contact with potassium hydroxide in the presence of water. C. T. Dowell and W. C. Bray found that when **sodium hydroxide** reacts with nitrogen trichloride there is a rapid evolution of nitrogen, and 7 per cent. of the nitrogen is recovered as ammonia; they also observed that **ferrous sulphate** reacts with nitrogen trichloride in carbon tetrachloride soln., forming nitrogen and ammonia.

The well-known bluish-violet colour reaction of aniline is or is not obtained with a hypochlorite according as ammonia is added after or before the hypochlorite and the aniline soln. are mixed. Moreover, whilst conc. soln. of ammonium hydroxide and sodium hypochlorite immediately evolve nitrogen when mixed, gas is evolved from dil. soln. only after some time. F. Raschig [2] inferred from these facts that there is formed an intermediate compound between ammonia and nitrogen. He showed that soln. containing equimolar proportions of ammonia and sodium hypochlorite react quantitatively: $NaOCl+NH_3=NH_2Cl+NaOH$; by adding, say, 50 c.c. of a soln. of 3·7 grms. of sodium hypochlorite—free from an excess of chlorine—to 100 c.c. of an aq. soln. containing 0·85 grm., the penetrating smell characteristic of monochloramide, NH_2Cl, appears. Some nitrogen is at the same time evolved owing to the decomposition of the monochloramide: $3NH_2Cl=N_2+NH_4Cl+2HCl$. No ammonium hypochlorite is formed. By distilling the liquid in vacuo at a low temp., *chloroamide*, or **chloroamine,** NH_2Cl, can be obtained as an unstable, pale yellow oil floating on the water in the receiver. There is much decomposition during the distillation. W. Marckwald and M. Wille said that the yellow liquid contains 10–12 per cent. of chloroamine. F. Raschig found that it can be distilled in vacuo in the presence of 50 per cent. zinc chloride without decomposition. For the action of soln. of hypochlorites on ammonia, *vide supra.* Chloroamine obtained as just described is a yellow mobile liquid. It attacks the eyes and nose like nitrogen chloride. When a conc. aq. soln. of chloroamine is kept at a low temp., it deposits yellow crystals of chlorine hydrate. W. Marckwald and M. Wille said that even at 0° the soln. soon commences to evolve nitrogen and to separate oily drops of nitrogen chloride. Its instability rapidly increases when it is preserved, decomposition being catalytically accelerated by the liberated acid. The course of the change is represented by the equations: $3NH_2Cl=NH_4Cl+2HCl+N_2$, $NH_2Cl+2HCl=NH_4Cl+Cl_2$, and $NH_2Cl+2Cl_2=NCl_3+2HCl$. Attempts to extract chloroform from its aq. soln. by means of benzene, chloroform, carbon tetrachloride, or ether had only limited success, the last-named solvent being the most suitable. The isolation of pure chloroamine has been rendered possible by the observations that its aq. soln. are greatly stabilized by the presence of very small amounts of ammonia. Even under those conditions, however, the concentration of the 10–12 per cent. soln. cannot be effected by distillation, since violent explosions invariably occur which are obviously due to the formation of nitrogen chloride. The vapours of the 10–12 per cent. soln. were therefore dried, and the unabsorbed portions condensed in a U-tube cooled in liquid air. For this purpose, calcium chloride and soda lime are unsuitable, since they influence the slight hydrolysis of chloroamine by water, $NH_2Cl+H_2O=NH_3+HClO$, in such a manner that the condensate consists of chlorine monoxide. Better results are obtained with anhydrous potassium carbonate. *Chloroamine* is thus obtained as a colourless, crystalline substance, m.p. $-60°$. It decomposes suddenly at about $-50°$ into nitrogen, chlorine, ammonium chloride, and nitrogen trichloride, and frequently explodes violently, so that its physical properties could not be further investigated. F. Raschig, and A. Stock found that chloroamine reacts with ammonia to form hydrazine and hydrogen chloride. According to F. Raschig, chloroamine reacts with *potassium iodide*, forming a brown soln., supposed to contain *iodamide*, NH_2I, which soon decomposes, forming ordinary nitrogen iodide, $NH_3.NI_3$. An acidified soln. reacts as symbolized: $2HI+NH_2Cl=NH_3+HCl+I_2$. Amidosulphonic acid is not formed by the action of *hydrosulphites* or *sulphurous acid*; rather is the sulphurous acid oxidized: $NH_2Cl+SO_2+2H_2O=NH_3+H_2SO_4+HCl$. The reaction with *potassium cyanide* is symbolized: $NH_2Cl+KCN+H_2O=NH_3+CNCl+KOH$. Chloroamine reacts with a soln. of *potassium hydroxide* almost quantitatively: $3KOH+3NH_2Cl=NH_3+N_2+3KCl+3H_2O$, and this the more rapidly the more conc. the soln. The alkali is always present in the mixture employed in making chloramide, so that there is a side reaction involving the production of ammonia and nitrogen—possibly from triimide, $N_3H_3=NH_3+N_2$. It was not found possible to realize the reaction, $NH_2Cl+NaOH=NaCl+H_2O+NH$, but the presence of traces of hydrazoic acid was established. The reaction between chloroamine and ammonia is similar to that with alkali-lye: $3NH_2Cl+2NH_3=N_2+3NH_4Cl$. At the same time, a small quantity of a reducing substance is formed. This was first observed by J. Thiele in his study of the action of ammonia on sodium hypochlorite. It is hydrazine formed by the consecutive reaction: $NH_2Cl+NH_3=N_2H_5Cl$. F. Raschig succeeded in hindering the first reaction and accelerating the second; by treating normal sodium hypochlorite soln., with 50 times the calculated quantity of ammonium hydroxide, in the presence of a little glue, there is produced 75–80 per cent. of the theoretical quantity of hydrazine (*q.v.*). In the presence of conc. alkali-lye, ammonia reacts in an analogous way, $NH_2Cl+NH_3+NaOH=N_2H_4+NaCl+H_2O$. This reaction also is favoured by the presence of formaldehyde, sugars, gum, or gelatin. According to W. Marckwald and M. Wille, the reaction with alkali-lye runs smoothly only when dil. soln. are employed; with conc. soln., the reaction takes place partly in accord with the scheme: $NH_4Cl+KOH=NH_3+KCl+H_2O$. F. Raschig obtained phenylhydrazine by the action of aniline in place of ammonia, and many substituted ammonias furnish substituted chloramides by treatment with hypochlorites. Thus, W. Meigen and W. Normann converted *p*-nitroaniline into *p*-nitrophenylmonochloramine. F. Raschig likewise treated *p*-amidophenol, *p*-phenylenediamine, *o*-toluidine, *p*-toluidine, β-naphthylamine, etc., with hypochlorites, and C. F. Cross and co-workers, proteids. H. Henstock gave for the electronic structure:

$$\begin{matrix}+\mathrm{H}\\+\mathrm{H}\end{matrix}\!>\overset{+}{\mathrm{N}}\!-\!\overset{-}{\mathrm{Cl}}$$

Nitrogen does not form a pentachloride. There are often curious changes in the degree of stable valency of the elements in a particular group. Nitrogen and arsenic do not form pentachlorides, while phosphorus and antimony do; nitric and arsenic acids readily give up oxygen, but phosphoric and antimonic acids are comparatively stable; the higher oxides of chlorine and iodine furnish a marked contrast with those of fluorine and bromine; and likewise the higher oxides of sulphur and tellurium, with those of oxygen and selenium.

According to N. A. E. Millon,[3] if an aq. soln. of potassium bromide is added drop by drop to nitrogen chloride covered by a layer of water, the yellow colour of the chloride slowly changes to red, which becomes deeper and deeper in tint. The dense black oil so obtained was considered to be a **nitrogen bromide.** It is very volatile, offensive-smelling oil which attacks the eyes very strongly. It explodes violently in contact with phosphorus or arsenic; under water, it is slowly decomposed, forming nitrogen, bromide, and ammonium bromide; and is decomposed by ammonia with the production of dense white fumes. H. W. B. Roozeboom obtained no trace of an explosive compound during the electrolysis of soln. of ammonium bromide.

The chocolate-coloured amorphous powder which was made by B. Courtois,[4] about 1813, by the action of an aq. soln. of ammonia on solid iodine, was thought by J. L. Gay Lussac, J. J. Colin, J. W. Mallet, and C. Stahlschmidt to be **nitrogen**

iodide, NI_3, analogous to nitrogen chloride, NCl_3. On account of the ease with which the product decomposes it is difficult to determine the composition; different results have been obtained by different methods of preparation. Nitrogen iodide is made by mixing iodine in various solvents—alcohol, chloroform, carbon disulphide, or aq. potassium iodide—with ammonia. R. Bunsen mixed cold sat. soln. of iodine and of ammonia in absolute alcohol, and washed the black product free from ammonium iodide by means of absolute alcohol: $2NH_3+3I_2=3HI+NH_3.NI_3$. G. S. Sérullas, J. H. Gladstone, and C. Stahlschmidt treated an alcoholic soln. of iodine with a conc. aq. soln. of ammonia, and washed with water. R. Bunsen, and G. S. Sérullas added ammonia to a dil. soln. of iodine in aqua regia and washed the precipitate rapidly with cold water: $2ICl+3NH_3=2NH_4Cl+NHI_2$, according to J. H. Gladstone; or $3NH_4OI=NH_3.NI_3+NH_3+3H_2O$, according to C. F. Schönbein. J. S. Stas purified iodine by first transforming it into nitrogen iodide, and then recovered the iodine. F. D. Chattaway and K. J. P. Orton mixed 300 c.c. of hydrochloric acid, sp. gr. 1·15, 28 c.c. of nitric acid, sp. gr. 1·41, and 100 grms. of iodine, at 40°, and then at 0°, added ammonia. Good crystals of nitrogen iodide can be obtained by adding ammonia to a soln. of potassium hypoiodite containing 0·02 mol per litre: $3NH_4OI=N_2H_3I_3+NH_4OH+2H_2O$. F. Raschig said that the precipitate obtained by the action of potassium iodide on a soln. of chloroamine, in the presence of ammonium chloride, is similar to that obtained by the action of iodine on aq. ammonia.

Nitrogen iodide does not appear to be formed by the direct substitution of iodine for hydrogen in ammonia, but the iodine reacts with ammonium hydroxide as it does with other alkalies, forming ammonium iodide; and T. T. Selivanoff considered that nitrogen iodide is most probably formed by the action of ammonia on hypoiodous acid which, along with ammonium iodide, is the first product of the reaction between ammonia and iodine: $NH_3+H_2O+I_2=NH_4I+HOI$, for the addition of a dil. soln. of iodine to ammonia gives a clear liquid containing hypoiodous acid; if more iodine is added, nitrogen iodide is precipitated and the clear liquor contains less of that acid than before. On the other hand, nitrogen iodide is soluble in a large amount of ammonia, forming hypoiodous acid so that the reactions $2NH_3+3HOI\rightleftharpoons NH_3.NI_3+3H_2O$, $NH_3+2HOI\rightleftharpoons NHI_2+2H_2O$, or $NH_3+3HOI\rightleftharpoons NI_3+3H_2O$, are reversible. It is claimed that this interpretation is supported by the fact that when a dil. soln. of iodine is added to ammonia, the liquid remains clear and contains hypoiodous acid. When a further quantity of iodine is added, iodide of nitrogen is precipitated, and the clear liquid then contains less hypoiodous acid than before. On the other hand, nitrogen iodide is soluble in a large amount of ammonia, yielding a soln. which contains hypoiodous acid, so that the three equations given above are reversible. It is to this formation of hypoiodous acid that many of the characteristic reactions of iodide of nitrogen must be referred, such as the liberation of oxygen from hydrogen peroxide, the formation of chloride of iodine by the action of hydrochloric acid, and the production of iodine derivatives from phenol. The accuracy of this view is further confirmed by the action of potassium iodide soln. and of dil. acids on iodide of nitrogen. Potassium iodide dissolves all the iodides of nitrogen more or less readily, and the soln. formed contains ammonia, iodine, and caustic potash, the reaction being represented by the following equations: $NHI_2+2H_2O=NH_3+2HOI$; and $2HOI+2KI=2I_2+2KOH$. Dil. acids, on the other hand, convert iodide of nitrogen into iodine and iodic acid, both of which are formed from hypoiodous acid according to the equation $5HOI=2I_2+HIO_3+2H_2O$. The change is usually accompanied by a certain amount of decomposition into iodine and nitrogen, but this can be wholly avoided if (1) a small amount of acid be employed, (2) sufficient water be present to dissolve the whole of the iodine formed, and (3) the iodide of nitrogen be in the form of a very fine powder. T. T. Selivanoff therefore proposed to call $NH_3:NI_3$, *sesquiiodylamine;* NHI_2, *diiodylamine;* and NI_3, *triiodylamine.* This view of the formation of nitrogen iodide is virtually that suggested by C. F. Schönbein, and is confirmed by the formation of this compound when ammonia is added to an alkaline soln. of potassium hypoiodite : $KIO+NH_4OH=NH_4OI+KOH$, and the ammonium hypoiodite thus formed decomposes into nitrogen iodide. L. Playfair made nitrogen iodide by the action of bleaching powder on a soln. of ammonium chloride, a reaction which J. H. Gladstone represented by $Ca(OCl)_2+2NH_4I=NH_4I_2+CaCl_2+2H_2O+NH_3$. J. J. André treated iodine trichloride, or a hydrochloric acid soln. of iodic acid with ammonia—J. H. Gladstone could not verify this method, but F. Raschig showed iodic acid and conc. hydrochloric acid form chlorine, and then iodine chloride, that which, when treated with ammonia, furnishes nitrogen iodide ; with dil. soln. the temp. should be raised. G. S. Sérullas obtained nitrogen iodide by treating a mixture of ammonium iodate, ammonium iodide, and hydrochloric acid with potassium hydroxide. J. Szuhay added an excess of aq. ammonia to a conc. soln. of iodine in one of potassium iodide. He represented the reaction by $3NH_3+2I_2=2NH_4I+NHI_2$. L. Dobbin and D. O. Masson found nitrogen iodide is formed in the decomposition of tetramethylammonium dichloroiodide, $(CH_3)_4NICl_2$; and C. Rice, in the action of alcohol and iodine on white precipitate —in this case, the presence of carbolic acid inhibits the reaction.

The composition and constitution of the so-called nitrogen iodide is uncertain. It will be observed that the equations for these various reactions depend on what view is taken of the composition of the final product. A. Bineau, F. Raschig, J. Szuhay, T. T. Selivanoff, and J. H. Gladstone represented its composition by NHI_2 ; N. A. E. Millon, and R. F. Marchand, gave NH_2I ; A. Guyard, $N_5H_5I_{10}$ and $N_8H_9I_{15}$; R.Bunsen obtained $NH_3.NI_3$ for the composition of the product formed in alcoholic soln., free from water ; and with iodine chloride and ammonia in aq. soln., $NH_3.4NI_3$. F. Raschig said that the first precipitate formed has the composition $NH_3.NI_3$, and with the washing it passes to explosive NHI_2, and then to NI_3. J. W. Mallet obtained $NI_3 : NI_3$; $NI_3 : NHI_2$; $NI_3 : NH_2I$; and $NHI_2 : NHI_2$. According to F. D. Chattaway and co-workers, the product of the different reactions is virtually the same if precautions be taken to remove free iodine and ammonia, and to prevent partial decomposition. When alcoholic soln. are used, the yield is reduced because of a secondary reaction between nitrogen iodide and alcohol giving iodoform, which contaminates the products. O. Ruff said that the formula is either $H_3N : NI_3$ or $I_3N : NI$; and it is generally agreed that in the so-called nitrogen iodide two nitrogen atoms are linked together to form either $H_3N : NI_3$, or $HI_2N : NHI_2$. The **nitrogen amminotriiodide** hypothesis is considered the more likely by F. D. Chattaway and co-workers, and others because nitrogen iodide which has stood under water for some time is very liable to explode, and analysis shows that an unstable nitrogen iodide, NI_3, is probably formed, but, if such a compound does exist, it is stable only in the presence of a large excess of iodine, and it has not been isolated. The term "nitrogen iodide" employed in describing the preparation and properties, refers probably to nitrogen amminotriiodide, $H_3N : NI_3$, when the nitrogen atoms are quinquevalent.

Nitrogen iodide as usually obtained by the different methods is a very dark brown or black powder. F. D. Chattaway and K. J. P. Orton obtained it in acicular crystals which were copper-red in reflected light, and red in transmitted light. The crystals are therefore dichroïc ; and probably belong to the rhombic system. The sp. gr. is 3·5. Although moist nitrogen iodide can be handled without danger of explosion, the dry compound is very explosive. Explosions are said to have been produced as a result of the shock of a falling dust-particle, and by a fly walking over the dry powder. N. A. E. Millon said that the iodide explodes when merely dried in air, and this the more readily, the higher the temp. The slightest movement, the least elevation of temp., or the addition of sulphuric or any other strong acid, whereby heat is probably developed, causes it to explode. When *under* water, the iodide does not usually explode unless strongly rubbed. Contact with oils and other fatty bodies does not usually cause it to explode. The explosion, said

N. A. E. Millon, is attended by a violet light, visible in the dark; the nitrogen is set free as a gas, and the iodine as a very fine powder. The white vapour formed during the explosion is probably ammonium iodide. R. F. Marchand also observed that traces of ammonium iodide are formed during the explosion; and R. Bunsen said that the first action is $NH_3+NI_3=N_2+3HI$, followed by the decomposition of the hydrogen iodide into its elements, while a little reacts with ammonia, forming ammonium iodide. P. Champion and H. Pellet showed that the explosion of nitrogen iodide at a distance can produce a second sympathetic explosion at some distance away by mechanical vibrations. The lowest number of vibrations are about 30 per second. Vibrations which give a deep sound have no effect, but shriller sounds readily explode the iodide. Heat unless accompanied by mechanical vibrations of the proper kind does not produce an explosion of the iodide.

Iodide of nitrogen was placed at the focus of a parabolic mirror, and at the focus of a second similar mirror, nitroglycerol, fulminate of mercury, and gunpowder were exploded. The quantity of nitroglycerol necessary to cause the explosion of the iodide of nitrogen in the other focus was determined; and it was found that as much powder was required as would produce ten times the heat given out in the burning of the required quantity of nitroglycerol. The mirrors were afterwards covered with lamp-black, and then even this large quantity of powder would not cause the iodide of nitrogen to explode, On the other hand, the lamp-black covering did not in the least prevent the nitroglycerol in one focus from exploding the iodide of nitrogen in the other.

J. Egert showed that the inter-molecular decomposition of nitrogen iodide takes place according to the equation $8NH_3NI_3=5N_2+6NH_4I+9I_2$, whether the decomposition takes place in the dark or in the light or is occasioned by detonation. Nitrogen iodide is not sensitive to shock, and many effects which were previously attributed to detonation are due to secondary mechanical effects. The sensitiveness of nitrogen iodide is not materially changed by lowering the temp. to —190°. Gradual isothermal increase of press. to 5000 atm. brings about a decomposition in 70 per cent. of the samples of nitrogen iodide. J. W. Mallet, and A. Guyard found that nitrogen iodide is decomposed by exposure to **light**, forming nitrogen, ammonium iodide and iodate; under water this decomposition usually proceeds quietly, but may end with an explosion; in ammonia the reaction proceeds quietly to the end. F. D. Chattaway and K. J. P. Orton found that the products with dry nitrogen iodide are nitrogen, iodine, and ammonium iodide; similar products are obtained when the iodide is decomposed by percussion or heat. A. Guyard found that the rapidity of the decomposition is proportional to the intensity of the light; and he added that heat rays are without action; the yellow rays are most active, the violet rays least active; but F. D. Chattaway and K. J. P. Orton said that the red rays are the most active, and that with decreasing wave-length the time required for the first appearance of gas bubbles increases; there is a second maximum with the blue rays. H. N. Warren found that nitrogen iodide instantly explodes, when exposed to the magnesium-light, while a few minutes' exposure is required with the limelight. According to F. D. Chattaway and K. J. P. Orton, nitrogen iodide in ammonia is decomposed by sunlight or artificial light: $NH_3.NI_3=N_2+3HI$; with the simultaneous reaction $NH_3.NI+3H_2O=2NH_3+3HOI$; and $NH_3+HOI=NH_4OI$; while the hypoiodite then decomposes into ammonium iodide and iodate. Nitrogen iodide suspended in **water** behaves in a similar way, but under water, there is also the additional reaction: $NH_3.NI_3+5HI=2NH_4I+3I_2$. The ammonium iodate produced represents 2 to 4 per cent. of the original nitrogen iodide. The production of the hypoiodite is a hydrolytic process and proceeds in light or in darkness, but the formation of nitrogen and hydrogen iodide only occurs in light. According to G. S. Sérullas, N. A. E. Millon, and J. S. Stas, nitrogen iodide gradually dissolves under cold water, forming in 4–6 weeks ammonium iodide and iodate; and some free iodine. If the temp. be raised, the dissolution proceeds more rapidly; at 70°, the reaction is turbulent; and in boiling water, an explosion occurs. G. S. Sérullas, and

N. A. E. Millon said the aq. soln. is neutral; J. H. Gladstone, acid. A. Guyard said that the nearer the composition of the iodide approaches NHI_2, the less is it changed by washing with water; and F. D. Chattaway and K. J. P. Orton found that nitrogen iodide is hydrolyzed by water and alkaline soln.—ammonia and an hypoiodite are formed: $N_2H_3I_3+3KOH=2NH_3+3KOI$; or $N_2H_3I_3+3H_2O=2NH_3+3HOI$. The hypoiodite breaks down more or less rapidly into iodide and iodate: $3KOI=2KI+KIO_3$; or $3HOI=2HI+HIO_3$. In the latter case, the products of the reaction interact, forming iodine: $5HI+HIO_3=3I_2+3H_2O$. In darkness, the hydrolytic action of water with the production of iodine, and ammonium iodide and hypoiodite explains how with washing, the nitrogen content of ammonium iodide is reduced; until finally nothing but iodine remains. F. Raschig said that the original precipitate, $NH_3.NI_3$, reacts with sodium hydroxide as symbolized: $NH_3.NI_3+4NaOH=NH_3+3NaI+2H_2O+NaNO_2$; and $NH_3.NI_3+3NaOH=N_2+3NaI+3H_2O$. According to C. F. Schönbein, an aq. soln. of **hydrogen dioxide** decomposes nitrogen iodide turbulently with the evolution of oxygen and a little nitrogen, and the formation of a brown soln. of iodine, hydriodic acid, ammonium iodide, and a trace of iodic acid. F. D. Chattaway found that in alkaline soln., hydrogen dioxide forms ammonia, alkali iodide, a trace of iodate, oxygen, and a little nitrogen.

J. H. Gladstone found that **chlorine** slowly decomposes nitrogen iodide; a similar result was obtained with **bromine** water. P. Champion and H. Pellet said that the iodide explodes by contact with chlorine or bromine. According to G. S. Sérullas, and N. A. E. Millon, when dil. **hydrochloric acid** is gradually added to nitrogen iodide, under water, the iodide dissolves completely with the evolution of gas, and the soln. contains ammonium chloride, iodide, and iodate. Nitrogen iodide is again precipitated from the soln. if alkali-lye be added because the ammonia set free by the alkali reacts with the two salts of iodine present. J. H. Gladstone represented the reaction, $NHI_2+3HCl=NH_4Cl+2ICl$; R. Bunsen, $NH_3.NI_3+5HCl=2NH_4Cl+3ICl$; and C. Stahlschmidt, $NI_3+4HCl=NH_4Cl+3ICl$. F. D. Chattaway found that in contact with dil. **acids,** nitrogen iodide is hydrolyzed $N_2H_3I_3+3H_2O=2NH_3+3HOI$. The ammonia combines with the acid, and the hypoiodite breaks down in a way which depends upon the nature of the acid used: with **phosphoric, acetic, boric, or sulphuric acid,** the reaction is of the type $3HOI=2HI+HIO_3$, followed by $5HI+HIO_3=3I_2+3H_2O$; with acids which can react with hypoiodous acid, other changes occur, for instance, with **hydriodic acid and hydrochloric acids,** $HOI+HI=I_2+H_2O$; $HOI+HCl=ICl+H_2O$, and with **hydrocyanic acid,** $HOI+HCy=ICy+H_2O$. With conc. acids, a violent explosion results. F. D. Chattaway and K. J. P. Orton also examined the action of **lead and silver iodides.** A. Guyard said that **potassium iodide** and nitrogen iodide, in darkness form potassium polyiodide free from ammonia; and **cupric iodide** forms cuprous iodide, and ammonium polyiodide. When an ammoniacal soln. of a copper salt is mixed with potassium diiodide, a brilliant, crystalline, garnet-coloured precipitate of **copper nitrogen iodide,** $CuI_2,2NH_2I$, is gradually deposited. When dried, this compound is very stable, but it is entirely decomposed by water, with formation of ammonium diiodide, and a bronze-coloured cupric oxyiodide, CuO_2I, which is decomposed by heat into black cupric oxide, iodine, and oxygen. The double copper nitrogen iodide is decomposed by aq. ammonia, with formation of an ammoniacal soln. of cupric iodide and a residue of an explosive nitrogen iodide free from copper. When the double iodide is heated, iodine and the products of the decomposition of nitrogen iodide are given off, and a residue of perfectly pure cuprous iodide is left. When distilled, the double iodide yields cuprous iodide, and brown, violet, and ammoniacal vapours. The brown vapours condense to a black product, decomposed by water with formation of a black crystalline nitrogen iodide, which resembles iodine in appearance, but which differs from all the other nitrogen iodides by dissolving with effervescence in a soln. of potash or soda, nitrogen or hydrogen being given off, and a considerable quantity of ammonia formed.

According to G. S. Sérullas, A. Bineau, J. H. Gladstone, F. D. Chattaway, and C. Stahlschmidt, nitrogen iodide is almost instantly decomposed by **hydrogen sulphide** with the separation of sulphur, but with no evolution of gas; the resulting soln. contains ammonium iodide mixed with a slight excess of hydriodic acid. J. H. Gladstone, and F. D. Chattaway found that an aq. soln. of **sulphur dioxide** decomposes nitrogen iodide into hydriodic acid. The former gave for the equation $NHI_2+2SO_2+4H_2O=NH_3+2HI+2H_2SO_4$. A. Bineau represented the reducing action of sulphurous acid, $NHI_2+2H_2=NH_4I+HI$. F. Raschig represented the reaction with **sodium sulphite**: $NH_3.NI_3+3Na_2SO_3+3H_2O=2NH_3+3HI+3Na_2SO_4$. A. Guyard found that **sodium thiosulphate** furnishes sodium iodide, ammonia, and ammonium sulphate, and F. D. Chattaway represented the reaction: $N_2H_3I_3+3Na_2S_2O_3+3H_2O=2NH_4I+HI+3Na_2SO_4+3S$, and some sodium tetrathionate is formed. According to F. D. Chattaway and H. P. Stevens, **reducing agents** rapidly decompose nitrogen iodide, the reducing agent is oxidized, and hydriodic acid and ammonia are formed. The contained iodine behaves like the contained chlorine in hypochlorites. If R represents the reducing agent, $N_2H_3I_3+3H_2O+R=(RO_3)+2NH_4I+HI$. One mol. of hydrogen iodide is produced for every mol of **sodium sulphite, sulphurous acid, stannous chloride** or **hydrogen sulphide** oxidized, and two mols of hydrogen iodide for every mol of **arsenic or antimony trioxide** oxidized. A. Bineau found that arsenic trioxide in aq. soln. slowly dissolves nitrogen iodide without the evolution of gas: $NHI_2+2H_2O+As_2O_3=NH_4I+HI+As_2O_5$.

W. Biltz discussed the stabilization of nitrogen triiodide by **ammonia.** C. Stahlschmidt showed that nitrogen iodide is decomposed by **methyl iodide**; H. von Gilm, by **ethylamine**; and O. Silberrad, by **zinc ethyl.** A. Guyard showed that a soln. of **potassium cyanide** dissolves nitrogen iodide with the evolution of nitrogen. F. Raschig represented the reaction: $NI_3+3KCy+3H_2O=NH_3+3KOH+3ICy$. The reaction was also studied by N. A. E. Millon, and F. D. Chattaway. A. Bineau found that **zinc** is dissolved when in contact with water and nitrogen iodide: $NHI_2+2Zn+H_2O=NH_3+ZnO+ZnI_2$. F. D. Chattaway examined the action of **arsenic** and **antimony** on nitrogen iodide. J. Szuhay observed that moist **silver oxide** or an ammoniacal soln. of **silver nitrate** gives a black, insoluble, explosive silver iodoamide, $AgNI_2$. If iodine chloride be added to an ammoniacal soln. of a silver salt, O. Silberrad found that silver iodoamide, $AgNH_2.NI_3$, is formed. G. S. Sérullas showed that a soln. of **potassium or calcium hydroxide** slowly dissolves nitrogen iodide suspended in water, forming ammonia, potassuim iodide, and iodate, and a trace of nitrogen: $3NHI_2+6KOH=2KIO_3+4KI+3NH_3$. More nitrogen is given off with a conc. soln. of potash-lye owing to the rise of temp. which occurs at the same time. F. D. Chattaway and K. J. P. Orton say that the main reaction is an hydrolysis: $N_2H_3I_3+3KOH=2NH_3+3KOI$, followed by $3KOI=2KI+KIO_3$—a part of the nitrogen iodide is simultaneously transformed with nitrogen and hydriodic acid. With soln. of potassium or sodium carbonate, ammonia, and alkali iodide and hypoiodite are simultaneously formed. C. Hugot represented the action of **sodammonium:** $3NaNH_3+NH_3.NI_3=4NH_3+3NaI+N$.

N. A. E. Millon,[5] and A. Bineau found that dry iodine absorbs dry ammonia such that, according to the former, 100 grms. of iodine takes up 8·3 grms. of ammonia at 10°; 9 grms. at 0°; 9·4 grms. at −18°. At −0°, and over, the rise of temp. accompanying the absorption leads to the evolution of a little nitrogen. J. J. Colin, and A. Bineau also said that a combination of ammonia and iodine is obtained by gently warming a mixture of iodine and ammonium sesquicarbonate. According to N. A. E. Millon, the reddish-brown liquid is **iodomonammine,** NH_3I; and, according to A. Bineau, **iodohemitriammine,** $I_2(NH_3)_3$. F. Raschig found that at 20° the amount of ammonia taken up by iodine corresponds with A. Bineau's formula: at 80°, with N. A. E. Millon's; at 0°, with **iododiammine,** $I(NH_3)_2$; and at −10°, with **iodohemipentammine,** $I_2(NH_3)_5$. According to J. L. Gay Lussac, the iodoammine is decomposed when heated, and ammonia is evolved. G. Landgrebe noted that if an excess of ammonia be employed the product is as limpid as water, but on exposure to air, the liquid thickens. Water was found by J. L. Gay Lussac to decompose the iodammine into aq. ammonia iodide, and nitrogen iodide; a current of hydrogen chloride was found by N. A. E. Millon, to convert it into nitrogen, ammonium chloride, ammonium iodate, and free ammonia. F. Raschig said that iodammine dissolves readily in alcohol without suffering any change. The work of C. Hugot, and O. Ruff makes it doubtful if any of the iodammines are chemical individuals—*vide supra*, nitrogen iodide.

§ 47. Nitrosyl Halides

G. Gore[1] found that when a mixture of sodium fluoride and nitrate, and sulphuric acid is distilled, a colourless liquid which fumes less than hydrofluoric acid is formed. It does not attack platinum or paraffin; and it vulcanizes caoutchouc rapidly. O. Ruff and K. Stäuber could not obtain any definite compound in this way, but by treating silver fluoride with nitrosyl chloride, at 200°–250°, and fractionating the cooled product, they obtained **nitrosyl fluoride,** NOF, as a colourless solid which melts at about —134°, forming liquid which boils at —56°. O. Ruff and co-workers also obtained it by heating the complex $SbF_5.NOF$, or $AsF_5.NOF$, in a platinum tube with powdered potassium fluoride for 4–5 hrs. at 320°. A complex with the arsenic or antimony fluoride is set free. The gas is colourless, attacks dry glass slowly, and moist gas rapidly. The vap. density 1·683–1·699 at about 23° and 760 mm. is 1·683, which is very near that required for NOF. The gas, in many respects, behaves like fluorine and nitroxyl fluoride. With water, it forms a blue soln. which decomposes, forming nitric oxide and nitric acid; and it does not react with iodine in the cold or when heated; it does not react with sulphur—cold or hot; similar remarks apply to carbon. The reaction between nitrosyl fluoride and silicon, boron, or red phosphorus in the cold is accompanied by incandescence; arsenic and antimony also react in the cold with the development of much heat; tin, when warmed in the gas, gives a white vapour; sodium under similar conditions forms sodium fluoride with incandescence; copper, aluminium, lead, and bismuth react feebly with the gas; many organic substances—starch, caoutchouc, etc.—are attacked with the formation of hydrogen fluoride. In reactions with the metals, nitric oxide is formed; and in double decompositions, nitrogen peroxide is produced. W. Lange prepared **nitrosyl fluosulphonate,** $NO.SO_3F$, mixed with a little nitrosylsulphuric acid, by passing nitrogen trioxide, dried by calcium nitrate and phosphorus pentoxide, into ice-cold fluosulphonic acid. The colourless crystals are very hygroscopic. The compound is decomposed by water, and alkali-lye. It softens at 118°, and melts at 140°.

According to J. L. Gay Lussac,[2] two vols. of nitric oxide unites with one vol. of chlorine to form a gas which, at —15° to —20° condenses to form a mixture of **nitrosyl chloride,** NOCl, and nitrosyldichloride, $N_2O_2Cl_4$, or $NOCl_2$. E. Briner and Z. Pylkoff said that the product contains chlorine in soln., and N. Boubnoff amd P. A. Guye found that the excess of nitric oxide can be removed by distillation at —150° to —160°; and the excess of chlorine by fractional distillation at —80°—the chlorine is retained at —150°. E. Wourtzel, and E. Briner and Z. Pylkoff purified nitrosyl chloride by crystallization and fractional distillation in the presence of phosphoric oxide. L. Francesconi and G. Bresciani obtained a good yield of nitrosyl chloride by passing the dried mixture of nitric oxide and chlorine over dried animal charcoal at 40°–50°. E. Briner and Z. Pylkoff said the animal charcoal is necessary as a catalyst, for its presence does not affect the yield. E. Schering patented the use of activated charcoal as a catalyst, claiming that the nitrosyl chloride is formed in better yields; and more rapidly than when a mixture of the nitric oxide and chlorine is led over ordinary porous charcoal. A. Kiss found that the reaction is not much accelerated by one to two per cent. of nitrogen peroxide, but 10 per cent. considerably hastens the reaction. This catalysis involves the rapid reaction: $2NO_2+Cl_2=2NO_2Cl$; and the slow reaction of the second order:

$NO_2Cl+NO=NOCl+NO_2$. These reactions are independent of the surface of the containing vessel, and are not affected by light. M. Trautz and W. Gerwig measured the velocity of absorption of nitric oxide by liquid chlorine, and they calculated velocity constants of the reactions involved, which are (1) $2NO+Cl_2 \rightarrow 2NOCl$, for which the velocity constant k is of the order 10^7, (2) $NO+Cl_2 \rightarrow NOCl_2$, and (3) $NOCl_2+NO \rightarrow 2NOCl$, for which k (mols. per c.c. and seconds) is of the order 10^2. Within the limits of error of the method, the velocities of the pseudo-bimolecular reaction (1) and of the termolecular decomposition of $NOCl_2$ (2) are the same if the reaction takes place in the gaseous state or in liquid nitrosyl chloride as solvent. F. A. Henglein observed no difference in the rate of formation of nitrosyl chloride when the system is exposed to a magnetic field of 20,000 gausses.

E. Davy obtained impure nitrosyl chloride—or as he called it *chloronitrous acid*—as an orange-yellow gas when nitric acid acts on potassium or sodium chloride; J. L. Gay Lussac showed that the product also contains hydrochloric acid; and that the proportions of nitrosyl chloride and hydrochloric acid so formed depends on the conc. of the acid, and the temp. W. C. Williams obtained nitrosyl chloride by the action of chlorine on nitrogen peroxide; R. Müller, by passing hydrogen chloride through nitrogen peroxide at −22°; $NO_2+2HCl=NOCl+H_2O+Cl$. The liquid becomes red, and some chlorine is evolved. When fractionated, nitrosyl chloride passes off at −10°; nitroxyl chloride at 10°–12°; and there remains nitric acid mixed with some nitrogen peroxide. E. Briner and Z. Pylkoff found the product is contaminated with chlorine and nitrogen oxides; and likewise also with that prepared by the action of hydrogen chloride on liquid nitrogen trioxide: $N_2O_3+2HCl=2NOCl+H_2O$. E. Briner and A. Wroczynsky observed that nitroysl chloride is formed when a mixture of nitric oxide and hydrogen chloride is submitted to a press. of 300 atm. When nitric oxide is allowed to remain at high press. in a sealed tube, it is colourless at first, but after a day appears bluish-green. If the tube contains a large quantity of the gas, drops of a blue liquid appear. The reaction is supposed to be represented by $6NO=2N_2O_3+N_2$; the synthesis of nitrosyl chloride would then be explained by the action $N_2O_3+2HCl=2NOCl+H_2O$. No action occurs unless the nitric oxide is above a certain minimum press. When the press. in the tubes was gradually increased, the blue gaseous phase was first noticed at 28 atm. The rate of formation of nitrosyl chloride increases with the press. M. Trautz and H. Schlüter showed the empirical identity of the chemical conception—formation of an intermediate compound—and the physical conception—duration of molecular impacts—inter- and multi-molecular collisions. The reaction between nitric oxide and chlorine, which is purely termolecular within wide ranges of temperature and concentration, is shown to proceed in two stages in accordance with the impact duration law, thus: $NO+Cl_2=NOCl_2$ and $NOCl_2+NO=2NOCl$. The velocity constants for each stage of the reaction are in agreement with those deduced from the law of mass action, and the temp. coeff. agree with the requirements of the reaction velocity isochore. All reactions of an order higher than the second occurring in dil. systems of liquids or gases are considered to be superimposed reactions of the first or second order.

A. Lachmann prepared nitrosyl chloride by the action of hydrogen chloride on diphenylnitrosamine at 0°. A. C. Girard and J. A. Pabst, W. A. Tilden, R. H. Pickard and H. Hunter, and J. J. Sudborough and J. H. Millar made nitrosyl chloride by distilling a mixture of potassium or sodium chloride and nitrosyl sulphonic acid; E. Briner and Z. Pylkoff said that this mode of preparation gives a product with the least contamination. Nitrosyl chloride is the chief constituent of aqua regia (*q.v.*). According to E. Divers and T. Haga, if nitric acid and hydrogen chloride are allowed to react with an excess of stannous chloride hydroxylamine chloride is produced, but if insufficient stannous chloride is present nitrosyl chloride and nitrous oxide are formed. W. C. Williams obtained nitrosyl chloride by the action of nitric acid on an excess of phosphoryl chloride; A. Geuther, from hyponitrous acid and hydrogen chloride or phosphorus trichloride or pentachloride; and by the action of nitrous acid on phosphorus trichloride. A. Naquet made nitrosyl chloride by mixing molar proportions of potassium nitrate and phosphorus pentachloride in the cold, and separating the resulting phosphoryl and nitrosyl chlorides by fractionation; and V. Thomas prepared it by the action of nitric oxide on ferric chloride—*vide supra*, nitric oxide and chlorine. A. Pinkus and M. de Schulthess studied the ionization which occurs during the combination of chlorine with nitric oxide. The ionization is due to the emission of bipolar nuclei produced by the chemical reaction itself, and is not in any way influenced by any physical process. Generally, the ionization is very intense, but the number of charged particles received by the electrode is always very much less than the number of nitrosyl chloride mols. formed. This is explained, at least in part, by the recombination of the ions before they reach the electrode. The ionization is favoured by an excess of chlorine, the strongest effect being observed when 1 to 4 vols. of chlorine are mixed with one vol. of nitric oxide. The number of charges received by the electrode in a given time is independent of the press. of the reacting mixture. The ionization persists generally for a few minutes only, and its intensity decreases much more rapidly than the rate of formation of the nitrosyl chloride. The results generally indicate that the ionization is brought about by the reaction of at least one mol. of chlorine with one mol. of nitric oxide, and it occurs more rapidly than the reaction $2NO+Cl_2=2NOCl$.

Nitrosyl chloride was analyzed by R. Müller, E. Wourtzel, and P. A. Guye and G. Fluss; the results agree with the empirical formula NOCl. At ordinary temp., nitrosyl chloride is a gas which condenses, when cooled, to a yellowish-red liquid. E. Wourtzel found the vap. density is normal. R. Müller, and A. C. Girard and J. A. Pabst gave —5° for the b.p.; A. Baudrimont, —7·2°; W. A. Tilden, —8°; A. Geuther, 2°; and L. Francesconi and G. Bresciani, —5·6°. A. Geuther gave 1·4165 for the sp. gr. of the liquid at —12°, and A. Baudrimont, 1·3677 at 8°. E. Briner and Z. Pylkoff gave for the sp. gr., D, at different temp., θ,

	40°	24·9°	11·9°	0·5°	—8·6°	—26·7°	—47·6°	—56·8°
Sp. gr., D	1·221	1·285	1·319	1·346	1·367	1·406	1·478	1·552

They represented the results by $D=1{\cdot}349-0{\cdot}00242\theta$. E. Rabinowitsch gave 48·1 for the mol. vol. E. Briner and Z. Pylkoff found for the viscosity 0·00547 at —20°; 0·00567 at —25·2°; 0·00586 at —27°; 0·00604 at —29·5°; and 0·00642 at —33·3°. The surface tensions at —33°, —22°, and —5·5° were respectively 34·5, 32·7, and 30·3 dynes per centimetre; the specific cohesion, 0·0492, 0·0474, and 0·0456 mgrm. per millimetre respectively; and the surface energy, $\sigma(M/D)^{\frac{2}{3}}$, 441, 424, and 400 ergs respectively. F. de Block represented the surface tension at $\theta°$ by $\sigma=\sigma_0(\theta_c-\theta)^{0{\cdot}891}$, where θ_c represents the critical temp.—*vide supra*, nitrogen. A. Baudrimont gave 5 mm. for the capillary ascent at —6·8° in a tube 1·2 mm. bore. According to W. J. van Heteren, nitrosyl chloride freezes, forming blood-red crystals which melt at —65°; N. Boubnoff and P. A. Guye said —64·5°, Fig. 99. L. Francesconi and G. Bresciani found that nitrosyl chloride furnishes lemon-yellow crystals at the temp. of liquid air, and the crystals were said to melt at —60° to —61°. P. A. Guye and G. Fluss gave —61° for the b.p. and —5·6 for the m.p.; M. Trautz and W. Gerwig, —5·8° for the m.p., and 61·5° for the b.p. The critical temp. is 163°–164°. E. Briner and Z. Pylkoff gave 167° ±2°, and for the critical press., 92·4 atm. W. A. Tilden gave from 33 to 33·5 for the vap. density of 10°—hydrogen unity. The at. vol. of chlorine and nitrogen being uncertain, E. Briner and Z. Pylkoff showed that the mol. wt. of nitrosyl chloride cannot be estimated from density measurements alone, but the application of G. Longinescu's relation between the b.p. and density, and W. Ramsay and J. Shields' observations on the surface energy indicate that nitrosyl chloride is slightly polymerized. The last relation, of course, refers to the state of the molecules in the surface film, and not in the bulk of the liquid. W. A. Kistiakowsky's relation between the b.p. and surface tension; P. Dutoit and P. Mojoiu's relation between the b.p., surface tension, and vap. press.; P. Walden's relation between the b.p., surface tension, and critical temp.; and A. J. Batschinsky's relation between the viscosity and temp.—all indicate that the mol. of nitrosyl chloride is not polymerized. According to J. J. Sudborough and J. H. Millar, the vap. density at 700° is 32·65—hydrogen unity—which agrees with the formula NOCl; and at higher temp., the compound dissociates. The vap. density, *D* (hydrogen), and the percentage dissociation at different temp. are:

	784°	796°	815°	928°	968°	985°
	31·77	31·36	31·00	29·00	27·30	27·00
Dissociation	5·54	8·22	10·64	25·17	39·19	41·85 per cent.

They therefore said that nitrosyl chloride is a very stable compound, and is to be regarded as the chloride of nitrous acid, O=N—Cl. M. Trautz and co-workers showed that the dissociation of nitrosyl chloride can be detected at 250°. According to H. A. Taylor and R. R. Denslow, 3·54 per cent. is dissociated at 733°; 4·00 per cent. at 752°; 4·47 per cent. at 806°; and 5·64 per cent. at 1123°. The effect of increasing the surface is negligible, so that a purely gas reaction is involved. The energy of activation is 6000 Cals.; this corresponds to a wave-length of 4·769μ, but, so far as is known, this does not correspond to any band in the absorption spectrum. E. Briner and Z. Pylkoff gave for the vap. press. *p* mm.:

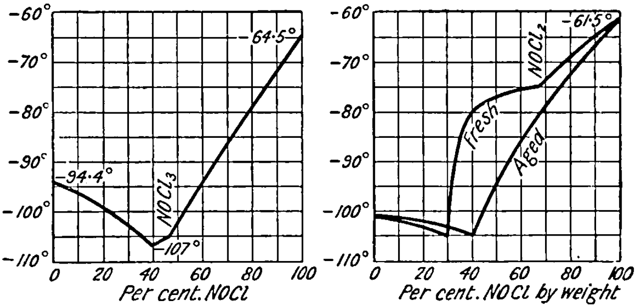
	−68·6°	−60°	−50°	−40°	−30°	−20°	−10°	0°	10°
p	55	130	210	280	360	470	660	890	1420

M. Trautz and W. Gerwig obtained different values and represented their results by log $p=-1332T^{-1}+7\cdot867$ mm. They gave 5·35 Cals. for the mol. heat of vaporization; while E. Briner and Z. Pylkoff gave $\lambda=5\cdot56$ Cals., or $\lambda/T=9\cdot5 \log T -0\cdot007T$. M. Trautz and C. F. Hinck calculated the heat of formation to be 18 Cals.; and G. N. Lewis and M. Randall, the free energy change, between 500° K. and 750° K., to be $-9100+14\cdot3T$.

J. E. Coates and A. Finney measured the rate of formation of nitrosyl chloride from eq. mixtures of nitric oxide and chlorine, by the decrease in press. The results agreed best with the assumption that the reaction is termolecular. The velocity constant is $4\cdot2\times10^{-6}$ at 0° when the press. is expressed in millimetres of mercury and time in minutes. A. Kiss gave $2\cdot62\times10^{-6}$ at 18°. The temp. coeff. is small, being about 1·23 per rise at 10°; M. Trautz gave 1·15. A. Kiss said that the termolecular reaction is accelerated by the presence of water vap., although water does not act as a catalyst in the reaction between nitric oxide and chlorine at 18°. The formation of nitrosyl chloride either directly or through the intermediate stage of nitrosyl bromide is not affected by light; the direct formation is stimulated by the catalytic effect of a rough surface. The reaction velocity is not affected by the presence of hydrogen chloride or carbon dioxide, and if light is excluded both hydrogen and carbon monoxide are without effect. The rate of formation of nitrosyl chloride between 0° and 78° is the same whether the mixture is illuminated or preserved in the dark. The decomposition of nitrosyl chloride under the influence of white light is strictly unimolecular. The temp. coeff. of the velocity constant over the range 0° to 78° is unity. D. Alexejeff calculated the dissociation constant to be log $K_c=-5\cdot01$ at 450° K.; $-3\cdot78$ at 503° K.; $-3\cdot08$ at 543° K.; and $-1\cdot90$ at 593° K. The reaction was studied by S. Dushman, and E. Moles; and the photochemical decomposition of nitrosyl chloride, by A. Kiss; and also by E. J. Bowen and J. F. Sharp who worked with light in the spectral range 4400 A. to 5200 A. They estimated that two quanta are absorbed per mol decomposed; and showed that the heat of the reaction $NOCl+45{,}000\text{ cals.}\rightarrow NO+Cl$ agrees with the assumption that the maximum wave-length capable of causing decomposition is 6270 A., which corresponds almost exactly with the point at which the absorption of nitrosyl chloride begins, but the absorption in red light is too weak to enable the decomposition to be studied.

Since the quantum of blue light is greater than the minimum quantum necessary for decomposition, it is probable that the decomposition is a true unimolecular process, $NOCl+h\nu=NO+Cl$, followed by spontaneous reactions re-forming nitrosyl chloride, possibly through the intermediate compound $NOCl_2$. For the meaning of $h\nu$, *vide* 1. 13, 15. The rate of reaction does not therefore follow the unimolecular equation, in contradiction to the assumption of A. Kiss. G. Magnanini found that the absorption spectrum of nitrosyl chloride has six bands in the orange and green parts of the spectrum.

H. O. Jones and J. K. Mathews found that when nitrosyl chloride and hydrogen are passed over reduced platinum cooled by a freezing mixture, the ammonium chloride produced contains 5 per cent. of hydroxylamine chloride. W. J. van Heteren found liquid chlorine and liquid nitrosyl chloride are miscible in all proportions. N. Boubnoff and P. A. Guye examined the f.p. of the binary system: $NOCl–Cl_2$, and found that the liquidus curve exhibits no maximum, and there is no sharp minimum at the eutectic temp., —109°, Fig. 99. The bending of the curve near —107° indicates the possible presence of an additive compound, *nitrosyl trichloride*, $NOCl_3$, which is highly dissociated even at —107°. M. Trautz and W. Gerwig's results are illustrated by Fig. 100. They found that mixtures kept for some time show a normal eutectic f.p. diagram with nitrosyl chloride and chlorine as solid constituents, but freshly prepared mixtures show a break in the liquidus at the composition of an unstable intermediate compound, *nitrosyl dichloride*, $NOCl_2$. M. Trautz and W. Gerwig found that mixtures kept for some time show a normal eutectic f.p. diagram with nitrosyl chloride and chlorine as solid constituents, but freshly-prepared mixtures show a break in the liquidus at the composition of an unstable intermediate compound, nitrosyl dichloride, $NOCl_2$. M. Trautz and H. Schlüter said that nitrosyl dichloride cannot be formed by the interaction of nitrosyl chloride and chlorine, but only from nitric oxide and chlorine; it is extremely unstable, and the equilibrium of the reaction by which it is formed lies very close to the left-hand side of the equation above. The heat of formation of nitrosyl dichloride is 7000 cals. (±700 cals.), and its formation and decomposition velocity constants are $1{\cdot}5\times10^{-5}$, respectively. H. O. Jones and J. K. Mathews found that with hydrogen sulphide at a low temp. in ethereal or petroleum soln., $NOCl+3H_2S=NH_4Cl+H_2O+3S$. M. Trautz and W. Gerwig measured the solubility of nitric oxide, in nitrosyl chloride, toluene, and pentane; E. V. Lynn and O. Hilton studied the action of nitrosyl chloride on heptane; W. Meisel, the action as *un agent de nitrosation* on organic compounds; P. A. Guye and G. Fluss, the action on selenium and sulphur to form the lower chlorides, Se_2Cl_2 and S_2Cl_2; W. Solonina, the action on amines: $R.NH_2+NOCl=RCl+N_2+H_2O$; and H. O. Jones and co-workers, the action on mercaptans—in ethereal soln., at —80°, a small proportion of hydroxylamine chloride is formed; with nickel as catalyst ammonium chloride is formed. J. J. Sudborough found that magnesium is not attacked at temp. up to 100°; silver, manganese, and nickel are slightly attacked when kept at 100° for many days;



FIGS. 99 and 100.—The Liquidus Curve of Mixtures of Nitrosyl Chloride and Chlorine.

under similar conditions, copper, gold, cadmium, thallium, lead, and platinum are attacked; and zinc, mercury, aluminium, tin, arsenic, antimony, bismuth, and iron are attacked in the cold. P. A. Guye and G. Fluss said that aluminium is not attacked in the cold, but above 500°, aluminium chloride is formed; silver-foil does not completely decompose the gas but finely divided silver does so at 400°–500°, forming silver chloride and nitric oxide; finely divided copper acts similarly. H. O. Jones and J. K. Mathews found that with palladium at ordinary temp. the metal chloride, nitric oxide, and nitrogen are formed; and at higher temp. ammonium chloride is produced. In agreement with J. J. Sudborough, V. Cuttica and co-workers found that nitrosyl chloride forms an unstable compound with cupric oxide which decomposes in air, forming cupric chloride; cuprous oxide or chloride forms **cuprous nitrosyl chloride,** $Cu_2Cl_2.NOCl$; thallous oxide forms **thallous nitrosyl chloride,** $2TlCl.3NOCl$, which is moderately stable in air, but in vacuo it forms thallosic chloride. R. Weber observed that nitrosyl chloride unites with the aluminium, titanium, antimonic, stannic and ferric chlorides. H. Gall and H. Mengdehl found that nitrosyl chloride reacts with the metal halides, forming primarily an addition product, which may be stable or may become transformed into the compound of nitric oxide and the higher chloride by transference of the chlorine atom from the nitrosyl chloride to the metal. If the latter compound is unstable, nitric oxide is evolved, and the residual higher chloride may unite with nitrosyl chloride. Thus, at —10°, manganous and nitrosyl chlorides form **manganese nitrosyl trichloride,** $MnCl_3.NO$, which is decomposed by water with the evolution of nitrous fumes, and when heated furnishes manganous chloride, chlorine, and nitric oxide; cuprous chloride similarly forms **copper nitrosyl dichloride,** $CuCl_2.NO$, which gives off nitric oxide when heated, and yields a dark blue soln. with acetone or alcohol resembling that obtained by W. Manchot by the action of nitric oxide on a soln. of a cupric salt. Sublimed ferrous chloride furnishes **ferric nitrosyl chloride,** $FeCl_3.NOCl$, obtained by J. J. Sudborough, and this is assumed to be a secondary product since $FeCl_3.NO$ is formed as an intermediate product; H. Rheinboldt and R. Wasserfuhr gave 128° for the m.p. Antimony trichloride yields **antimonic nitrosyl chloride,** $SbCl_5.NOCl$, m.p. about 170°; **bismuth nitrosyl chloride,** $BiCl_3.NOCl$, m.p. 115°–120°; aluminium chloride gives **aluminium nitrosyl chloride,** $AlCl_3.NOCl$, m.p. 108°-110°; and mercurous chloride gives **mercuric nitrosyl chloride,** $HgCl_2.NOCl$. W. Hampe, and V. Thomas represented the complex salt formed with stannic chloride by $3SnCl_4.4NOCl$, but R. Weber, A. Bäyer, S. M. Jörgensen and W. J. van Heteren agree that **stannic nitrosyl chloride** has the composition $SnCl_4.2NOCl$, which, according to H. Rheinboldt and R. Wasserfuhr, melts at about 188°. Similarly, **plumbic nitrosyl chloride,** $PbCl_4.2NOCl$, was prepared, as well as **titanic nitrosyl chloride,** $TiCl_4.2NOCl$, which did not melt below 220°. J. J. Sudborough prepared complex compounds with cuprous, auric, zinc, titanous, ferric, antimonic, bismuth, and platinum chlorides. The nitrosyl chlorides of the other metal chlorides were not stable at ordinary temp. E. V. Lynn and co-workers found that nitrosyl chloride acts on *n*-heptane in light; it also reacts with toluene in light, but not with benzene. R. H. Pickard and H. Hunter examined the action of nitrosyl chloride on nonanol; and O. Diepenbruck, on mercaptan and mercaptides. I. Guareschi found that nitrosyl chloride is readily absorbed at ordinary temp. by soda-lime or potash-lime. A. C. Girard and J. A. Pabst used nitrosyl chloride for preparing nitroso-derivatives of organic compounds; and J. A. Wesener used it in the bleaching of flour. The Badische Anilin- und Sodafabrik constructed containing vessels magnesium alloys. For *nitrosyl perchlorate, vide* **2.** 19, 17.

As previously indicated, the twelfth-century Latin work *De inventione veritatis*, attributed to the eighth-century Arabian, Geber, obtained what is now known as *aqua regia*, and he stated that the liquid will dissolve gold. In the literature of the Middle Ages, frequent reference is made to a mixture of nitric and hydrochloric acids, or a soln. of a nitrate in hydrochloric acid, or of a chloride in nitric acid as a solvent for gold—*aqua regia, aqua regis, Königwasser, Goldscheidewasser,* and *l'eau régale;* and it has also been called *nitromuriatic acid,* and *nitrohydrochloric acid.*

The twelfth-century Albertus Magnus, in his *Compositum de compositis,* called it *aqua secunda* to distinguish it from nitric acid, which he called *aqua prima;* and Raymond Lully, in his *Testamentum novissimum,* called it *aqua salis ammoniaci,* and *salis nitri.* M. Odomar, in his *Practica ad discipulum* (*Theatrum chemicum,* Argentorati, 1659), called the acid *aqua calcinationis omnium metallorum,* and made it by distillation from a mixture of vitriol, saltpetre, and common salt. Basil Valentine, in his *Letztes Testament* (Hambourg, 1717), and J. R. Glauber, in his *Furnis novis philosophicis* (Amstelodami, 1648), described aqua regia. J. B. van Helmont, in *De flatibus* in his *Ortus medicinæ* (Amsterdam, 1648), alluded to the peculiar gas which is exhaled by aqua regia; and T. Bergman, in his *De attractionibus electivis* (Upsala, 1775), seems to have regarded aqua regia as a specific acid.

The usual way of making aqua regia is to mix one part of nitric acid with two to four parts of hydrochloric acid. According to J. J. Berzelius,[3] the mixture is unstable and soon becomes yellow owing to the production of chlorine and nitrogen oxides. The change takes place rapidly if the soln. be warmed. In a closed vessel the decomposition ceases as soon as the liquid is saturated with the gas, but in an open vessel, from which the chlorine can escape, the action continues until all the nitric acid, or all the hydrochloric acid is decomposed. If the liquid is heated until chlorine ceases to be evolved, it no longer dissolves gold; and further, a mixture of hydrochloric acid and liquid nitrogen peroxide does not dissolve gold; but J. L. Gay Lussac, and C. J. Koene said that it does dissolve that metal; C. J. Koene found a mixture of hydrochloric and nitrous acid does not form aqua regia. C. J. Koene found that a mixture of conc. hydrochloric and nitric acids reacts at 0°. N. A. E. Millon made the interesting observation that mixtures of hydrochloric and nitric acids can be made which are free from nitrous acid, and which at ordinary temp. neither decompose nor attack arsenic, antimony, platinum, or gold. The action, however, commences by gently heating the mixture or by adding a small proportion of potassium nitrite. The addition of chlorine has no effect. Consequently, he concluded that *the presence of nitrous acid—whether produced by the mutual decomposition of the two acids by heat, or by direct addition to the mixture—is necessary before aqua regia can dissolve the noble metals.*

The products of the decomposition, and the nature of aqua regia, have been studied by H. Davy, A. Baudrimont, J. L. Gay Lussac, W. A. Tilden, and H. Goldschmidt. The peculiar properties of aqua regia were stated by H. Davy to be due to the presence of what he called *chloronitrous acid,* a compound of equal vols. of nitric oxide, and chlorine. A. Baudrimont heated a mixture of nitric and hydrochloric acid (2 : 3 by wt.) at 82°, and obtained the red gas which attacked gold, platinum, arsenic, and antimony, but not phosphorus; it condensed to a red liquid; and at 0°, water dissolved 121 times its vol. of gas. A. Baudrimont called this product *chloronitric acid,* and represented it by the symbol $N_2O_3Cl_4$. It was probable that dissolved chlorine was present in A. Baudrimont's product, and the *rôle* played by chlorine in aqua regia is ignored. Both H. Davy, and J. J. Berzelius had previously stated that the solvent action of aqua regia on gold is due to the presence of chlorine. J. L. Gay Lussac found that at the temp. of boiling water, aqua regia gives off a gas which condenses to a lemon-yellow liquid which he called *l'acid chlorhypoazotique,* or *hypochloronitric acid,* $N_2O_2Cl_4$. Its formation in modernized symbols was represented: $2HNO_3+6HCl=N_2O_2Cl_4+4H_2O+Cl_2$; it was further assumed that hypochloronitric acid is immediately decomposed by water, $N_2O_2Cl_4+2H_2O=N_2O_4+4HCl$. J. L. Gay Lussac also found that the lemon-yellow liquid also contained what he called chloronitrous acid, and which is now called nitrosyl chloride (*q.v.*). Consequently, he inferred that the products of the interaction of nitric and hydrochloric acid are chlorine, nitrosyl chloride, nitrosyl dichloride, and water; and that *the peculiar action of aqua regia on the metals is due to the chlorine liberated by its decomposition—the nitrosyl chlorides pass off as they do when the liquid alone is heated.* W. A. Tilden represented the reaction between nitric and hydrochloric acids by $3HCl+HNO_3=NOCl+Cl_2+2H_2O$; and this was confirmed by H. Goldschmidt, and G. Lunge and L. Pelet.

According to E. Briner, in a closed system, the reaction $HNO_3+3HCl\rightleftharpoons NOCl+Cl_2+2H_2O$ is reversible; the equilibrium press. at 0° is 2·84 atm., and at 20·5° to 21° it is 5·1 atm. Within these limits of temp., the system is univariant, having three phases and two independent components. This system is called *l'eau régale stabilisée*—that is, *stabilized aqua regia.* One liquid phase consists of nitrosyl chloride and chlorine in equilibrium with the aq. phase, which contains, in addition to the original acids, some chlorine and nitrosyl chloride. The gaseous phase contains all the constituents of the system. If the acids used are too dil. the phase consisting of the liquefied gases does not exist, and the equilibrium press. diminishes as the dilution increases. When the two conc. acids are mixed there is first a rapid rise of several degrees in the temp., which then descends steadily and remains constant at about 2° below the original temp. of the acids. The preliminary rise in temp. is due to the action of the hydrogen chloride on the water of soln. of the nitric acid. Taking into account the heats of soln., the heat of the reaction, using 37 per cent. hydrochloric acid and 70 per cent. nitric acid, is −20 Cals., and if the dilution of the acids is doubled, the value is −27 Cals. R. Heberlein confirmed these observations on *l'eau régale stabilisée,* for in the presence of the three phases, the electrical conductivity is constant for a given temp. whatever be the proportions and concentrations of the nitric and hydrochloric acids. This is characteristic of a univariant system. The stabilized aqua regia is therefore *un système tampon* for each kind of ion represented in the system. E. Briner gave 2·84 atm. for the vap. press. at 0°; and 5·1 atm. at 20°. The sp. conductivity of the non-aqueous layer is a maximum 0·324 mho at 0° after 24 hrs.

According to J. L. Gay Lussac, aqua regia prepared by mixing one part of nitric acid with two or three parts of hydrochloric acid is a yellow, fuming, highly corrosive liquid which is used for dissolving in hydrochloric acid those metals which have but a feeble affinity for oxygen. When copper, silver, mercury, phosphorus, arsenic trioxide, or ferrous chloride is treated with aqua regia, nitric oxide is formed: $3Cu+2HNO_3+6HCl=3CuCl_2+4H_2O+2NO$; tin, and the metals which decompose water readily give off no gas, but form ammonium chloride; and stannous chloride furnishes nitrous oxide. G. Bunge said that the vapour of aqua regia generally behaves towards organic compounds like free chlorine. F. Leblanc used aqua regia in Bunsen's cell—1. 16, 5; and A. K. Fedoroff recommended it for the sterilization of potable waters.

According to H. H. Landolt,[4] reddish-brown fumes are evolved during the action of conc. nitric acid on potassium bromide, and when condensed by cooling the product is possibly a mixture of nitrosyl bromide and dibromide. If nitric oxide be passed into bromine cooled between −7° and −15°, **nitrosyl bromide,** NOBr, is formed. E. Moles showed that the product always contains a slight excess of bromine. W. A. Tilden did not obtain this compound by treating nitrosyl chloride with potassium bromide, but rather obtained a heavy black liquid resembling bromine, while nitric oxide was evolved. He also said that two other bromides are produced, $NOBr_2$ and $NOBr_3$, and that nitrosyl bromide is to be separated from these by fractional distillation; but O. Fröhlich showed that distillation separates nitrosyl bromide and bromine; the two higher bromides are simply soln. of bromine in nitrosyl bromide at this temp. A. C. Girard and J. A. Pabst obtained nitrosyl bromide by the action of sodium bromide on nitrosyl sulphonic acid, $NO_2.HSO_3$. H. H. Landolt described nitrosyl chloride as a dark brown liquid which begins to boil at −2°, furnishing a vapour which is a mixture of nitrosyl bromide and nitric oxide, and the former constituent condenses on cooling; if the temp. be 20°, the residue contains 81·1 per cent. of bromine and corresponds with $4NOBr=2NO+N_2O_2Br_4$; and at a higher temp., the $N_2O_2Br_4$ is decomposed. S. Dushman, and M. Trautz and V. P. Dalal studied the equilibrium conditions in the reaction $2NO+Br_2=2NOBr$ at temp. between −15° and 15°, and with the bromine at 11–26 mm. press., and the nitric oxide, at 11–12 mm. press. At higher temp., the nitrosyl bromide decomposes, and at lower temp., bromine condenses on the glass containing vessel. The reaction appears to be of the third order, with the velocity constant between $0{\cdot}9\times10^{-10}$ and $1{\cdot}6\times10^{-10}$; and $\log K = -9416/4{\cdot}573T + 2{\cdot}5 \log T + 1{\cdot}59$. The temp. coeff. is too small to be determined with certainty. It is thought that the reaction was complicated by the concurrent or superimposed reaction $NO+Br_2 \rightleftharpoons NOBr_2$, which comes to equilibrium very quickly, and $NOBr_2+NO \rightleftharpoons 2NOBr$, which is measurable. In studying the equilibrium between −15° and 330°, with the bromine between 13 and 500 mm. press., and the nitric oxide between 28 and 900 mm. press., it was found that equilibrium is rapidly attained. With the bromine below 50 mm. press., and above 140°, the amount of tribromide formed is negligibly small, and the reaction is $2NO+Br_2=2NOBr$, with the velocity constant $1{\cdot}1\times10^{-10}$ at −15°—*vide supra*, nitric oxide and bromine. The fusion curve, Fig. 101, shows that the m.p. of nitrosyl bromide is about −55°. The results neither confirm nor deny the existence of a dibromide. The heat of formation of nitrosyl bromide is estimated to be between 9000 and 10,500 cals. The observed value is $2NO+Br_2=2NOBr+9416\pm500$ cals. It is concluded that with liquid mixtures of bromine and nitrosyl bromide, the chief product is the tribromide; in gaseous mixtures rich in bromine at moderate temp., the dibromide; and under other conditions, nitrosyl bromide and its dissociation products. H. W. B. Roozeboom measured the vap. press. of mixtures of nitrosyl bromide and bromine, but obtained no evidence of the existence of the higher bromides; he found that the vap. press. with 1·0, 0·9, and 0·79, 0·68, 0·60, and 0·42 mol of nitric oxide per mol of bromine was respectively 889, 700, 631, 545, 491, and 401 mm. Unlike M. M. P. Muir, he observed no sign of a discontinuity. M. Trautz and V. P. Dalal gave for the vap. press. of nitrosyl bromide :

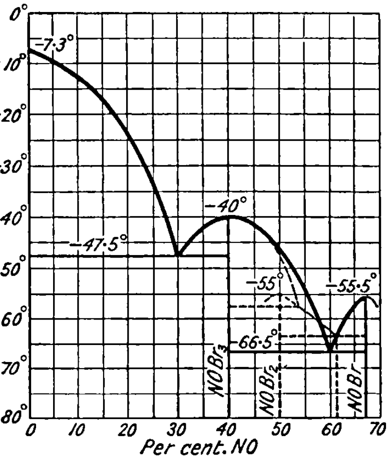


FIG. 101.—Melting-point Curve of Mixtures of Nitric Oxide and Bromine.

	−57·5°	−50°	−40°	−30°	−20°	−10°
Vap. press. .	327	334	347	384	472	693 mm.

The heat of vaporization is 6242 cals., and the critical temp., 210°. H. H. Landolt found that nitrosyl bromide sinks in cold water, and remains unchanged, but at 14°, bubbles of nitric oxide arise. The vapour attacks leaf-gold and mercury, forming the metal bromides. A. Kiss said that in the reaction between nitrosyl bromide and chlorine, no alteration is brought about by carbon dioxide. L. G. de Koninck found that nitrosyl bromide is hydrolyzed by a soln. of potassium hydroxide. M. Trautz and V. P. Dalal give : $2KOH+NOBr+Aq.=Aq.+KBr+KNO_2+H_2O+28{\cdot}658$ Cals. L. G. de Koninck said that with mercuric oxide, mercuric bromide and nitrous acid are formed; and that it behaves like nitrogen trioxide towards aniline. E. Briner found that mixtures of nitric acid and hydrobromic acids behave like mixtures of nitric and hydrochloric acids, forming a univariant system with vap. press. 0·25 atm. and 0·50 atm. respectively at 0° and at 16°.

According to H. H. Landolt, if nitrosyl bromide be gradually heated to about 30°, the residue which remains contains from 82·64 to 83·64 per cent. of bromine. This corresponds with **nitrosyl dibromide,** $N_2O_2Br_4$, or $NOBr_2$. He called it *Bromuntersalpetersäure*. The product is very dark brown, and resembles bromine ; it begins to boil at about 46°, and then partially decomposes into nitrosyl bromide. W. A. Tilden could not make this compound, and, as indicated above, O. Fröhlich regarded it as a soln. of bromine in nitrosyl bromide. As indicated above, M. Trautz and co-workers consider that the dibromide is present in gaseous mixtures of nitrosyl bromide and bromine; and the evidence obtained from the f.p. curve is indecisive. There is possibly a dibromide with the m.p.—55°, Fig. 101. H. W. B. Roozeboom said that the vap. press. of a soln. of nitric oxide in bromine, in the proportions, $NOBr_2$, is 601 mm. at —10°, 631 mm. at —8°, 729 mm. at —4°, and 889 mm. at 0°. If gas be allowed to escape at 0°, the proportion of bromine in the residue increases, and the vap. press. decreases. H. H. Landolt said that in the presence of water the dibromide absorbs oxygen: $2NOBr_2+3H_2O+O=4HBr+2HNO_3$; and the dibromide sinks in water, and is rapidly hydrolyzed to hydrobromic acid and nitrogen peroxide.

According to H. H. Landolt, if nitric oxide be passed into well-cooled bromine until the product is decolorized when shaken with water, **nitrosyl tribromide**, $NOBr_3$, is formed; and M. M. P. Muir obtained a similar product by the action of nitric oxide on bromine at different press. H. H. Landolt obtained it by distilling nitrosyl bromide or nitrosyl dibromide at 40°–55°. O. Fröhlich regarded it as a mixture of nitrosyl bromide and bromine. M. Trautz and V. P. Dalal showed that this compound is present in liquid mixtures of nitric oxide or nitrosyl bromide and bromine as indicated on the m.p. diagram, Fig. 97. They found the equilibrium constant for $2NO+3Br_2\rightleftharpoons 2NOBr_3$ to be $2{\cdot}1\times10^2$ at —14·6°, and $7{\cdot}5\times10^5$ at 80°; or $\log K_p=-5287T^{-1}+7{\cdot}5\log T+5{\cdot}15$ mm. At about 22°, the heat of formation of $NOBr_3$ is between 22,000 and 27,000 cals.; the observed value is $2NO+3Br_2=2NOBr_3+24{,}182\pm800$ cals. They obtained for the equilibrium constant of $NOBr+Br_2\rightleftharpoons NOBr_3$, $\log K=-1614T^{-1}+2{\cdot}5\log T+1{\cdot}78$ mm. H. H. Landolt gave 2·628 for the sp. gr. of the liquid tribromide at 22·6°; and M. Trautz and V. P. Dalal, 2·637 at 20°/4°. Its m.p. is —40°. The dark brown, almost opaque liquid begins to boil at 32° with partial decomposition. H. H. Landolt said that if rapidly heated, the tribromide can be distilled almost unchanged; when slowly distilled, an excess of nitrogen oxides escapes with the earlier fractions and bromine finally remains. The tribromide is rapidly decomposed when shaken with water: $NOBr_3+2H_2O=HNO_3+3HBr$; it dissolves in ether, and is decomposed slowly by absolute alcohol; it is decomposed in contact with silver or mercuric oxide, forming the metal bromide, nitrogen peroxide, and oxygen. Powdered sodium antimonide strewn in the vapour is inflamed. R. L. Datta and N. R. Chatterjee found that a mixture of nitric and hydrobromic acids reacts with many organic compounds giving nitrosyl tribromide, etc.

As indicated in connection with iodine tetroxide, N. A. E. Millon[5] observed the formation of what he considered to be *nitroso-iodic acid*, and H. Kämmerer what he considered to be *iodine dinitrosyl tetroxide*, $I_2O_4(NO)_2$, or maybe O : I.O.NO, by treating iodine with nitric acid, or nitrosylsulphuric acid. The yellow powder was considered by H. Kappeler to be *iodine nitrate*, $I.NO_3$, *vide* 2. 19, 9. E. Briner said that mixtures of nitric and hydriodic acids do not form a univariant system like stabilized aqua regia, for the iodine produced as a result of the primary reaction is oxidized to iodic acid, with the evolution of nitric oxide.

§ 48. Nitroxyl or Nitryl Halides

According to H. Moissan and P. Lebeau,[1] a white solid is formed when nitric oxide is passed into an excess of fluorine at the temp. of liquid oxygen; as the temp. rises, the solid melts to a colourless liquid, and if a U-tube at —80° is attached to the containing vessel, a colourless liquid is condensed. The admixed fluorine can be removed by two rectifications, and there remains **nitroxyl fluoride,** or *nitryl fluoride*, NO_2F. This compound is a colourless, fuming gas at ordinary temp., and it attacks the mucous membrane, producing painful and persistent irritation. Its sp. gr. lies between 2·17–2·31 at 0°, the mean value is 2·24 ; its b.p. —63·5° ; and its m.p., —139°. Nitroxyl fluoride is very active, chemically, and it reacts with many metals at ordinary temp. It does not react with hydrogen, in the cold ; but it is hydrolyzed by water: $NO_2F+H_2O=HNO_3+HF$. The reaction is quantitative, and was utilized in analyzing the gas. Nitroxyl fluoride does not react with fluorine, or chlorine in the cold, but with dry iodine it forms iodine pentafluoride. It liberates the halogen from the iodides and bromides. It does not react with sulphur, selenium, or nitrogen at ordinary temp., but it reacts with phosphorus, arsenic, and antimony. It does not react with amorphous carbon even at dull redness. It readily reacts with many organic compounds like alcohol, ether, chloroform, carbon tetrachloride, and turpentine; with benzene it forms nitrobenzene and a volatile product which attacks the eyes. It reacts energetically with silicon, and attacks glass at ordinary temp. ; it also reacts at ordinary temp. with the alkali metals, the metals of the alkaline earths, mercury, aluminium, thorium, iron, and boron.

C. W. Hasenbach [2] made **nitroxyl chloride,** or *nitryl chloride*, NO_2Cl, as a pale yellowish-brown gas, by passing a mixture of chlorine and nitrogen peroxide through a strongly heated tube. A. Exner used this process. Nitroxyl chloride is also obtained from a mixture of hydrogen chloride and nitrogen peroxide. A. W. Williamson prepared it by the action of chlorosulphonic acid on nitric acid: $(HO)ClSO_3+HNO_3=NO_2Cl+H_2SO_4+H_2O$. The colourless vapour is said to react with water, forming nitric and hydrochloric acids. E. Bamberger prepared nitroxyl chloride by A. W. Williamson's method; and N. Zuskine, by the action of phosphorus pentachloride on nitric acid. M. Odet and L. Vignon obtained what they considered to be nitroxyl chloride by passing a slow current of dry chlorine over silver nitrate at 95°–100°, and passing dry carbon dioxide through the condensate to remove free chlorine ; and also by the action of phosphoryl chloride on lead or silver nitrate. A. Exner used M. Odet and L. Vignon's process. H. Schiff dropped conc. nitric acid on phosphorus pentachloride, and found that hydrogen chloride is evolved together with a red liquid condensate. When this is heated, phosphoryl chloride and yellowish-brown fumes—probably nitroxyl chloride—were said to be formed. J. Heintze heated nitrogen peroxide with potassium chlorochromate, and claimed that nitroxyl chloride was formed. M. Odet and L. Vignon said that the brownish-yellow gas condenses to a pale yellow liquid which does not solidify. R. Muller found the sp. gr. at 14° to be 1·32; and the vapour density, 2·52–2·62. M. Odet and L. Vignon said that the liquid does not freeze at —31°, and that its b.p. is 5°. The chloride becomes dark green in contact with ice, and decomposes with water, forming nitric and hydrochloric acids, without giving off gas. Silver nitrate converts it into silver chloride and nitric anhydride, and R. Müller said that it forms platinum chloride in contact with platinum. E. Bamberger studied its action on aniline; and N. Zuskine on magnesium alkyl halides.

There are doubts about the individuality of nitroxyl chloride. F. Meissner, A. Gutbier and J. Lohmann, and W. C. Williams could not make it by the above methods, and A. Geuther said that its existence is not very probable because it is not produced by the action of phosphorus pentachloride on liquid nitrogen peroxide. C. W. Hasenbach claimed to have made **nitroxyl bromide,** or *nitryl bromide*, NO_2Br, by the action of bromine on nitrogen peroxide ; and J. Heintze, by the action of nitrogen peroxide on potassium bromochromate, but these statements have not been verified. N. Zuskine, however, reported this compound to be formed when bromine vapour saturated with nitrogen peroxide, at 200°–250°, is passed through a tube filled with bone-ash. C. W. Hasenbach could not prepare **nitroxyl odide,** or *nitryl iodide*, NO_2I, by the action of nitrogen peroxide on iodine.

§ 49. Nitrogen Sulphides or Sulphur Nitrides

The normal sulphide N_4S_3 is not known, but higher sulphides have been prepared. Probably sulphur is the positive and nitrogen the negative constituent, and it can be called *sulphur nitride*. In 1835, W. Gregory [1] reported an impure nitrogen sulphide to be formed by slowly dropping sulphur chloride into aq. ammonia in excess, and allowing the mixture to stand until the red product becomes yellow. The yellow substance dissolves in boiling alcohol, and as the soln. cools, it deposits crystals of sulphur; the conc. of the mother-liquor yields colourless crystals of nitrogen sulphide with a composition corresponding approximately with NS_6. M. J. Fordos and A. Gélis considered the alleged sulphide was an allotrope of sulphur insoluble in carbon disulphide; more probably it was **nitrogen sulphide,** or **nitrogen tetrasulphide,** N_4S_4, contaminated by much sulphur. E. Soubeiran obtained a sulphide contaminated by less sulphur than that of W. Gregory by the action of ammonia on the so-called sulphur dichloride, SCl_2. The product was treated with cold water which dissolved ammonium chloride and sulphide, leaving the nitrogen sulphide as a residue. This was rapidly washed with cold water, then with alcohol, and dried over sulphuric acid in vacuo. E. Soubeiran's product has a composition corresponding with N_2S_3; but A. Laurent supposed that it contained hydrogen, and had the empirical composition HNS.

The compound is endothermal, and therefore M. Berthelot and P. Vieille said that it must be prepared by indirect processes. Ammonia is the source of the nitrogen, and the sulphur can be obtained from the element, carbon disulphide, thionyl chloride, or sulphur chloride, S_2Cl_2. M. J. Fordos and A. Gélis passed dry ammonia into a soln. of one vol. of brown sulphur in 8–10 vols. of carbon disulphide until the red precipitate dissolved, forming a yellow soln.; the ammonium chloride was separated by filtration. The spontaneous evaporation of the clear liquid yields crystals of nitrogen sulphide and later of sulphur. The reaction can be represented $6SCl_2+16NH_3=N_4S_4+2S+12NH_4Cl$. R. Schenck passed dry ammonia into a soln. of sulphur chloride in benzene cooled by a freezing mixture; H. B. van Valkenburgh and J. C. Bailar used a soln. of 150 c.c. of dry ether and 5 c.c. of sulphur monochloride. The precipitate contains sulphur, nitrogen sulphide, and ammonium chloride. O. Ruff and E. Geisel, S. A. Vosnessensky, and F. P. Burt and F. J. Usher extracted the sulphide with dry benzene in Soxhlet's apparatus. A. K. Macbeth and H. Graham used ammonia and sulphur monochloride in chloroform soln.: $6S_2Cl_2+16NH_3=N_4S_4+12NH_4Cl+4S_2$. F. E. Francis and O. C. M. Davis thus describe the mode of preparation:

> The sulphide is best prepared by passing ammonia into a 10–15 per cent. soln. of sulphur dichloride in benzene. When the ordinary chloride is employed, the yield is much smaller. A rapid current of the dry gas is passed into the soln. until red fumes appear, the flask in which the operation is being conducted is then cooled, and on maintaining the current for a short time the reaction is completed. After filtering off the ammonium chloride formed, the soln., on evaporation, deposits long, orange-red prisms of nitrogen sulphide. This is a beautifully crystalline substance, and may be readily purified by recrystallization from either boiling benzene, toluene, or carbon disulphide.

F. P. Burt and F. J. Usher finally purified the sulphide by sublimation in vacuo over silver-gauze at 100°. Some nitrogen sulphide can be recovered from the mother-liquor. R. Schenck obtained a 44 per cent. yield, and he said that the resulting sulphide is so explosive that it is best kept in paper boxes ; the friction of the stopper of a glass bottle may cause an explosion. O. Ruff and E. Geisel consider R. Schenck's method to be the best mode of preparation, and believe that sulphur tetrachloride is the active agent concerned in the reaction: $12SCl_4+16NH_3=3N_4S_4+48HCl+2N_2$. A. Michaelis obtained nitrogen sulphide by the action of ammonia on thionyl chloride. The sulphide was extracted by carbon disulphide and crystallized from the soln. A 10 per cent. yield was obtained. O. Ruff and E. Geisel obtained nitrogen sulphide by the action of ammonia on a soln. of carbon disulphide in benzene. According to O. Ruff and E. Geisel, hydrogen sulphide and nitrogen sulphide are formed by the action of sulphur on liquid ammonia according to the equation $10S+4NH_3=6H_2S+N_4S_4$—*vide supra,* sulphammonium. The hydrogen sulphide is completely precipitated as silver sulphide, and the blue colour of the sulphammonium is changed into the orange-red of a soln. of nitrogen sulphide in ammonia when silver iodide (12 mols.) is added to sulphur (10 atms.) dissolved in liquid ammonia. The nitrogen sulphide is isolated by evaporating the filtrate, heating the residue at 100° for two hours, and extracting with carbon disulphide. On evaporating the soln., crystals of the tetrasulphide were obtained. E. Divers and T. Haga found that the thermal decomposition of barium amidosulphonate furnishes some nitrogen sulphide : $4(NH_2.SO_3)_2Ba=4BaSO_4+8H_2O+2N_2+N_4S_4$.

Nitrogen tetrasulphide forms golden-yellow or yellowish-red, transparent, prismatic crystals, which, according to R. Schenck, appear in orange-red needles when crystallized from benzaldehyde. When nitrogen tetrasulphide is strongly cooled by liquid air, O. Ruff and E. Geisel found that its colour is pale yellow. The crystals belong to the monoclinic system, and, according to J. Nicklès, the angle of the prism of the rhombic crystals is approximately the same as that of monoclinic sulphur. According to G. F. H. Smith, the sublimed crystals have the appearance of cubes with truncated edges and corners. E. Artini gave for the axial ratios $a:b:c=0{\cdot}8806:1:0{\cdot}8430$, and $\beta=89°\ 20'$; and G. F. H. Smith, $a:b:c=0{\cdot}8879:1:0{\cdot}8480$, and $\beta=89°\ 37'$. The indices of refraction are 2·046 and 1·908 ; these values are near to those of monoclinic sulphur. E. Artini said that twinning usually occurs on the $(\bar{1}01)$- or (101)-plane. A. Michaelis gave 2·1166 for the sp. gr. of the crystals at 10° ; S. A. Vosnessensky, 2·2 ; M. Berthelot and P. Vieille, 2·22 at 15° ; and F. P. Burt and F. L. Usher, 2·20 at 24° if it has not been sublimed, and 2·24 at 24° if sublimed. According to M. J. Fordos and A. Gélis, E. Soubeiran found that with friction the compound becomes electrical and sticky. The crystals explode when struck—say in a mortar by a pestle, and also when suddenly heated. M. Berthelot and P. Vieille said that the tetrasulphide burns without detonation in contact with a hot body ; and they gave 207° for the temp. of explosion. R. Schenck said that the crystals can be melted at 178°, but M. J. Fordos and A. Gélis found that the crystals sublime at 135°, and melt at 150° with a slow development of gas ; they explode at 160° with a feeble flash, forming nitrogen and sulphur. C. Hoitsema observed that at 170° the tetrasulphide partly volatilizes and in part slowly decomposes into its elements. S. A. Vosnessensky showed that it melts at 179° ; the presence of sulphur lowers the m.p. ; sublimation occurs near the m.p., and at higher temp. an explosion occurs. F. P. Burt said that the vap. press. is appreciable at 100° ; and the tetrasulphide sublimes in vacuo without decomposition. F. E. Francis and O. C. M. Davis found that the temp. of decomposition is very definite at 185° ; W. Muthmann and co-workers obtained 178°. A. Andreocci gave 178°–179° for the b.p. M. Berthelot and P. Vieille found the compound is endothermal having the heat of formation —127·6 Cals. They found the press., in kgrms. per sq. cm., developed with charges of 0·1, 0·2, and 0·3 grm. of nitrogen tetrasulphide and mercury fulminate to be respectively 815 to 480 ; 1703 to 1705 ; and 2441 to 2700. The press. developed by the explosion of nitrogen sulphide are, as may be seen, very similar to those obtained with the fulminate in the two latter experiments. If the explosion detonated in its own volume, the press. would be double with the fulminate, but the rapidity of the decomposition being very different, the effects produced by the two substances, supposing them to be used as detonators or "fuses," would be very dissimilar. According to F. P. Burt and F. L. Usher, nitrogen sulphide is decomposed into its elements when sublimed in vacuo over silver-gauze at 360°, forming silver sulphide and nitrogen; and it also decomposed by passage over quartz-glass wool in a quartz-glass tube at a red-heat. According to H. B. van Valkenburgh and J. C. Bailar, the hydrolysis of nitrogen tetrasulphide with a large excess of boiling water yields a neutral soln. in which 21·3 per cent. of the sulphur is present as pentathionic acid, 40·6 per cent. as sulphurous acid, 38·1 per cent. as free sulphur, and all the nitrogen as ammonia.

The compound was analyzed by M. J. Fordos and A. Gélis, M. Berthelot and P. Vieille, and F. P. Burt and F. L. Usher with results in agreement with the empirical formula NS. The data obtained by R. Schenck from the effect of the sulphide on the f.p. of naphthalene; by W. Muthmann and A. Clever, on the b.p. of carbon disulphide; and by A. Andreocci, on the b.p. of benzene and chloroform—agree with the quadrupling of the simple formula so as to give N_4S_4. R. Schenck argued that the sulphur in the tetrasulphide is bivalent by analogy with the sulphur diamine, $S(NH_2)_2$, and since ammonia is always produced in the reduction of the tetrasulphide while hydrazine is never formed, he also supposed that the nitrogen atoms are directly united by a triple bond because of the analogy of the tetrasulphide with the diazo-compounds with respect to colour and explosiveness. These assumptions led to the subjoined graphic formula. O. Ruff and co-workers discredited the assumption that the sulphur is bivalent. They showed that whenever sulphur is the electropositive part of a mol., as in the sulphur halides, it may be quadri- or sexivalent, but never bi-valent. Arguments based on the bivalency of sulphur in SCl_2 are ill-founded because of the doubts as to the individuality of this chloride—it is considered to be a soln. of S_2Cl_2 in SCl_4. The argument as to the quinquevalency of nitrogen, based on the colour-analogy with the diazo-compounds, is of little value because the azo-compounds with tervalent nitrogen exhibit similar colours; and both azo- and diazo-compounds can be reduced to hydrazine. Hydrazine, however, cannot be formed from nitrogen tetrasulphide. Observations on the hydrolysis, the action of hydrochloric acid, the action of ammonia, and on the formation of the thiodiimides show that the total number of active valencies in the mol. exceeds twelve. There is nothing to show that nitrogen atoms are joined each to each in the mol., and the reduction products make it doubtful if the contained nitrogen atoms are more than tervalent. The sulphur atoms are at least tervalent, but since no such valency for sulphur is known, it is assumed that some sulphur atoms are united each to each. O. Ruff and E. Geisel therefore argued in favour of one of the two formulæ indicated above—preferably the latter. The production of nitrogen tetrasulphide from sulphur and liquid ammonia supports this view. S. A. Vosnessensky also favoured the latter, in harmony with the behaviour of the compound on hydrolysis, and with its action on hydrochloric acid: $N_4S_4+12HCL=4NH_3+4S+6Cl_2$. The formation of lead and mercuric *thiodiimides* is assumed to occur through the change from $S:S(:N.S{\equiv}N)_2$ into $N{\equiv}S.HN_2$, and $S:S(NH)_2$, and the former furnishes $N{\equiv}S.NiHg$, and the latter $S:S(:N)_2Pb$. S. A. Vosnessensky said that the formula does not explain the reaction: $N_4S_4+CH_3.COCl{\rightarrow}N_3S_4Cl$, etc., and the production of the compounds N_3S_4Br, $N_3S_4NO_3$, and N_3S_4CyS; and the reaction: $N_3S_4Cl+NH_3{\rightarrow}N_4S_4$, etc.

$$S<\begin{matrix}N & \equiv\equiv\equiv & N\\ & >S\ S< & \\ N & \equiv\equiv\equiv & N\end{matrix}>S$$

R. Schenck's formula.

$$N<\begin{matrix}S=N-S\\ \ddot{S}-N=\dot{S}\end{matrix}>N \qquad S=S<\begin{matrix}N.\equiv SN\\ N.\equiv SN\end{matrix}$$

O. Ruff and E. Geisel's formulæ.

F. P. Burt obtained what he regarded as a **blue allotropic nitrogen tetrasulphide** by passing the vapour of the ordinary sulphide under reduced press. over silver-gauze at 100°. There was formed a conspicuous sublimate of yellow sulphide, and further on, a faint blue film appeared. The blue film gradually increased in quantity and spread in both directions. Finally the colour became deep blue and almost opaque in transmitted light; and bronze with a metallic lustre in reflected light. Analyses agreed with $(NS)_n$. The blue sulphide was quite insoluble when boiled with several organic liquids which dissolve the yellow sulphide, such as ether, chloroform, benzene, or carbon disulphide. On shaking or warming a piece of the tubing in water, the film rapidly scaled off, and was slowly decomposed. On adding a few drops of bromine water, soln. was accelerated, and the resulting liquid gave a precipitate of barium sulphate when mixed with a soln. of barium salt. When another portion was warmed with a soln. of sodium hydroxide, ammonia was evolved. When heated in air, the substance was decomposed with the evolution of vapours having an odour somewhat like that of iodine. When heated in vacuum, the substance showed no signs of volatilizing at 100°, and it could be freed in this manner from any accompanying yellow sulphide. When a small quantity was heated in a melting-point tube, decomposition occurred without liquefaction, the substance turning yellow at about the m.p. of the yellow sulphide (188°).

M. J. Fordos and A. Gélis said that nitrogen sulphide has a feeble smell, and that it irritates the mucous membranes; A. Michaelis said that the smell does not appear until the substance is warmed to 120°. M. J. Fordos and A. Gélis found that the sulphide is decomposed by water; but it suffers a slow decomposition in contact with water, forming ammonia and ammonium thiosulphate and trithionate: $2N_4S_4+15H_2O=(NH_4)_2S_2O_3+2(NH_4)_2S_3O_6+2NH_3$; but M. Berthelot and P. Vieille said that the sulphide can be moistened, and dried at 50° several times without appreciable change. O. Ruff and E. Geisel found that when one part of the sulphide is shaken with eight parts of cold water in a sealed tube for 24 hrs., the liquid smells of ammonia, and a sulphite, sulphate, thiosulphate, and trithionate can be detected in the liquid. According to M. J. Fordos and A. Gélis, the reaction with a soln. of potassium hydroxide can be represented: $N_4S_4+6KOH+3H_2O=4NH_3+2K_2SO_3+K_2S_2O_3$—if the nitrogen sulphide be contaminated with sulphur, the red-liquor observed by E. Soubeiran is produced. O. Ruff and E. Geisel found that when hydrolyzed with alkali-lye, nitrogen sulphide furnishes sulphurous and thiosulphuric acids with a small proportion of hydrogen sulphide and possibly dithionic acid, but not sulphuric and trithionic acids as obtained during the hydrolysis with water.

According to E. A. Demarçay, if chlorine be passed into nitrogen sulphide suspended in chloroform, the sulphide dissolves with the evolution of heat producing an orange-red, then an olive-green, and finally a brownish-red liquid which, on cooling, furnishes large, pale yellow crystals with the empirical formula SNCl, but which W. Muthmann and E. Seitter represent as **nitrogen tetrachlorotetrasulphide,** $N_4Cl_4S_4$. Similar crystals were made by S. A. Vosnessensky, and A. Andreocci. E. A. Demarçay said that this chloride unites with nitrogen sulphide, forming a compound, $(SN)_3Cl$, or **nitrogen tetrachlorododecasulphide,** $(N_4S_4)_3Cl_4$. W. Muthmann and A. Clever, and S. A. Vosnessensky prepared nitrogen tetrabromotetrasulphide, $N_4Br_4S_4$, by the action of a soln. of bromine in carbon disulphide on nitrogen sulphide, and when exposed to the vapour of bromine, **nitrogen hexabromotetrasulphide,** $N_4S_4Br_6$. Both substances form **nitrogen dibromopentasulphide,** $N_4S_5Br_2$, when exposed to air. O. Ruff and K. Thiel observed that nitrogen sulphide is decomposed when heated in the presence of copper oxide, water, and hydrofluoric acid, forming thionyl fluoride, etc. According to A. Michaelis, dry hydrogen chloride reacts vigorously with warm nitrogen sulphide, forming ammonium chloride, and a red sublimate—probably $N_4S_4.SCl_2$; A. Andreocci obtained a pale yellow chloride by the action of dry hydrogen chloride on a soln. of nitrogen sulphide in benzene. O. Ruff and E. Geisel showed that dry hydrogen chloride gas at ordinary temp. forms a brown powder which does not change in vacuo; while if nitrogen sulphide be treated with two or three vols. of liquid hydrogen chloride at ordinary temp., in a sealed tube, the reaction which occurs may be represented: $N_4S_4+12HCl=4NH_3+4S+6Cl_2$—no free nitrogen is produced. Nitrogen sulphide with barium chlorate forms very explosive red crystals.

The action of hydrogen sulphide on nitrogen tetrasulphide in the presence of liquid ammonia has been discussed in connection with sulphammonium. The reaction was investigated by K. Rötgers. E. A. Demarçay studied the action of nitrogen tetrasulphide on the chlorides of sulphur—*vide infra,* thiotrithiazyl-compounds. M. J. Fordos and A. Gélis, and S. A. Vosnessensky obtained the complexes $N_4S_4.2SCl_2$; $N_4S_4.SCl_2$; and $3N_4S_4.2SCl_2$ by the action of sulphur chloride on a soln. of nitrogen sulphide in carbon disulphide. According to H. B. van Valkenburgh and J. C. Bailar, the prolonged passage of ammonia through an ethereal soln. of sulphur monochloride yields, after evaporation, a viscous liquid of offensive odour which does not lose ammonia on heating. A similar compound was obtained with selenium. Liquid ammonia gives a black solid when mixed with sulphur monochloride. H. Wölbling found that sulphur and selenium chlorides react with nitrogen sulphide very slowly. A. Michaelis found that dry ammonia does not react with nitrogen sulphide, and in ethereal soln., ammonia produces a white compound. The reaction was studied by H. Wölbling. S. A. Vosnessensky, and O. Ruff and E. Geisel said that nitrogen sulphide copiously absorbs dry ammonia, forming **nitrogen diamminotetrasulphide,** $N_4S_4.2NH_3$, as an orange-red product which, at ordinary temp., exercises a considerable vap. press. Liquid ammonia, at —40°, form the same compound, which is stable in vacuo at 0°. If a liquid ammonia soln. of nitrogen sulphide be heated for some hours in a sealed tube at 100°, a bluish-violet soln. is obtained which, on evaporating the ammonia, leaves nitrogen tetrasulphide as a residue. The soln. of nitrogen sulphide in liquid ammonia reacts with some metal oxides soluble in the same solvent, forming a series of coloured complexes. F. A. Smith measured the conductivity of soln. of the tetrasulphide in liquid ammonia. M. J. Fordos and A. Gélis said that nitric acid very slowly oxidizes nitrogen sulphide. E. A. Demarçay also studied the action of nitrogen sulphide on phosphorus and arsenic chlorides. O. Ruff and E. Geisel observed that no action occurred when a liquid ammonia soln. of nitrogen sulphide is treated with arsenic or antimony trichloride; nitrogen sulphide dissolves in arsenic trichloride, forming a slightly turbid soln., and in antimony trichloride, forming a clear, blood-red soln. H. Wölbling said that no complexes are formed with the phosphorus, arsenic, or antimony trichlorides. O. C. M. Davis, and H. Wölbling prepared the complex $N_4S_4.SbCl_5$.

According to M. J. Fordos and A. Gélis, nitrogen tetrasulphide is slightly soluble in alcohol, ether, and turpentine, while 100 grms. of boiling carbon disulphide dissolve 1·5 grms. of nitrogen sulphide ; and, according to A. Andreocci, it is soluble in benzene and in carbon tetrachloride. S. A. Vosnessensky gave for the solubility in grams per litre, in carbon disulphide, benzene, and alcohol:

	0°	10°	20°	30°	40°	50°	60°
CS_2 . .	3·705	6·845	9·391	13·188	16·887	—	—
C_6H_6 . .	2·266	4·260	6·301	8·692	11·107	13·721	17·100
C_2H_5OH .	0·645	0·830	1·050	1·271	1·478	1·640	—

R. Schenck said that when nitrogen tetrasulphide is added to a soln. of sodium ethoxide (4 mols.) in alcohol, the liquid acquires a colour which is purple-red by transmitted, and dark green by reflected light, gradually becoming violet and ultimately brown; this coloration is permanent in absence of water, but if water is added the soln. becomes yellow and acquires a most offensive odour. Absolute ether precipitates from the alcoholic soln. a substance which crystallizes in lustrous scales, and exhibits dichroism; it is excessively unstable, and the soln. in alcohol is red. W. Muthmann and A. Clever said that if a soln. of nitrogen tetrasulphide in carbon disulphide or carbon tetrachloride is heated under 5 atm. press., nitrogen pentasulphide is formed; if similarly heated to 110° with ether, no pentasulphide is produced, but a substance smelling like acetamide is produced; and if similarly heated to 125° with benzene, no pentasulphide is produced, but a substance with a smell like oleum absynthii is formed. W. Muthmann and E. Seitter obtained thiotrithiazyl-chloride by the action of acetyl chloride on nitrogen tetrasulphide. According to R. Schenck, nitrogen tetrasulphide is indifferent towards primary and secondary bases of the aromatic series and all tertiary bases. If the substance is covered with piperidine, heat is generated, ammonia and nitrogen being evolved, whilst the mass, on cooling, deposits thiopiperidine; the action proceeds quantitatively in accordance with the equation $3N_4S_4+24C_5H_{10}NH=12(C_5H_{10}N)_2S+8NH_3+2N_2$. When nitrogen tetrasulphide is heated for one hour with dimethylamine, and the product distilled, the fraction which boils below 100° is a colourless oil, which solidifies in a mixture of ice and salt; this substance is thiodimethylamine, crystallizing in lustrous leaflets having a disagreeable, irritating odour. Ethylamine acts on nitrogen tetrasulphide, producing tetraethylthiodiamine, $S(NEt_2)_2$. Nitrogen tetrasulphide converts benzylamine into polymerized benzonitrile—*i.e.* cyanophenine—ammonia and nitrogen are evolved; when, however, the generation of heat is checked, and excess of benzylamine is employed, the *thionamide* of thiobenzoic acid, S : CPh.N : S, is produced, crystallizing from ethylacetate in beautiful yellow prisms, melting at 104°–105°. Along with this, a liquid is formed which becomes deep red when exposed for some days to air; on acidification, ether extracts the colouring matter, which consists of dithiobenzoic acid. Cold phenylhydrazine is without action on nitrogen tetrasulphide, but on application of heat, there is a violent disengagement of ammonia and nitrogen, benzene, sulphur, and hydrogen sulphide being also produced. F. E. Francis and O. C. M. Davis studied the action of nitrogen tetrasulphide on various aromatic aldehydes—*e.g.* benzaldehyde, tolualdehyde, and anisaldehyde. H. Wölbling said that nitrogen sulphide does not form complexes with carbonyl chloride, or with ethyl bromide, ethylene bromide, or benzyl chloride.

E. A. Demarçay prepared complexes of nitrogen tetrasulphide with silicon, titanium, zirconium, and stannic chlorides; and O. C. M. Davis reported the formation of $N_4S_4.Ti_2Cl_6$; or $2N_4S_4.SnCl_4$; and $N_4S_4.MoCl_4$; and $N_4S_4.WCl_4$. H. Wölbling made $N_4S_4.TiCl_4$, and $2N_4S_4.SnCl_4$, but stannous chloride does not form a complex. According to O. Ruff and E. Geisel, soln. of the metal iodides and of nitrogen tetrasulphide in liquid ammonia give precipitates. Lead and mercuric iodides form the corresponding dithiodiimides (*q.v.*), but the other iodides do not yield definite compounds—*e.g.*, cadmium, bismuth, and chromium iodides—because they are not sufficiently soluble in liquid ammonia; silver and aluminium iodides, because the products are too soluble; calcium iodide, because the precipitate is difficult to filter; and potassium iodide, because the precipitate is too difficult to wash.

F. L. Usher found that the sublimation of nitrogen sulphide containing free sulphur over silver gauze at about 125° yields a film of a ruby-red compound which turns deep blue on keeping (½ hr.–2 days) or on warming at 50°, and behaves like blue nitrogen sulphide of F. P. Burt—*vide supra.* Nitrogen sulphide free from sulphur yields directly the blue compound, from which the ruby compound could never be obtained. These modifications are considered to be produced from different intermediate volatile nitrogen sulphides, the one giving rise to the ruby compound being formed by the decomposition of **nitrogen persulphide** or **nitrogen disulphide,** NS_2, by silver. Nitrogen persulphide is obtained as a dark red liquid, resembling bromine, and solidifying to a pale yellow solid at the temp. of solid carbon dioxide, by subliming nitrogen sulphide with sulphur at 125° in the absence of silver gauze. It has a penetrating odour like that of iodine and can be distilled unchanged in a vacuum. At the ordinary temp., it decomposes slowly into sulphur and yellow nitrogen sulphide. Water decomposes it into ammonium salts and free sulphur. It is more volatile than the sulphide N_4S_4; hydrogen sulphide decolorizes an ethereal soln. with the probable formation of a thio-acid of nitrogen.

According to W. Muthmann and A. Clever, **nitrogen pentasulphide,** N_2S_5, can be prepared by heating nitrogen tetrasulphide with pure carbon disulphide at 100° for two hours under a press. of five atms. A deep red soln. is obtained together with a yellowish-brown, amorphous precipitate ; the filtrate is distilled until the greater part of the carbon disulphide is separated, and the residue is allowed to evaporate at the ordinary temp. in vacuo. The red oily product, consisting of a mixture of the pentasulphide with sulphur, is triturated with perfectly dry ether as quickly as possible, when the greater portion of the sulphur remains undissolved. The residual sulphur is crystallized out by means of a freezing mixture at −25° and the filtrate allowed to evaporate in dry air ; finally, the last traces of ether are removed by allowing the product to remain over calcium chloride, and the residual red oil is filtered. The formation of the pentasulphide takes place according to the equation $N_4S_4+2CS_2=N_2S_5+S+2CNS$. If the product is pure and contains no sulphur, it crystallizes from a well-cooled soln. in ether in metallic tablets resembling iodine.

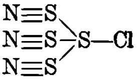
The amorphous by-product mentioned above, on analysis, gave numbers agreeing with the formula $C_3N_3S_3$; it is a very finely-divided, yellow powder, is extremely hygroscopic, and obstinately retains traces of carbon disulphide and nitrogen pentasulphide. It dissolves without alteration in concentrated sulphuric acid, and has properties similar to those of pseudocyanogen sulphide, $C_3N_3S_3H$.

The pentasulphide is also formed by heating a mixture of nitrogen sulphide and carbon tetrachloride, an amorphous black by-product being also formed containing carbon, nitrogen, sulphur, and chlorine ; this quickly decomposes on exposure to the air with evolution of sulphur dioxide. It is also produced by reducing with zinc dust thiotrithiazyl chloride, N_3S_4Cl, suspended in methyl alcohol ; and, generally, by the decomposition of nitrogen sulphide and its derivatives ; for instance, when nitrogen sulphide is exploded by friction, when the compounds of nitrogen sulphide with the halogens, or with nitrous acid, are boiled with water, and when nitrogen sulphide is heated cautiously with lead oxide. It is not, however, formed by heating nitrogen sulphide with ether or benzene at 110°–125° in a sealed tube. A. K. Macbeth and H. Graham found that some pentasulphide is formed in the action of sulphur monochloride on ammonia in chloroform soln.

Nitrogen pentasulphide is a deep red, mobile liquid, which in thin layers appears transparent. It does not wet glass. Its sp. gr. is 1·901 at 18°. When cooled, it furnishes a crystalline, steel-grey mass, resembling iodine, and it melts at 10°–11°. Its odour resembles to some extent that of iodine, and it attacks the mucous membrane. If a little is put on the tongue it appears to have no taste, but it very soon develops a severe burn. The analysis corresponds with N_2S_5, and its effect on the f.p. of benzene corresponds with the same formula. Nitrogen pentasulphide is easily decomposed ; in summer, or in moist air, it very soon gives off gas, forming sulphur and nitrogen tetrasulphide. It decomposes when boiled at atm. press. into nitrogen and sulphur—at first the decomposition proceeds slowly with the evolution of nitrogen, but the pentasulphide soon detonates. At 10 mm. press., and about 50°, about 10 per cent. passes into nitrogen tetrasulphide, and 90 per cent. into sulphur and nitrogen. It is insoluble in water ; and when boiled with water, a small quantity distils undecomposed, and the remainder forms ammonia and sulphur. It is decomposed by a soln. of potassium hydroxide in a similar manner. When a minute quantity of an alcoholic soln. of potassium or sodium hydroxide is added to an alcoholic soln. of nitrogen pentasulphide, an intense but transient violet-red coloration is produced, and this reaction is so characteristic that the smallest quantity of the pentasulphide can be detected. When the pentasulphide is added to alcoholic potassium, a dark-coloured soln. is obtained, from which ether precipitates a yellow, crystalline compound ; this is probably a **nitrogen sulphonitrate,** which decomposes directly it is removed from the soln. With alcoholic alkali sulphides, it yields polysulphides and ammonia, and with hydrogen sulphide, ammonium polysulphide and sulphur. It is violently oxidized by concentrated nitric acid with formation of sulphuric acid ; and with dil. hydrochloric or sulphuric acid, it yields ammonium salts and sulphur. Nitrogen pentasulphide is soluble in most organic solvents—carbon disulphide dissolves 8–12 per cent. dependent on the temp. ; ether, 2–3 per cent. ; but it is sparingly soluble in benzene, alcohol, and chloroform. The soln. of the pentasulphide in these solvents is stable provided it is not exposed to light ; an ethereal soln. can be kept for months in darkness. In light, nitrogen tetrasulphide and sulphur are formed. The absorption spectrum of the soln. of the pentasulphide shows a broad band extending from the *D*-line into the blue.

There are three **nitrogen oxysulphides** whose constitution and mol. wts. are unknown, and therefore they have not been given a name. (1) When a soln. of nitrogen tetrabromotetrasulphide in carbon disulphide is treated with nitrogen peroxide, there is deposited a pale yellow powder consisting of microscopic prisms. Its composition approximates NSO_2 or $N_5S_6O_4$. It is fairly stable in air, but slowly decomposes, giving off nitrogen peroxide. It dissolves in cold water, and the soln. is neutral ; and when the soln. is warmed, a black substance is precipitated which soon begins to decompose. Alcohol gives a dark red soln. which evolves sulphur dioxide when boiled, and deposits a white crystalline substance. (2) If nitrogen dibromopentasulphide is treated with nitrogen peroxide in a similar way, yellow needles of a substance with the composition $N_4S_3O_6$ are formed. It decomposes with incandescence at the temp. of a water-bath ; it dissolves in cold water, and the aq. soln. decomposes when heated. (3) If nitrogen tetrasulphide be treated with a soln. of nitrogen peroxide in carbon disulphide, a white crystalline mass separates in a few hours. The composition approximates NSO_4. The crystalline plates are doubly refracting ; and they are deliquescent in air. They react with water with a hissing noise, and the evolution of nitric oxide : $NSO_4+H_2O=NO+H_2SO_4$.

In 1880, E. A. Demarçay found yellow microscopic crystals of what was considered to be the chloride of a univalent radicle N_3S_4 among the products of the action of yellow sulphur chloride on nitrogen sulphide. He called the radicle NS, *thiazyl*, and N_3S_4, **thiotrithiazyl.** He considered the radicle to be constituted with quadrivalent sulphur and tervalent nitrogen, so that the chloride became $(N:S)_3S.Cl$; while W. Muthmann and E. Seitter assumed the sulphur to be bivalent, and the nitrogen tervalent, $(SNS)_2N.Cl$, or



E. A. Demarçay's formula.

W. Muthmann and E. Seitter's formula.

The compound prepared by E. A. Demarçay was therefore **thiotrithiazyl chloride,** N_3S_4Cl. W. Muthmann and E. Seitter prepared this compound from nitrogen sulphide by the action of warm sulphur dichloride diluted with chloroform ; it is more conveniently prepared by heating nitrogen sulphide with acetyl chloride (4 parts) in a reflux apparatus for half an hour, when it is obtained as an intensely yellow, crystalline powder, exhibiting the properties attributed to it by E. A. Demarçay. On boiling the substance with alcohol during a short period, and treating the liquid with a few drops of alcoholic potash, an intense, violet-red coloration is developed, and does not immediately disappear on dilution with water. Ammonia gas is rapidly absorbed by the dry compound, which explodes violently after a few minutes ; if thiotrithiazyl chloride is suspended in chloroform and submitted to the action of the gas, the liquid becomes orange-red, and ammonium chloride and sulphide are produced, nitrogen sulphide being regenerated. According to E. A. Demarçay, if the sulphur chloride and nitrogen sulphide react in the cold, black crystalline dithiotetrathiazyl dichloride, $S_6N_4Cl_2$, is formed. It is dissolved by sulphuric acid, giving off hydrogen chloride, and is decomposed by heat ; $3S_6N_4Cl_2=4S_4N_3Cl+S_2Cl_2$. E. A. Demarçay prepared **thiotrithiazyl hydrosulphate,** $N_3S_4.HSO_4$, by the action of conc. sulphuric acid on the chloride, and precipitation by the addition of 4–5 vols. of acetic acid. The pale yellow needle-like crystals are stable provided moisture be excluded. E. A. Demarçay also made **thiotrithiazyl nitrate,** $N_3S_4.NO_3$. W. Muthmann and E. Seitter also obtained the latter by dissolving the chloride in conc. nitric acid, and evaporating the yellow liquid in vacuo. The resulting nitrate is very explosive, and crystallizes in sulphur-yellow, long, transparent prisms, and when preserved during some days becomes opaque and acquire the colour of sulphur dioxide mixed with oxides of nitrogen. The soln. in water is yellow and transparent, but becomes opaque in a few minutes, depositing a black substance mixed with much sulphur; a red liquid is obtained on boiling the compound with alcohol. **Thiotrithiazyl bromide,** N_3S_4Br, obtained by dissolving nitrogen sulphide and sulphur bromide (5 parts) in carbon disulphide, crystallizes in small, yellow needles; it is also formed when excess of bromine acts on thiotrithiazyl chloride in warm carbon disulphide, and is identical with the compound produced on exposing the tetrabromide of nitrogen sulphide to the action of moist air. The substance is stable in air, and when water is boiled with it, ammonium bromide, sulphur, and sulphurous anhydride are produced; hot dil. alkalis give rise to ammonia, along with alkali bromide, thiosulphate, and sulphate, and sulphide. **Thiotrithiazyl iodide,** N_3S_4I, is prepared by dissolving thiotrithiazyl chloride in ice-cold water and immediately adding excess of an ice-cold soln. of potassium iodide; it is a dark red, crystalline powder which decomposes spontaneously on exposure to the air, vapours of iodine being evolved. The compound is also obtained by acting on the chloride with iodine dissolved in methyl alcohol, but it invariably contains chlorine when prepared in this way. **Thiotrithiazyl thiocyanate,** N_3S_4CNS, is obtained by adding a soln. of potassium thiocyanate to an ice-cold soln. of thiotrithiazyl chloride or nitrate; it crystallizes in lustrous, bronze leaflets and resists the action of air. The salt dissolves somewhat readily in benzene and chloroform.

§ 50. Amidosulphimic Acid and its Salts

The ammonia derivatives of sulphurous and sulphuric acids—forming respectively the monobasic sulphurous and sulphuric acids—include the amido-, the imido-, and the nitrilo-acids according as one, two, or all three atoms of ammonia are replaced by the sulphinic, HSO_2-radicle, or the sulphonic, HSO_3-radicle:

NH_3	$NH_2(HSO_2)$	$NH(HSO_2)_2$	$N(HSO_2)_3$
Ammonia.	Amidosulphinic acid.	Imidosulphinic acid.	Nitrilosulphinic acid.
NH_3	$NH_2(HSO_3)$	$NH(HSO_3)_2$	$N(HSO_3)_3$
Ammonia.	Amidosulphonic acid.	Imidosulphonic acid.	Nitrilosulphonic acid.

According to J. W. Döbereiner,[1] dry sulphur dioxide reacts energetically with dry ammonia, forming a pale brown mass, which is decolorized when treated with water, forming ammonium sulphite. H. Rose said that in whatever proportions the two gases are mixed, they always condense in equal vols., forming one homogeneous substance—*sulphitoammonia*—which is either yellowish-red and viscid, or red and crystalline; the product is very deliquescent dissolving in water without evolving ammonia. The soln. is neutral, and is at first yellow, but soon becomes colourless. The freshly prepared soln. gives reactions for ammonium sulphate and trithionate, and, to a less extent, for ammonium sulphite. Soln. of certain concentrations give a transient red coloration with hydrochloric acid. G. Forchhammer found the product contains some crystals which were assumed to be ammonium sulphate. He said the moist product is alkaline, and evolves ammonia. Alcohol extracts a substance which acquires temporarily a rose colour.

E. Divers and M. Ogawa found that if the gases are very thoroughly dried they do not combine at ordinary temp., but if the dried gases, with ammonia in excess, be mixed in a vessel cooled by a freezing mixture, the solid mass which is produced consists largely of ammonium amidosulphinate, $(NH_4)(NH_2.SO_2)$, mixed with other substances requiring more than 2 mols of sulphur dioxide to 3 mols of ammonia. If this product be warmed between 30° and 35° in a current of dry nitrogen or hydrogen, it contains no amidosulphinate, and gives up no sulphite to water. It then contains $N:S=1:1$ very nearly. If the temp. at which the gases are mixed does not rise above 30° or even 40°, the product contains very little sulphate, but if the temp. rises sufficiently high, much sulphate is formed. If prepared at the lower temp., trithionates are absent. F. Ephraim and H. Piotrowsky found that three different products are produced by the interaction of sulphur dioxide and ammonia: (i) with an excess of sulphur dioxide, amidosulphinic acid is always formed; (ii) with an excess of ammonia, ammonium amidosulphite; or (iii) a red product with the same ultimate composition, but with double the mol. wt. $2SO_2.4NH_3$, which is ammonium imidosulphinate, $NH_4.N:(SO_2NH_4)_2$.

M. Schumann observed that if the sulphur dioxide be in excess the compound $SO_2.NH_3$ is formed; and if the ammonia be in excess, $SO_2.2NH_3$ is formed. He described the compound $NH_3.SO_2$—previously called **amidosulphinic acid** or *amidosulphurous acid*—as a yellow, crystalline powder which is very hygroscopic. It is at once decomposed by water yielding a faintly acid soln. which, when treated with acids, evolves sulphur dioxide without the precipitation of sulphur. The freshly prepared soln. contains ammonium salts, and sulphuric, sulphurous, thiosulphuric, trithionic, and pentathionic acids: $4NH_3SO_2+2H_2O=(NH_4)_2SO_4+(NH_4)_2S_3O_6$; $NH_3SO_2+H_2O=NH_4HSO_3$; $4NH_4(HSO_3)=(NH_4)_2S_2O_3+2NH_4(HSO_4)+H_2O$; $10NH_3SO_2+6H_2O=(NH_4)_2S_5O_6+3(NH_4)_2SO_4+2NH_4(HSO_4)$. According to H. Rose, when the recently prepared soln. is boiled with some potassium hydroxide until ammonia ceases to be evolved, and hydrochloric acid is added, sulphur dioxide is evolved but no sulphur is precipitated. M. Schumann pointed out that if trithionates were present, such a treatment would form sulphites and thiosulphates with the deposition of sulphur. H. Rose found that when hydrochloric acid is added to the fresh soln., sulphur dioxide is given off, sulphur is deposited, and sulphuric acid remains in soln.; conc. sulphuric acid yields sulphur dioxide, but with a conc. soln., some sulphur is precipitated; and selenious acid gives a red precipitate of selenium with a fresh soln. of amidosulphinic acid, but not with a soln. which has been kept for some weeks. The freshly prepared soln. gives a precipitate of barium sulphate when treated with barium chloride. The fresh soln. is not affected by a soln. of copper sulphate at ordinary temp.; but, when heated, copper sulphide is precipitated; mercuric chloride gives a white precipitate, but if the amidosulphinic acid is in excess, black mercuric sulphide is precipitated; and with silver nitrate, the soln. behaves like a mixed soln. of a thiosulphate and trithionate, with a small proportion of silver nitrate; the white precipitate first formed redissolves; with a larger proportion, the precipitate is permanent, and then changes through yellow and brown to black. The black sulphide also contained some metallic silver, probably reduced by sulphurous acid. E. Divers and M. Ogawa, however, said the fresh soln. gives reactions which do not characterize trithionates—*e.g.* it may be acidified and left for hours without yielding more than traces of sulphur or sulphur dioxide; to obtain these in quantity the soln. must be heated under press. The absence of sulphate is considered to disprove the production of trithionate, since, as H. Rose himself has shown, sulphate and trithionate are complementary products of the decomposition. According to M. Schumann, if amidosulphinic acid be heated under dry carbon disulphide in a reflex apparatus, ammonia is evolved, and a dark red, crystalline sublimate with the composition and provisional name *trisulphitotetrammine*, $3SO_2.4NH_3$, is formed. This compound is very hygroscopic and yields a soln. in water similar to that of ammonium amidosulphinate. E. Divers and M. Ogawa consider this compound as a mixture of the decomposition products of ammonium amidosulphinate; and M. Schumann considers it is possibly *ammonium nitrilosulphite*, $N(SO_2NH_4)_3$.

The old ideas as to the nature of the compounds were somewhat vague. N. A. E. Millon, and G. Forchhammer supposed that the sulphur is combined either with amidogen, NH_2, or with nitrogen. H. Schiff regarded the compound $NH_3.SO_2$ as a *thionaminic acid*, $NH_2.SO_2H$; and it may be called *amidosulphinic* or *amidosulphurous acid*, and M. Schumann discussed the formula

$$O{=}\overset{\displaystyle S}{\underset{\displaystyle O}{\cdot}}{>}NH_3$$

H. Schiff regarded $2NH_3.SO_2$ as ammonium thionaminate, $NH_2.SO.ONH_4$; while A. Michaelis and O. Storbeck represented some organic derivatives of $SO_3.2NH_3$ by a formula $(NH_2)_2S(OH)_2$; and E. Divers and M. Ogawa assumed that the compound is ammonium amidosulphite, $NH_4.N(SO_2.NH_4)_2$, and not $NH_2.SO.ONH_4$. On account of its feeble activity as a reducing agent, and its easy passage into ammonium sulphite or ethyl ammonium sulphite, it is supposed to be a sulphuryl rather than a thionyl compound—*vide infra*, sulphuryl amide.

According to M. Schumann, when potassamide is heated to 200° in an atm. of sulphur dioxide there is a violent reaction, with evolution of light and heat; the products are a mixture of the compounds $SO_2.NH_3$ and $SO_2.2NH_3$, and a residue containing potassamide, potassium, sulphur dioxide, and a small quantity of ammonia. Similar compounds are obtained by the action of sulphur dioxide on the anhydrous fatty amines, when brought into direct contact without the presence of a solvent at about $-6°$. Ethylamine yields **ethyl amidosulphinate,** $SO_2.NH_2Et$, which crystallizes in yellow scales and yields a colourless soln. in water containing the amine and sulphuric, sulphurous, thiosulphuric, trithionic, and pentathionic acids. **Dimethyl amidosulphinate,** $SO_2,NHMe_2$, obtained from dimethylamine, is a yellow, crystalline mass, and with water gives a faintly acid soln. which contains the amine and sulphuric, sulphurous, and thiosulphuric acids only.

Amidosulphinic acid is monobasic, and furnishes salts, **amidosulphinates** or *amidosulphates*. M. Schumann prepared **ammonium amidosulphinate,** $2NH_3.SO_2$, or $NH_4(NH_2SO_2)$, from a mixture of dry sulphur dioxide and an excess of dry ammonia in a flask cooled to $-5°$ to $-7°$. It furnishes red fragments and nodules which are crystalline aggregates. When exposed to air, it gradually changes to a white powder. It dissolves in water with the evolution of ammonia; and the soln. gives a transient red coloration when treated with acids. The freshly prepared aq. soln. contains ammonium salts and sulphuric, sulphurous, thiosulphuric, trithionic, and pentathionic acids. E. Divers and M. Ogawa obtained the salt by saturating sodium-dried ether with dry ammonia in a well-cooled flask, and then passing in a very slow current of dry sulphur dioxide while frequently agitating the contents of the flask. A rise of temp. was avoided as much as possible. The ether was decanted from the yellow solid into a second flask, and the ether adhering to the precipitate removed by a current of dry ammonia continued some hours, while the flask was still cooled by a freezing mixture. Caking of the salt should be avoided. Neither air nor hydrogen can be used for drying the salt; and the flask cannot be removed from the freezing mixture while the solid is moistened with ether, without the salt acquiring a yellow colour. When dried in an atm. of ammonia the salt is more stable, but it cannot be kept long at ordinary temp. without being discoloured by decomposition. Ammonium amidosulphinate is white and probably crystalline. For a possible explanation of the formation of the red colour of M. Schumann's product by the heat developed during the reaction of the compound gases, *vide infra.*

E. Divers and M. Ogawa said that ammonium amidosulphinate appears to be slightly volatile in a current of ammonia. It is very deliquescent, and, on exposure to the air, decomposes, losing ammonia. It dissolves in water, giving out heat and a hissing sound, and if dissolved by ice or enough ice-cold water, furnishes a soln. answering all the tests for pure ammonium sulphite. In this respect, it is quite unlike ammonium amidosulphate or carbamate, since even the latter salt gives at first no precipitate with calcium chloride, which at once precipitates all sulphite from the new salt. When the salt is much decomposed, its soln. gives other reactions besides those of a sulphite. In anhydrous alcohol, it dissolves freely, evidently as ethyl ammonium sulphite; it is also slightly soluble in dry ether. It soon begins to change, and then assumes an orange colour, even at the common temp. When ammonium amidosulphinate is heated to 30°–35° in a dry atm., whether by the heat of reaction or by external heat, it is decomposed into an indistinctly crystalline, white solid, and a much smaller quantity of a coloured, effervescing liquid, part of which drains to the bottom of the vessel; after a time, however, the whole becomes solid again, and adheres tenaciously to the glass. When pure ammonium amidosulphate is similarly heated in a dry, inactive gas, it becomes coloured, softens, sinters together, vesiculates, gives off ammonia, and becomes a mass like that derived directly from the union of the gases. With very gradual heating, the temporarily liquid product is much less coloured than in the other case, its colour being evidently caused by the presence of red matter dissolved in it, which gives indications of being volatile. This orange-red substance is never formed except in very small quantities. It gives a yellow colour to the aq. soln. of the whole product, which, however, slowly fades. Alcohol, carbon disulphide, and other menstrua dissolve it out from the salts, leaving them white; but the soln. are not pure. The yellow soln. in water or alcohol takes a transient pink colour when mixed with dil. hydrochloric acid, and the alcoholic soln., an indigo-blue colour with concentrated ammonia. The residue left on evaporating the carbon disulphide soln. becomes explosive when heated above 150°, and may then have become nitrogen sulphide, but before being heated it is not this substance.

If ammonium amidosulphinate be heated for some time to 30°–35°, and extracted with 95 per cent. alcohol, E. Divers and M. Ogawa found that a small proportion of a very deliquescent salt is obtained on evaporating the alcoholic soln. The residue has the empirical composition $9NH_3+8SO_2$, and it is probably a mixture. If the alcoholic soln. be cooled, and sat. with ammonia, minute scaly crystals are obtained which, when dried over sulphuric acid, have the composition $(NH_2)_2S_2O_3$—the earlier analyses gave $(NH_3)_2S_2O_3$. E. Divers considers the constitutional formula to be **amidothioimidosulphonic acid,** $NH_2.S.NH.HSO_3$, or

$$HN{<}\begin{matrix}SO_2.O\\S.NH_3\end{matrix}{>}$$

The soln. is freely acid to litmus; when boiled with dil. hydrochloric acid, it gives very little sulphur and no sulphur dioxide; at higher temp., whether dry or in soln., it yields sulphur, sulphur dioxide, and sulphate; and when distilled with alkali-lye it yields no ammonia unless previously heated under press. with hydrochloric acid. This substance has acidic characteristics and furnishes salts:

ammonium amidothioimidosulphonate, $NH_4(N_2H_3S_2O_3)$; **potassium amidothioimidosulphonate,** $K(N_2H_3S_2O_3)$; **barium amidothioimidosulphonate,** $Ba(N_2H_3S_2O_3)_2$; and **lead amidothioimidosulphinate,** $Pb(N_2H_3S_2O_3)_2$.

In addition to the above-mentioned products of the decomposition of ammonium amidosulphinate there are formed as secondary products: sulphamide, amidosulphates, thiosulphates, imidosulphates, sulphur, and sulphates. E. Divers and M. Ogawa also obtained crystals of a substance with the empirical composition and provisional name *pentasulphitotetrammine*, $4NH_3.5SO_2$, by extracting the orange mass of decomposed ammonium amidosulphinate with 95 per cent. alcohol. F. Ephraim and H. Piotrowsky regarded it as $HSO_3.(NH.SO)_3.NH.HSO_3$, but M. Ogawa and S. Aoyama showed that it is more likely to be nothing but impure ammonium trithionate.

C. A. Cameron and J. Macallan[2] reported the formation of **ammonium amidoselenite,** $NH_4(NH_2SeO_2)$—analogous to ammonium amidosulphinite, $NH_4(NH_2SO_2)$—by the action of dry ammonia on a soln. of selenium in absolute alcohol. Minute crystals begin to deposit when the ammonia has been absorbed for some time; and the crystals can be washed with alcohol and dried over sulphuric acid in vacuo. The analysis agreed with the given formula. The deliquescent crystals are said to be hexagonal prisms and pyramids, which at ordinary temp. give off ammonia, forming the acid salt. Ammonium amidoselenite is said to be soluble in warm alcohol; but the soln. slowly deposits the salt in crystals when cooled. 100 parts of alcoholic ammonia at ordinary temp. dissolve 8·33 parts of the salt; more is dissolved at a higher temp. Hydrochloric and nitric acids have only a slight action; conc. sulphuric acid acts vigorously with the development of much heat. The salt is reduced to selenium by sulphur dioxide, or by stannous chloride; barium chloride gives a small precipitate with the warm soln.; and platinic chloride precipitates ammonium chloroplatinate. If the alcoholic soln. of the normal salt be boiled until crystals begin to separate, or if the normal salt be kept for 3 hrs. over sulphuric acid in vacuo, deliquescent crystals of **ammonium hydroamidoselenite,** $(NH_4)H(NH_2SeO_2)$, are formed. 100 parts of alcohol dissolve 7·14 parts of the salt, and it separates in large prisms from the alcoholic soln. When the salt is heated, part volatilizes unchanged, and part is transformed into ammonium selenite. The salt volatilizes in vacuo or in a current of air; it is oxidized by chlorine; and behaves towards sulphur dioxide, stannous chloride, barium chloride, and platinic chloride like the normal salt. Acids, including sulphuric acid, act feebly in the cold.

E. Divers and S. Hada were unable to confirm these results. They found that in the absence of water selenium dioxide is quite indifferent to ammonia in the cold or to its soln. in ether. Although not very soluble in alcohol alone, it dissolves freely in alcoholic ammonia to become, in absence of water, ammonium ethyl selenite, obtainable in the solid state, either by evaporating the alcohol or by precipitating the salt with dry ether. O. Hinsberg has found that an alcoholic soln. of selenium dioxide, free from all water, on evaporation leaves crystals of ethyl hydroselenite, which slowly decomposes again in dry air into alcohol and selenium dioxide, or at once, in contact with water, into alcohol and selenious acid. He also obtained what appeared to be the aniline salt of this compound, in an impure state, by mixing and evaporating soln. of selenium dioxide in alcohol and of aniline in ether, but only in absence of water. Water at once decomposed the salt into alcohol and the acid selenite of aniline. The production of ethyl ammonium selenite acquires interest from the fact that it can be effected only in the entire absence of water, to the action of which the salt is very sensitive. The salt is also of interest because, in mode of formation and in properties, it closely resembles ethyl ammonium sulphite. It is suggested that C. A. Cameron and J. Macallan used ammonia which was not thoroughly dried and that their products were impure ammonium selenites.

§ 51. Amidosulphonic Acid and its Salts

H. Rose[1] treated ammonium imidosulphonate with lead acetate, and decomposed the lead salt with hydrogen sulphide, and obtained what he called *sulphamic acid*, or *pyrosulphamic acid*. This product was probably impure **amidosulphonic acid,** $NH_2H.SO_3$. E. Berglund, in his memoir *Om imidosulfonsyra*, first definitely described the preparation of the pure acid; J. Sakurai regards this acid as sulphurous acid, $H.SO_2.OH$, with the H-atom replaced by the NH_2-radicle, $NH_2.SO_2.OH$; and just as sulphurous acid, in point of electrical conductivity measurements by W. Ostwald, and K. Barth, behaves like a monobasic acid with ions $H^{\cdot}$ and HSO'_3, so amidosulphonic acid furnishes the ions $H^{\cdot}$ and $NH_2SO'_3$. E. Berglund called it sulphamic acid and also amidosulphonic acid; and E. Divers and T. Haga said the name should be either amine-sulphonic acid, or amidosulphuric acid. E. Berglund obtained this acid by treating barium amidosulphonate with dil. sulphuric acid, and heating the product on a water-bath with the gradual addition of barium hydroxide, still maintaining an acid reaction. When an excess of ammonia and barium hydroxide no longer gives a precipitate of the imidosulphonate, the liquid is sat. with barium hydroxide, the barium sulphate filtered off, and the soln. sat. with carbon dioxide. The clear filtrate is evaporated for the acid. F. Raschig found that a large yield of amidosulphonic acid is obtained by evaporating an aq. soln. of hydroxylamine chloride sat. with sulphur dioxide; and F. Krafft and E. Bourgeois recommended keeping the soln. of hydroxylamine chloride sat. with sulphur dioxide for 2–3 days by means of a slow current of the gas. The acid was purified by crystallization from slightly warm water, but it is easily converted by hot water or by damp air at 130°–140° into ammonium hydrosulphate. E. Divers and T. Haga said that other salts of hydroxylamine or even the base itself can be used in place of the chloride. They preferred the sulphate because the liberated sulphuric acid reduces the solubility if the amidosulphonic acid, whereas hydrochloric acid has very little influence. They also worked with soln. cooled by a freezing mixture. They considered this method to be the most convenient, but it was found to be cheaper to prepare the acid by sulphonating sodium nitrite by means of sulphur dioxide and sodium carbonate, and hydrolyzing the resulting nitrilosulphonate to acid sulphate and amidosulphonate:

Two mols of sodium nitrite, and 3 mols of sodium carbonate are mixed with enough water to make the whole weigh 18 times as much as the sodium nitrite alone. Sulphur dioxide is passed into the soln. until it is acid to litmus. Usually the nitrilosulphonate changes rapidly into the imidosulphonate, but a drop of conc. sulphuric acid hastens the change. There is a marked development of heat, and much sulphur dioxide is evolved owing to the interaction of the acid sulphate and the metasulphite. Warming the mixture for a short time, or allowing it to stand for a few hours, will hasten the hydrolysis of imidosulphonate into amidosulphonate and acid sulphate. The soln. is neutralized by adding a mol of sodium carbonate, and evaporated by boiling or otherwise until it weighs 18 times as much as the sodium nitrite originally taken. The soln. is left overnight in a cool place when nearly all the sodium sulphate will be deposited in crystals. The mother-liquor is drained from the crystals, and the clear soln. of sodium amidosulphonate treated with conc. sulphuric acid weighing 3 to 3½ times that of the sodium nitrite originally employed. The mixture is set aside for a day in a cool place. The crystals of amidosulphonic acid which separate are drained on porous tubes, and washed with a little ice-cold water. The salt can be purified by cooling a soln. of the salt in about 2¾ times its weight of boiling water. The mother-liquors can be worked up by evaporation, and by precipitating the acid with conc. sulphuric acid or alcohol. A yield of 75 per cent. is readily obtained.

A soln. of the acid is also obtained by treating, say, barium amidosulphonate (*q.v.*) with the calculated quantity of dil. sulphuric acid. E. Divers and T. Haga found that the acid is formed by reducing hydroxylamine sulphonic acid, $HO.N(HSO_3)_2$, in acid soln. by a copper-zinc couple, by sodium amalgam, or by zinc and sulphuric acid. E. Divers and T. Haga found that potassium nitrososulphate forms some amidosulphonate when reduced by sodium amalgam. E. Berglund observed that a mixture of sulphur trioxide with an excess of ammonia sometimes yields a little ammonium amidosulphonate along with imidosulphonate; W. Traube found that sulphamide is decomposed by boiling alkali-lye into amidosulphonate and ammonia. F. Krafft and E. Bourgeois, and P. Eitner obtained acetyl acetamidosulphonate by the action of fuming sulphuric acid on acetonitrile, and this readily hydrolyzes into acetamide and amidosulphonic acid. M. Schmidt obtained amidosulphonic acid by treating acetoxime with sulphurous acid. E. Berglund showed that methyl sulphate and ammonia do not form methyl amidosulphonate, but rather primary, secondary, and tertiary sulphates and ammonium sulphate. W. Traube and E. Brehmer found that the salts of fluosulphonic acid possess the remarkable property of exchanging the fluorine atom for an amine-group when treated with an aq. soln. of the requisite base; under these conditions, a portion of the fluosulphonic acid, greater or less according to the strength of the base, is hydrolyzed to hydrofluoric and sulphuric acids, which represent the sole by-products of the change and which can be removed readily by chalk or barium hydroxide. A number of alkyl amidosulphonates were prepared in this manner.

Amidosulphonic acid is described by E. Berglund as being colourless and odourless, and having a sharp, purely acid taste; it crystallizes from its aq. soln. better than most of its salts. The crystals are rhombic plates which, according to A. Fock, have the axial ratios $a:b:c=0{\cdot}9048:1:1{\cdot}1487$, and are isomorphous with the potassium salt. E. Divers and T. Haga found the sp. gr. in ether to be 2·03 at 12°. M. Schmidt said that the m.p. is near 200°; and E. Divers and T. Haga found the apparent m.p. to be near 205°, but added that the acid has no real m.p. because in the act of melting it decomposes. The evolution of vapour at the m.p. is but slight in dry air, but is greatly affected by the presence of moisture in the acid or in the surrounding air. E. Berglund said that when amidosulphonic acid is rapidly heated in the absence of moisture, it is decomposed, forming sulphur dioxide, nitrogen, water, sulphuric acid, and, added E. Divers and T. Haga, ammonia. Below the temp. at which these changes occur, near 205°, the acid undergoes an intramolecular change. In a closed space protected from air, the acid sustains no loss in half an hour when heated to 220°, and only about 1 per cent. when heated to 260°; just below 260° small bubbles very slowly form in the liquid, but become reabsorbed if the temp. is lowered; they consist, almost certainly, of ammonia. There is much expansion in the act of melting, the unmelted particles sinking freely in the melted part; on cooling, the liquid forms a vitreous mass, which contracts so much as partly to detach itself from the glass, even cracking this when very thin. The vitreous product is brittle, exceedingly deliquescent, and very soluble in water. If kept dry, it remains quite transparent, and shows no tendency to crystallize even after the lapse of several days. The vitreous mass has the same ultimate composition as the acid, and when dissolved in water it furnishes ammonium hydrosulphate owing to its interaction with the solvents. It is therefore inferred that nearly half the amidosulphonic acid is converted into a sulphate. When the vitreous mass is dissolved in alkali-lye, sulphuric acid and ammonia are the chief products, though the proportion of the former is less than before, but the amount of the latter is about the same, and in excess of that required for ammonium sulphate; imidosulphate is also present in the alkaline soln. Some ammonia is present in the vitreous mass as ammonium imidosulphonate which hydrolyzes into sulphate and amidosulphonic acid more readily in water than in alkali-lye. It is therefore inferred that ammonium sulphate and imidosulphonate are produced by heat without any escape of gas. This is only possible if the sulphate and imidosulphonate exist as their unknown pyrosalts. Analyses agree with the presence of mol. proportions of *ammonium pyrosulphate*, $(NH_4)_2S_2O_7$, and *ammonium imidosulphate*, $(NH_4)NS_2O_5$; thus, $4NH_2.HSO_3=(NH_4)_2S_2O_7+(NH_4)NS_2O_5$. When the acid is heated above 260°, dense white vapours of sulphur trioxide, sulphur dioxide, and nitrogen appear; as the temp. rises decomposition proceeds more rapidly, and the vapours become more transparent. The pyro-salts formed below 260° are supposed to decompose as represented by $5(NH_4)_2S_2O_7+5(NH_4)NS_2O_5=6NH_4HSO_4+3HN(NH_4SO_3)_2+2N_2+NH_3+6SO_2+2SO_3$. The decomposition at still higher temp. causes the residue to become richer in water, and poorer in ammonia and imidosulphate until at last ammonium hydrosulphate alone remains. When heated in ordinary damp air at 100°, amidosulphonic acid slowly fixes water by hydrolysis, and the surface of the crystals becomes sticky. F. Krafft and E. Bourgeois said that this change proceeds freely at 130°–140°, while E. Berglund found that the change does not occur below 190°; but in the latter case, moisture was not concerned in the reaction.

D. Takahashi found that subcutaneous injections of sodium amidosulphonate into a frog, and intravenous injections in a dog produced no injurious symptoms, indicating that the amidosulphonates have no direct toxic action on animals. O. Loew observed no injurious effects on infusoria, rotatoria, and copepoda; but amidosulphonic acid has a decidedly noxious action on phanerogams; while mould fungi and bacteria can utilize amidosulphonic acid as a source of nitrogen. Amidosulphonic acid is stable in air, and not deliquescent when cold, but generally retains about one per cent. of moisture either hygroscopically or as ammonium hydrosulphate. According to E. Berglund, the acid is very soluble in water; but it is less soluble than any of its salts excepting the silver and basic mercury salts. E. Divers and T. Haga found that 100 parts of water at 0° dissolve 20 parts of amidosulphonic acid, and at 70°, 40 parts. Hot water has some chemical action on the salt so that an accurate determination of the solubility is not practicable. No other solvent has been found. The addition of sulphurous acid greatly depresses the solubility; sodium hydrosulphate acts similarly. Nitric and acetic acids act similarly but to a less degree; while fuming hydrochloric acid does not reduce the solubility. A. Hantzsch and B. C. Stuer found the mol. electrical conductivity, μ, of soln. with a mol of the acid in v litres of water at 0°; and J. Sakurai, at 25°, to be:

	0°				25°			
v .	75·7	151·4	302·8	1211·2	32	128	512	∞
μ .	216·9	229·1	239·7	246·8	295·8	341·9	361·9	374·0

Amidosulphonic acid has about the same strength as iodic acid, and is a much stronger acid than sulphurous acid. The percentage degree of ionization is 79·09 for the 32 v soln., 91·42 for the 128 v soln., 96·79 for the 512 v soln.; and 97·99 for the 1024 v soln. E. Berglund found that the acid is fairly stable in cold aq. soln., and the presence of neither dil. hydrochloric acid, nor a mixture of hydrochloric acid and barium chloride, affects its stability in the cold; but a mixture of hydrochloric acid and barium chloride may be boiled for an hour before barium sulphate is precipitated. He said that the acid in aq. soln. can be boiled for an hour without decomposition, though it is broken down by continued boiling. Hydrochlorous acid hastens the hydrolysis of the acid. F. Raschig also emphasized the stability of aq. soln. of the acid, and F. Krafft and E. Bourgeois emphasized the instability of the acid in warm aq. soln. According to E. Divers and T. Haga, an aq. soln. of the acid can be boiled for a moment, or kept at 100° for a very few minutes, without showing any sign of sulphuric acid with the barium chloride test, but when kept for 2 hrs. at 45°, the soln. gives a turbidity with barium chloride in 20 secs. Platinum black acts slowly on an aq. soln. of amidosulphonic acid exposed to air, producing sulphuric acid by simple hydrolysis. E. Berglund found that amidosulphonic acid is not decomposed by a boiling soln. of potassium hydroxide, while F. Raschig said that the alkali-lye made the acid less stable; E. Divers and T. Haga found alkali-lye to be inactive. The potassium salt can be evaporated on the water-bath without noticeable change; and W. Traube prepared an alkali amidosulphonate by boiling sulphamide with alkali-lye. F. Raschig stated that the presence of acids accelerates the hydrolysis, but E. Divers and T. Haga found that the hydrolysis of a boiling soln. in the presence of hydrochloric acid is not completed in a few hours; but 3–4 hrs.' heating at 150° completes the hydrolysis. Crystals of amidosulphonic acid may be kept for months over conc. sulphuric acid without change, and when heated, the acid dissolves and decomposes as it does when heated alone. Amidosulphonic acid is decomposed with effervescence due to the escape of nitrous oxide, when treated with a mixture of conc. sulphuric acid and a nitrate or nitric acid, even at ordinary temp.—*vide* imidosulphonates. According to M. Gurewitsch, amidosulphuryl chloride is produced by the action of thionyl chloride on amidosulphonic acid: $NH_2.SO_2.OH+SOCl_2=SO_2+HCl+NH_2.SO_2.Cl$, and it is formed as a complex with phosphorus trichloride by the action of phosphorus pentachloride on amidosulphonic acid: $NH_2.SO_2.OH+2PCl_5=POCl_3+HCl+Cl_2+NH_2.SO_2Cl.PCl_3$ —*vide infra.* The reaction of amidosulphonic acid with sulphuric and nitric acids was observed by J. Thiele and A. Lachmann, but no nitramide was obtained. E. Divers and T. Haga found that amidosulphonic acid is oxidized by hot or cold nitric acid, and by chlorine or bromine; while E. Berglund found that it is oxidized by a mixture of nitric acid or potassium chlorate and hydrochloric acid. E. Divers and T. Haga found that amidosulphonic acid is not acted on by soln. of chromic acid, potassium permanganate, or ferric chloride; but it is slowly oxidized at a boiling heat by silver oxide and alkali-lye and the glass containing vessel is silvered. Sulphates are not oxidized by silver oxide in alkaline soln. so that the reaction is taken to be: $NH_2.KSO_3+Ag_2O=AgKSO_3+Ag+N+H_2O$. F. Krafft and E. Bourgeois showed that amidosulphonic acid combines with alcohol, forming ammonium ethyl sulphonate; and C. Paal and F. Kretschmer, that with aniline, ammonium phenylamidosulphonate is formed. E. Divers and T. Haga found that amidosulphonic acid retards the precipitation of sulphates and sulphites by barium chloride; it also prevents the precipitation of silver and mercuric salts by alkalies. The aminic character of the acid is emphasized in the latter reaction. E. Berglund said that amidosulphonic acid dissolves zinc, and iron; and E. Divers and T. Haga, that when acted on by sodium it furnishes hydrogen and the sodium salt. It does not decompose alkali chlorides or nitrates when mixed with the salt in a damp state or in a soln.; but if mixed dry and heated, the acid itself is decomposed. F. Raschig said that the acid crystallizes unchanged from a soln. in hydrochloroplatinic acid. L. Herboth recommended amidosulphonic acid as a standard for titrimetric work because of the ease of preparation, its keeping qualities in air, and the accuracy of titrations made with it when dimethylaminedoazobenzene, methyl-red, phenolphthalein, or rosolic acid is used as indicator.

As indicated above, amidosulphonic acid is monobasic, forming a series of salts, the **amidosulphonates** or *amidosulphites.* The methods of preparation employed by E. Berglund, and F. Raschig can be much simplified because the isolation of the acid is now usually easier than the preparation of the salts. E. Berglund made **ammonium amidosulphonate,** $NH_4.SO_3NH_2$, by double decomposition with, say ammonium sulphate, and barium amidosulphonate. It forms large plates which melt at 125°. The ammonium salt is liable to hydrolysis if not quite dry; when heated to 160°, it decomposes: $2(NH_4)NH_2SO_3=NH_3+NH(NH_4SO_3)_2$, but the yield of imidosulphonate is small. After heating to 170°, the cold residue is a gum-like mass. E. Divers and T. Haga treated hydroxylamine sulphate with an eq. of barium amidosulphonate and obtained a soln. of **hydroxylamine amidosulphonate,** $NH_2.HSO_3.NH_2OH$, as a viscous, hygroscopic liquid. A. P. Sabanéeff succeeded in crystallizing the liquid ; and he also obtained the salt by passing sulphur dioxide into an excess of a methyl-alcoholic soln. of hydroxylamine. The dry salt is fairly stable ; the crystals are isomeric with those of hydrazine sulphate ; and the aq. soln. decomposes on a water-bath. A. P. Sabanéeff also prepared **hydrazine amidosulphonate,** $N_2H_4.HSO_3.NH_2$, from neutral hydrazine sulphate and barium amidosulphonate. No acid salt could be made. The soln. concentrated in a desiccator crystallizes with great difficulty. The salt is easily soluble in water. F. Ephraim and E. Lasocky were not successful in the nitration of amidosulphonic acid because of its insolubility in both nitric and sulphuric acids ; but by treating the silver salt with methyl iodide, they obtained microscopic rhombohedra of **methyl amidosulphonate,** $NH_2.SO_2.OCH_3$. The crystals begin to fuse at 170° and have a m.p. about 198° (decomp.). The ester cannot be nitrated, but by treatment with liquid ammonia, sulphamide can be obtained from it.

E. Berglund prepared acicular, deliquescent crystals of **lithium amidosulphonate,** NH_2SO_3Li, by double decomposition. The salt decomposes at 160°–170° into ammonia and imidosulphonate. It is insoluble in alcohol. E. Divers and T. Haga observed that amidosulphonic acid forms a complex salt with sodium sulphate—**sodium sulphatoamidosulphonate,** $6NH_2(HSO_3).5Na_2SO_4.15H_2O$—which appears in short, thick, deliquescent prisms. E. Berglund obtained **sodium amidosulphonate,** $NH_2.NaSO_3$, in bundles of striated needles by double decomposition. E. Divers and T. Haga obtained it by the action of sodium carbonate on the acid. E. Berglund said that the salt is easily soluble in water ; insoluble in alcohol ; and at 160°–170° forms ammonia and the imidosulphonate. E. Berglund made **potassium amidosulphonate,** by double decomposition ; and F. Raschig, by hydrolyzing potassium imidosulphonate, or nitrilosulphonate with boiling water, removing the free sulphuric acid by calcium carbonate, and evaporating the filtrate. The less soluble potassium sulphate crystallizes out first. According to A. Fock, the rhombic plates have the axial ratios $a:b:c=0{\cdot}9944:1:0{\cdot}7097$. E. Berglund, and E. Divers and T. Haga showed that at 160°–170°, ammonia and imidosulphonate are formed. The salt is easily soluble in water, and it readily forms supersaturated soln. It is insoluble in alcohol. H. Stamm found that the salt is more soluble in water if ammonia be present. W. Traube and E. von Drathen found that eq. proportions of soln. of potassium amidosulphonate and hypochlorous acid react in the cold to form **potassium chloroamidosulphonate,** $NHCl.SO_3K$, which may be isolated by evaporating the mixture to a small bulk, in a high vacuum, at as low a temp. as possible and precipitating with alcohol. The salt forms limpid, hygroscopic crystals, and is comparatively stable. When warmed with mineral acids, hydrolysis takes place according to the equation: $NHCl.SO_3H+H_2O=NH_2Cl+H_2SO_4$. The corresponding **potassium bromoamidosulphonate** is very similar. Similar salts may be prepared by the interaction of free aminosulphonic acid and metallic hypochlorites. Alkylaminosulphonates apparently give very unstable products, for evolution of gas is noticed as soon as hypochlorous acid is added. There are indications that a double amount of hypochlorous acid produces less stable **dichloroamidosulphonates.**

E. Berglund prepared **copper amidosulphonate,** $Cu(NH_2SO_3)_2.2H_2O$, by double decomposition, and A. Callegari by the action of the acid on the carbonate. The evaporation of the soln. in vacuo over sulphuric acid, or precipitation with alcohol gives a pale blue, microcrystalline powder which is fairly soluble in water ; and loses its water at a high temp. with decomposition. C. Paal and F. Kretschmer also made the copper salt. E. Berglund obtained **silver amidosulphonate,** NH_2SO_3Ag, from barium amidosulphonate, and a soln. of silver sulphate in boiling water. The silver salt was also described by P. Eitner, and C. Paal and F. Kretschmer. E. Divers and T. Haga said that the silver salt is best made directly from the acid ; it cannot be prepared from the potassium salt and silver nitrate since the most conc. soln. of these salts, mixed in equimolar proportions, give no crystalline precipitate, and when the mixture is evaporated to dryness mixed crystals of silver and potassium nitrates, and amidosulphates. E. Berglund said that the silver salt crystallizes best of all the amidosulphonate results. It forms bundles of striated prisms, and the crystals are as hard and brittle as glass. The salt blackens very slowly. Silver amidosulphonate is also least soluble since 100 parts of water at 19° dissolve 6·7 parts of salt. The aq. soln. is neutral. F. Ephraim and M. Gurewitsch found that when a soln. of amidosulphonic acid is neutralized with ammonia, and the calculated quantity of silver nitrate added to form the silver salt, no precipitate forms until the liquid has been evaporated to a syrupy consistence. It then solidifies suddenly to a radiating crystalline mass, which, after crystallization from water, gives rhombohedral crystals of **ammonium silver amidosulphonate,** $NH_2.SO_3Ag.NH_2.SO_3NH_4$. According to E. Divers and T. Haga, when potassium hydroxide is added to a soln. of silver amidosulphonate, an ochre-yellow colloidal precipitate is deposited. This compound has one of the amido-hydrogen atoms replaced by silver so as to form **potassium argentamidosulphonate,** $AgHN.SO_3K$. If the potassium hydroxide be in excess, the supernatant liquor is golden yellow; if much water is added, the colour of precipitate and soln. becomes brown and the precipitate dissolves. Both the brown and yellow soln. give brown precipitates when heated, or when mixed with an excess of potassium hydroxide, silver nitrate, or potassium amidosulphonate. The yellow soln. gelatinizes and becomes colourless on standing. The brown substance in soln. and the precipitate are said to be essentially silver oxide. The yellow compound is not blackened by light, is soluble without colour in potassium amidosulphonate, is slowly converted to a whitish, pulverulent precipitate by digestion with silver nitrate soln., and into a white flocculent precipitate by excess of potassium hydroxide. Its soln. in a minimum of potassium amidosulphonate silvers glass at a boiling heat, so does a soln. of potassium amidosulphonate, silver nitrate, and potassium hydroxide. A soln. of silver amidosulphonate does not sensibly dissolve silver oxide. A soln. containing silver nitrate and its eq. of potassium amidosulphonate behaves towards potassium hydroxide like silver amidosulphonate. If the silver nitrate is present in excess, and the soln. not too dil., precipitation of the amidosulphonic compound precedes that of silver oxide, but if the proportion of potassium amidosulphonate is as 2 mols. to 1 of the silver nitrate, potassium hydroxide causes no precipitate in soln. of moderate conc., that is to say, amidosulphonic acid prevents the precipitation of silver oxide by alkalies. A soln. of 2 mols. of potassium amidosulphonate, 2 mols. of potassium hydroxide, and 1 mol. of silver nitrate dries up in the desiccator to a white, homogeneous mass of minute, silky fibres, soluble in water again without change. Alcohol extracts from it no notable quantity of potassium hydroxide. The white fibrous salt is a complex of potassium argentamidosulphonate, and *potassium potassamidosulphonate*, $KNH.SO_3K$, and potassium nitrate. K. A. Hofmann and co-workers found that the *hydrate*, $NHAg.SO_3K,H_2O$, is obtained, by the action of silver nitrate on an alkaline soln. of potassium amidosulphonate, in the form of silky, colourless, flat needles, which are strongly double-refracting, with parallel extinction. The stability of the combination of silver with the amide-nitrogen is of the same order as in the silver ammines. The salt is soluble in ammonia, the soln. giving a precipitate of silver with formaldehyde, and a beautiful silver mirror with tetraformaltrisazine. **Potassium gold amidosulphonate,** $Au_2(N.SO_3K)_3$, is prepared from gold chloride and an alkaline soln. of potassium amidosulphonate; it forms small, yellow, transparent, granular crystals, and detonates on heating. The ammoniacal soln. gives a gold mirror with formaldehyde or tetraformaltrisazine. The aq. soln. catalyzes hydrogen peroxide, colloidal gold being formed.

E. Berglund prepared thin plates of **calcium amidosulphonate,** $Ca(NH_2SO_3)_2.4H_2O$, which were very soluble in water; also prismatic crystals of **strontium amidosulphonate,** $Sr(NH_2SO_3)_2.4H_2O$, more soluble than the barium salt; and acicular and prismatic crystals of **barium amidosulphonate,** $Ba(NH_2SO_3)_2$. The aq. soln. can be kept a long time without change. The solid does not decompose at 200°. E. Divers and T. Haga represented the thermal decomposition by $3Ba(NH_2SO_3)_2 = 3BaSO_4 + HN(SO_3NH_4)_2 + NH_3 + NS + N$. W. Traube and E. von Drathen prepared **barium chloroamidosulphonate,** $(NHCl.SO_3)_2Ba$, by the method indicated for the potassium salt. No *magnesium amidosulphonate* has been reported. E. Berglund prepared a radiating mass of crystals of **zinc amidosulphonate,** $Zn(NH_2SO_3)_2.4H_2O$, by double decomposition, etc.; and rhombic plates of **cadmium amidosulphonate,** $Cd(NH_2SO_3)_2.5H_2O$, in a similar way. The latter salt is very soluble in water.

E. Divers and T. Haga said that **mercurous amidosulphonate** cannot exist (in aq. soln.), for, when a soln. of mercurous nitrate is treated with the acid, metallic mercury and **mercuric oxyamidosulphonate,** $Hg(NH_2.SO_3HgO)_2.2H_2O$, is formed. According to E. Berglund, when silver amidosulphonate is mixed with mercuric chloride, a mixed precipitate of silver chloride and mercuric oxyamidosulphate is set free, and amidosulphonic acid passes into soln. According to E. Berglund, and E. Divers and T. Haga, normal **mercuric amidosulphonate** cannot be prepared. The oxyamidosulphonate is formed when mercuric oxide and moist amidosulphonic acid are ground together—any excess of mercuric oxide can be removed by dil. nitric acid, and any excess of amidosulphonic acid passes into soln. When potassium hydroxide is added to a mixed soln. of mercuric chloride and potassium amidosulphonate a precipitate of the basic salt is produced when the mercuric chloride is not in excess. Amidosulphonic acid can precipitate all the mercury from a soln. of mercuric nitrate leaving only nitric acid in soln.; and the acid is precipitated completely on adding a slight excess of mercuric salt. Mercuric oxyamidosulphonate is best obtained by mixing a dil. soln. of the acid with a conc. soln. of mercuric nitrate in a minimum quantity of nitric acid. The snow-white, voluminous, finely divided precipitate is troublesome to wash, and to dry. It is very stable and can be washed with hot water. The air-dried salt is dihydrated, but the water is all expelled at 115°. The basic salt is soluble in cold conc. nitric acid, in hydrochloric acid, and in an excess of a soln. of potassium hydroxide; if the alkali be not in excess, the basic salt is partially decomposed, forming yellow mercuric oxide. Mercuric chloride in the presence of an excess of amidosulphonic acid is not precipitated by an excess of potassium hydroxide; and the addition of more mercuric chloride, or of a little acid, causes the white basic salt to be precipitated, but not mercuric oxide. It is supposed that in alkaline soln., **potassium mercurammonium hydroxysulphonate,** $Hg_3N_2(HO)_2(KSO_3)_2$, is present; and like other mercurammonium salts it does not yield up its ammonia when treated with alkalies; it is resolved into its amine and mercuric bromide by a sat. soln. of ammonium bromide: $Hg_3N_2(HSO_3)_2(OH)_2 + 12NH_4Br = 3HgBr_2(NH_4Br)_2 + 2NH_2SO_3NH_4 + 4NH_3 + 2H_2O$; and it is converted into white precipitate when treated with a dil. soln. of ammonium chloride—at the same time, a soln. of mercury ammonium chloride and ammonium amidosulphonate is formed without the liberation of ammonia. K. A. Hofmann and co-workers prepared **potassium mercuric amidosulphonate,** $NHg.SO_3K$, by neutralizing 40 grms. of amidosulphonic acid with 10 per cent. potassium hydroxide, adding a further 40 c.c. of the alkali, and then digesting on the water-bath with the freshly precipitated mercuric oxide prepared from 100 grms. of mercuric chloride. On concentrating the soln. the required salt separates, after cooling, in the form of thin, lancet-shaped flakes, which are strongly doubly-refracting. The salt crystallizes only very slowly from soln., even when inoculated with a crystal, the various phenomena observed indicating that the crystals are probably polymerides of the mols. in soln.; the same holds for the other salts to be described. The interaction of the salt with a number of reagents is described, the results all pointing to the fact that it is a true derivative of amidosulphonic acid. If carbon dioxide is passed for some time through the mother-liquors obtained in the preparation of the above salt, an amorphous white precipitate of **potassium mercuric hydro-amidosulphonate,** $KH(SO_3N)_2Hg(Hg.OH)_2,H_2O$, is obtained. Complete saturation with carbon dioxide under press. gives finally the free acid, $(HSO_3.N)_2Hg.OH)_2$. **Sodium mercuric amidosulphonate,** $NHg.SO_3Na$, is prepared similarly to the potassium salt; it forms radiating clusters, or often felted masses, of slender, colourless needles. It differs from the potassium salt in that it is soluble in water on heating, whereas the addition of alkali is necessary to dissolve readily the former salt.

E. Berglund reported **thallium amidosulphonate,** $TlNH_2SO_3$, to be formed in prismatic crystals by the process of double decomposition. The crystals are isomorphous with those of potassium. He also made short needles of **lead amidosulphonate,** $Pb(NH_2SO_3)_2.H_2O$, by the double decomposition process. The salt is very soluble in water, but not deliquescent. C. Paal and F. Kretschmer also made this salt. E. Berglund obtained a soluble **uranyl amidosulphonate ;** and he prepared rose-red crystals of **manganese amidosulphonate,** $Mn(NH_2SO_3)_2.3H_2O$, in an analogous way. These salts are very soluble in water.

E. Divers and T. Haga made **ferrous amidosulphonate,** $Fe(NH_2SO_3)_2.5H_2O$, by dissolving iron wire in amidosulphonic acid with the exclusion of air. The acid is best kept sat. The bluish-green soln. is evaporated in vacuo. The soln. like that of most other amidosulphonates is very liable to supersaturation. The crystals appear in the form of a cake of radiating prisms. The salt is deliquescent, and is not precipitated by alcohol. They also obtained a soln. of **ferric amidosulphonate** by dissolving ferric hydroxide in amidosulphonic acid. The bright brown soln. dries to an opaque, amorphous, brittle mass. It is soluble in water, but not at all deliquescent. It has the full astringent taste of the inorganic salts, not that of the citrate or tartrate.

E. Berglund prepared **cobalt amidosulphonate,** $Co(NH_2SO_3)_2.3H_2O$, and nickel amidosulphonate, $Ni(NH_2SO_3)_2.3H_2O$, by the action of barium amidosulphonate on the corresponding sulphates. F. Ephraim and W. Flügel prepared **cobalt hexamminoamidosulphonate,** $[Co(NH_3)_6]NH_2SO_3)_2$, with a solubility at 20° of 0·2470*N*-; **cobalt aquopentamminoamidosulphonate,** $[Co(NH_3)_5(H_2O)](NH_2SO_3)_3$, with a solubility 0·723*N*- ; **cobalt diaquotetramminoamidosulphonate,** $[Co(NH_3)_4(H_2O)_2](NH_2SO_3)_3$, with a solubility of 1·002*N*- ;. **cobalt nitritopentamminoamidosulphonate,** $[Co(NH_3)_5(NO_2)](NH_2SO_3)_2$, with a solubility of 0·5076*N*-; **cobalt cis-dinitritotetramminoamidosulphonate,** $[Co(NH_3)_4(NO_2)_2](NH_2SO_3)$, with a solubility of 0·158*N*-; **cobalt trans-dinitritotetramminoamidosulphonate,** $[Co(NH_3)_4(NO_2)_2](NH_2SO_3)$, with a solubility of 0·123*N*- ; and **cobalt carbonatopentamminoamidosulphonate,** $[Co(NH_3)_5(CO_3)](NH_2SO_3)$, which is very freely soluble.

H. Kirmreuther prepared two **potassium dichlorodiamidosulphonatoplatinites** by the action of potassium chloroplatinite on amidosulphonic acid. The α-salt, $[Cl_2Pt(NH_2.SO_3)_2]K_2,2H_2O$, is yellow and readily soluble, whilst the β-salt, $[Cl_2Pt(NH_2.SO_3)_2]K_2$, is almost colourless and more difficultly soluble. Both salts contain only the potassium in an ionogenic condition, and both are neutral, so that they cannot be structural isomerides in accordance with the formulæ: $[Cl_2Pt(SO_3.NH_2)_2]K_2$ and $[Cl_2Pt(NH.SO_3H)_2]K_2$. Both salts dissolve in potassium hydroxide, giving an intense golden-yellow soln. containing a tetra-potassium salt; they must, therefore, be derived from the second of the above formulæ, that is, they are platosimines. Acids re-precipitate the salts from the soln. in potassium hydroxide. These salts are considered to be stereoisomerides, similar to the dichloroplatosamines, and from their analogy with already known isomerides of platinum, the α-salt is characterized as the *cis*-form, and the β-salt as the *trans*-form,

$$\left[{}^{Cl}_{Cl}\!>\!Pt\!<\!{}^{SO_3.NH_2}_{SO_3.NH_2}\right]K_2$$

Cis-form.

$$\left[{}^{\quad\ \ Cl}_{NH_2.SO_3}\!>\!Pt\!<\!{}^{SO_3.NH_2}_{Cl}\right]K_2$$

Trans-form.

H. Kirmreuther also prepared **potassium cis-dichlorodiamidosulphonatoplatinite** by the interaction of a mol of potassium platinochloride and two mols of amidosulphonic acid in cold aq. soln. After keeping for 24 hrs. the soln. deposits tabular, golden-yellow crystals, which are weakly pleochroic; they belong probably to the rhombic system, and are soluble to the extent of one part in 38 parts of water at 21°. One mol of water is lost at 90° and two mols at 130°. Barium chloride and hydrochloric acid give no precipitate, even on warming, proving that the sulphamic acid residue is in the inner complex sphere. Pyridine replaces the amidosulphonic acid from the residue, giving *cis*-dichloro-pyridine platinum. **Potassium trans-dichlorodiamidosulphonatoplatinite** is obtained when more than two mols of amidosulphonic acid react with 1 mol of potassium chloroplatinate, the reaction being best carried out on the water-bath. After heating for two to three hours, the soln., on cooling, deposits a mass of almost colourless, felted needles, which dissolve in water to the extent of one part in 342 parts at 21°. The reactions of this salt are similar to those of the *cis*-isomeride, except that pyridine gives the *trans*-dichlorodipyridineplatinite. **Potassium trans-dibromodiamidosulphonatoplatinite,** $[Br_2Pt(SO_3NH_2)_2)K_2$, and **potassium trans-diiododiamidosulphonatodiplatinite,** $[I_2Pt(SO_3NH_2)_2]K_2$, were obtained from the dichloro-compound by interaction with potassium bromide and iodide respectively. The former gives bright orange-yellow prisms, whilst the latter forms reddish-brown prisms. L. Ramberg and S. Kallenberg treated platinous hydroxide with an aq. soln. of amidosulphonic acid and obtained **ammonium tetramidosulphonatoplatinite,** $(NH_4)_2[Pt(NH_2SO_3)_4].6H_2O$; and when treated with sodium chloroplatinite it furnishes **sodium tetramidosulphonatoplatinite,** and this, with potassium nitrate, yields **potassium tetramidosulphonatoplatinite,** $K_2(Pt(NH_2SO_3)_4].2H_2O$; and the same salt was obtained by the action of silver amidosulphonate on the potassium *cis*-dichlorodiamidosulphonatoplatinite of H. Kirmreuther.

§ 52. Imidosulphinic Acid and its Salts

E. Divers and M. Ogawa[1] observed that when ammonium amidosulphinate is gently heated, it decomposes: $2NH_2SO_2NH_4=NH_3+NH(SO_2NH_4)_2$, thus furnishing the ammonium salt of **imidosulphinic acid,** or *imidosulphurous acid*, $NH(HSO_2)_2$. The acid has not been isolated. They prepared **ammonium imidosulphinite,** $NH(NH_4SO_2)_2$, or $3NH_3.2SO_2$, by keeping ammonium amidosulphinate for several hours at 35° protected from moisture.

In order to prepare the ammonium imidosulphite, ammonia in excess and sulphur dioxide are led into a closed flask, fitted with a thermometer and an exit-tube dipping in mercury. To absorb the heat caused by the combination of the gases, the flask is held in a bath of brine and crushed ice, which is more effective when the flask contains some ether and is kept in motion, because then the salt does not stick to the walls of the flask as a waxy, badly-conducting coating. The rate of flow of the gases is to be regulated by the operator's ability to prevent the temp. in the flask from rising much above 10°. The inside of the apparatus, the gases, and the ether are all to be dried before use. The mottled, orange-coloured mass of waxy consistence sticks to the walls of the containing vessel, and must be protected from air. Though only sparingly soluble, it can be nearly all removed by protracted digestion with successive portions of 95 per cent. alcohol until the residue is colourless, and then with 90 per cent. alcohol at about 50°. As the soln. cools, it deposits the almost pure imidosulphinite. The impure salt deposited from other extracts is washed with ammoniacal alcohol to dissolve out foreign salts, then crystallizing the residue from its soln. in 90 per cent. alcohol. The crystals are dried on a porous tile, while protected from air, and finally in a desiccator over potassium hydroxide.

Ammonium imidosulphinite forms minute, acicular crystals which are moderately deliquescent, and when freshly prepared are neutral to litmus. It has a mild, unpleasant, sulphurous taste. When heated slowly in a tube, it soon begins to decompose into volatile substances, and a residue of sulphur, ammonium sulphate, and the imidosulphonate, $NH(NH_4SO_3)_2$. The sublimates begin to appear at about 80°, and consist of ammonium pyrosulphite, $(NH_4)_2S_2O_5$, and unchanged imidosulphinite. No fusion occurs even at 150°. The salt is freely soluble in water, but is slowly decomposed, forming thiosulphate, and amidosulphonate. The change begins at once, and it is continued in the presence of hydrochloric acid, which, when hot, slowly hastens its completion: $2NH(NH_4SO_2)_2+2HCl=2NH_4SO_3NH_2+2NH_4Cl+SO_2+S$, in which the sulphur and sulphur dioxide represent undecomposed thiosulphuric acid. The salt is insoluble in alcohol, and in this respect differs from ammonium amidosulphinate. When boiled with an aq. soln. of potassium hydroxide, ammonium imidosulphinite yields two-thirds of its nitrogen as ammonia.

When an alcoholic soln. of potassium hydroxide is added to a soln. of ammonium imidosulphinite in 70 per cent. alcohol, until the liquid colours red litmus permanently blue in air, **potassium imidosulphinite,** $NH(KSO_2)_2$, soon separates in minute, micaceous crystals which adhere firmly to the glass walls of the containing vessel. After washing with absolute alcohol, the salt is still alkaline to litmus, possibly owing to the presence of the tripotassium salt as impurity. Potassium imidosulphinite is very soluble in water, and it gives the imidosulphinite reactions characteristic of that salt. When the orange mass of decomposed ammonium imidosulphinite is mixed with baryta-water so as to leave undecomposed some of the contained imidosulphinite, the concentration of the filtered soln. in a desiccator furnishes small, micaceous crystals of **ammonium barium imidosulphinite,** $Ba(SO_2.NH.SO_2.NH_4)_2$.

F. Ephraim and H. Piotrowsky obtained a red compound by the action of an excess of ammonia on sulphur dioxide. It has the same composition, but twice the mol. wt. of ammonium amidosulphite; and it is considered to be **triammonium imidodisulphinite,** $NH_4.N:(SO_2.NH_4)_2$. It furnishes **trisilver imidodisulphinite,** $Ag.N:(SO_2.Ag)_2$, which is also red in colour. It is not very stable, and gradually loses nitrogen. It was also found that when thionyl chloride is added drop by drop to liquid ammonia, the liquid assumes the same intense red colour as that possessed by the product formed from sulphur dioxide and excess of ammonia. On evaporation, a cinnabar-red residue is left, contaminated with ammonium chloride and other products. On digestion with absolute alcohol at —5°, a deep red soln. is obtained, which, on evaporation in a vacuum, gives a residue consisting of amorphous, red flakes, easily soluble in water, and mixed with a small quantity of stable, golden-yellow crystals (not enough to analyze completely), which are only slightly soluble in water. The red flakes consist of the above-mentioned triammonium imidodisulphinite, which gradually decomposes with loss of colour. The freshly prepared aq. soln., when added to ammoniacal silver nitrate, gives a purple-red precipitate of the trisilver imidodisulphinite. The reactions are symbolized;

$2SOCl_2+7NH_3=4NH_4Cl+HN:(SO.NH_2)_2$. This diamide is readily hydrolyzed by water, giving $NH(SO_2.NH_4)_2$, from which the silver salt is obtained by precipitation. The soln. of the diamide in liquid ammonia is red, probably containing the compound $NH_4N:(SO.NH_2)_2$; there is presumably enough water in the liquid ammonia to convert this amide into the above-mentioned triammonium imidodisulphinite on evaporation.

§ 53. Imidosulphonic Acid and its Salts

The more important memoirs on this subject are E. Berglund's[1] *Om Imidosulfonsyra*, and E. Divers and T. Haga's *Imidosulphates*. V. A. Jacquelain first prepared an aq. soln. of amidosulphonic acid, or imidosulphuric acid. His method, also employed by E. Berglund, and E. Divers and T. Haga, consists in treating the lead salt of the acid suspended in water with hydrogen sulphide. The filtered soln. when concentrated in vacuo contained very little sulphuric acid, showing that very little hydrolysis had occurred. The conc. soln. is unstable, and the acid is only known in aq. soln. E. Frémy attempted to obtain it by adding hydrofluosilicic acid to the potassium salt, but said the product decomposed immediately into sulphuric and sulphurous acids, and ammonia—but there is probably some misunderstanding here—*vide infra.* The aq. soln. of the acid prepared by E. Frémy was called *sulphamidinic acid*, and that by A. Claus and S. Koch was called *disulphammonic acid*. The aq. soln. is very unstable, and readily forms sulphuric and amidosulphonic acids. Aq. soln. of the salts decompose in a similar way, so that, as shown by F. Raschig, a feebly acid soln. of barium chloride, precipitates only half the sulphur as barium sulphate; and potassium hydroxide was shown by E. Berglund not to set the ammonia at liberty. F. Raschig found that if the acid of an imidosulphonate is heated with conc. hydrochloric acid in a sealed tube at 150°, the compound is completely decomposed. There are two series of **imidodisulphonates**; in one; all three hydrogen atoms of the acid are replaced by the basic radicle—these are sometimes called *basic imidosulphonates;* and in the other, only two of the hydrogen atoms are displaced—these are called the *neutral imidosulphonates.* The normal salts are usually more soluble than the basic salts. The unstable **imidomonosulphuric acid,** $NH:N.HSO_3$, or rather **potassium imidomonosulphonate,** $NH.N.KSO_3$, was stated by F. Raschig to be formed by the action of potassium permanganate on potassium hydrazinomonosulphonate—*vide infra*, diazomonosulphonic acid.

H. Rose found that when dry ammonia is conducted into a flask coated inside with sulphur trioxide, two products are formed—one is hard and vitreous; and the other is local and flocculent. V. A. Jacquelain obtained the flocculent substances by mixing the vapour of sulphur trioxide with an excess of dry ammonia. H. Rose said that both these substances when dissolved in water gave a soln. which yielded crystals of the same substance which he called *parasulfatammon*, and which is now known to be *diammonium imidosulphonate*, $NH(SO_2NH_4)_2$, *i.e.* $3NH_3.2SO_2$. Sometimes the vitreous product is acidic, which H. Rose attributed to the imperfect action of ammonia, but which E. Divers and T. Haga showed to be a consequence of hydrolysis. H. Rose thought that the crystals of parasulphatammon have the same composition as the flocculent matter, $2NH_3.SO_2$, which he called *sulfatammon.* V. A. Jacquelain showed that this is a mistake, and M. Woronin found that H. Rose's analyses of sulfatammon, $2NH_3.SO_3$, was correct, and that sulfatammon and parasulfatammon were really different salts of the same acid. E. Berglund then claimed that since *parasulfatammon* is diammonium imidosulphonate, *sulfatammon* must be *triammonium imidodisulphonate,* $N(NH_4)(NH_4SO_3)_2$, *i.e.* $4NH_3.2SO_3$. E. Divers and T. Haga showed that E. Berglund's view is correct; and confirmed M. Woronin's observation that the evaporation of the soln. of the triammonium salt furnishes the diammonium salt.

H. Rose prepared **triammonium imidodisulphonate,** $N(NH_4)(NH_4SO_3)_2$, by the action of ammonia on sulphur trioxide, and V. A. Jacquelain passed the dry sulphur trioxide in a flask filled with gaseous ammonia so as to keep the ammonia always in excess. The flocculent product was then fused in a current of ammonia until, on cooling, the mass began to solidify. The white crystals are stable in air. E. Divers and T. Haga exposed the finely divided and dry diammonium salt to an atm. of dry ammonia, and found that the absorption of the gas is attended by a considerable swelling of the powder, and the formation of the triammonium salt. According to H. Rose, this substance is a white, anhydrous, amorphous powder having a bitter taste resembling that of ordinary ammonium sulphate, and a neutral reaction. It is stable in air. E. Divers and T. Haga said that the product loses only about half per cent. of its weight when kept in a desiccator for 3 days over sulphuric acid. It seems to lose ammonia only in a damp atm.; and it lost 5·4 per cent. of its weight when heated in a current of well-dried air for $1\frac{3}{4}$ hrs. at 100°–120°, but the compound was then still losing ammonia. H. Rose said that when this compound is heated in air it gives off sulphur dioxide, ammonia, and ammonium sulphite, fuses to a clear liquid, and solidifies to a mass of ammonium hydrosulphate; and when heated in hydrogen, ammonia and ammonium sulphite are evolved, and the residue contains ammonium hydrosulphite and sulphate. The aq. soln. does not change on keeping, but when evaporated, crystals of the diammonium salt are deposited; 100 parts of water dissolve 11·1 parts of the salt at ordinary temp. If the soln. be mixed with barium chloride or nitrate, only part of the contained sulphur is precipitated as sulphate, and even after a prolonged boiling with nitric or hydrochloric acid, only about half the total sulphur is precipitated as sulphate. The whole of the sulphuric acid can be recovered as sulphate only by evaporating the soln. to dryness with barium chloride, and strongly igniting the residue. Strontium chloride gives a scanty precipitate with the aq. soln. after the lapse of about a week; and with calcium chloride the soln. was clear at the end of a week. In both cases, the boiling soln. gives a turbidity with these salts. When the aq. soln. is digested with calcium hydroxide until all the ammonia is evolved, calcium sulphate remains as a residue; lead acetate added to the aq. soln. gradually produces a turbidity, but even with a boiling soln., the sulphuric acid is only partially precipitated. Hot sulphuric acid dissolves the salt slowly, without the evolution of sulphur dioxide; the salt is decomposed again as the soln. cools. A soln. of the salt gives a precipitate with aluminium sulphate, tartaric acid, and racemic acid only after a long interval of time, and in less amount than would be obtained with an aq. soln. of ammonium sulphate. An alcoholic soln. of hydrochloroplatinic acid precipitates rather more than half the contained ammonia. The salt does not dissolve in alcohol, and does not suffer any change when digested with that liquid.

E. Divers and T. Haga prepared **monohydrated triammonium imidodisulphonate,** $N(NH_4)(NH_4SO_3)_2.H_2O$, by the union of ammonia with diammonium imidosulphonate in the presence of water. The ammonia must be in excess or the salt will be decomposed. Conc. aq. ammonia precipitates this salt from a sat. soln. of the diammonium salt, or from a sat. soln. of the sodium salt, but in that case the precipitate is contaminated with the double sodium ammonium salt. Ammonia gas acts similarly and more effectively. The crystalline powder can be recrystallized by cooling a hot conc. soln. of ammonia in a closed vessel. The crystals resemble those of the potassium salt. The clear, lustrous crystals gradually effloresce and become opaque and damp; and in a dry ammoniacal atm. over solid potassium hydroxide, the crystals slowly become opaque and anhydrous. When heated, the salt partly fuses and passes into the diammonium salt with the loss of both ammonia and water ; at the same time there is some hydrolysis into the sulphate. When the salt is dissolved in water, it decomposes incompletely into the diammonium salt and ammonia ; on evaporation, crystals of the diammonium salt are formed.

As just indicated, H. Rose showed that **diammonium imidodisulphonate,** $NH(NH_4SO_3)_2$, is produced by evaporating the aq. soln. of the triammonium salt; H. Rose, V. A. Jacquelain, and M. Woronin also found parasulfatammon to be a by-product in the preparation of sulfatammon from sulphur trioxide and ammonia. E. Berglund, and A. Mente made it by the action of ammonia on chlorosulphonic acid ; A. Mente, by the action of ammonia on sulphuryl or pyrosulphuryl chloride ; E. Frémy, by the action of nitrous gas on an ice-cold soln. of ammonium sulphite and hydrolyzing the product ; E. Berglund, by heating ammonium amidosulphonate to 160°; E. Divers and T. Haga, by treating either of the lead hydroxyimidosulphonates with ammonium carbonate; by treating barium imidosulphonate fused with dil. sulphuric acid, and then with ammonium sulphate until all the barium is precipitated; and finally, by stirring triargentic imidosulphonate with an eq. soln. of ammonium bromide. The filtered, aq. soln. of the salt is evaporated, while kept alkaline with a drop of conc. ammonia to prevent hydrolysis ; and allowed to crystallize.

The clear, colourless, lustrous, monoclinic crystals were shown by L. Münzing to have the axial ratios $a:b:c=1\cdot6443:1:0\cdot9672$, and $\beta=92°\ 45'$. They are isomorphous with the corresponding potassium salt. A. Mente gave 1·965 for the sp. gr. H. Rose said that the salt does not absorb moisture from the air. The salt is rather more stable in water than the triammonium salt, and the soln. is neutral, but V. A. Jacquelain found that the soln. reddens blue litmus even when free from sulphuric acid; this, said E. Berglund, is a result of hydrolysis. H. Rose said that the product obtained by heating this salt differs but little from those obtained by heating ammonium sulphate except that no water is present—ammonia and sulphur dioxide are evolved, and if the temp. is not too high ammonium hydrosulphate remains as a residue; ammonium sulphite and sulphate are present in the sublimate. V. A. Jacquelain reported that the salt can be fused without decomposition, and can be kept in a fused condition in an atm. of dry ammonia, without change ; but, according to E. Divers and T. Haga, in vacuo, diammonium amidosulphonate suffers no change until very near 357°, when it melts, effervesces, and boils. A little sublimate may appear at about 190°, most of the vapours from the molten salt consist of unchanged imidosulphonate, but there is a slow decomposition: $6NH(NH_4SO_3)_2=2N_2+14NH_3+6H_2O+6SO_2+6SO_3$; and there is also formed the pyrosulphite, $(NH_4)_2S_2O_5$, and the pyrosulphate, $(NH_4)_2S_2O_7$. Any ammonia evolved without admixed nitrogen is due to the action of moisture on the somewhat deliquescent salt: $NH(NH_4SO_3)_2+H_2O=H_2N.NH_4SO_3+NH_4HSO_4=NH_3+(NH_4)_2S_2O_7$. According to H. Rose, the evaporation of the aq. soln. in air gives the unchanged salt as well as some ammonium sulphate and sulphuric acid. The aq. soln. gives no precipitate with salts of barium, strontium, calcium, or lead even after standing a long time ; but if the soln. has become acidic, or if boiled with barium chloride, a little barium sulphate may be precipitated; barium chloride and hydrochloric acid together give a precipitate after the lapse of about 12 hrs. The aq. soln. in nine parts of water gives no precipitate with tartaric acid after standing several days ; with racemic acid it gives a scantier precipitate than is obtained with the triammonium salt; and it behaves like the triammonium salt with aluminium sulphate, and hydrochloroplatinic acid. No precipitation occurs when the aq. soln. is treated with manganese, copper, or silver nitrate.

E. Berglund prepared **trisodium imidodisulphonate,** $NaN(NaSO_3)_2.12H_2O$, by adding the potassium salt to a boiling soln. of sodium chloride and hydroxide ; the salt separates in thin plates on cooling the soln., and it can be recrystallized from water. E. Divers and T. Haga followed the process for the preparation of the disodium salt so far as to separate a crop of sodium sulphate crystals, the soln. is then diluted with water, sodium hydroxide added in slight excess, and the liquid is cooled. The trisodium salt begins to separate soon after the addition of the sodium hydroxide. The salt can be purified by recrystallization. The crystals, said E. Berglund, are large and micaceous; while E. Divers and T. Haga described them as thin, overlapping, hexagonal plates. The salt is stable, but the crystals effloresce in dry air, and have a mild alkaline taste. The salt is sparingly soluble in cold water, but is very soluble in hot water—at 27·5°, 100 parts of water dissolve 18·5 parts of salt. The soln. is readily supersaturated ; it is alkaline to litmus and to phenolphthalein ; and it has no action on a soln. of iodine. The salt is precipitated by alcohol from its aq. soln. without decomposition, and it can be repeatedly crystallized from its aq. soln. without the loss of alkali. The crystals melt when heated, and their water may be driven off, causing a decomposition of the salt. In vacuo over sulphuric acid, the crystals lose 11 mols. of water, and accordingly E. Divers and T. Haga write the formula $NaN(NaSO_3)_2.H_2O+11H_2O$. The salt loses more water when heated, but retains some at 160°—possibly through hydrolysis. If heated until decomposition begins, the salt yields a little water and ammonia, but more when heated in air than in vacuo. When the dried salt is heated strongly in an open tube, it melts and effervesces, yielding nitrogen, sulphur dioxide, and a sublimate of sulphur ; the saline mass at a red-heat is *hepar sulphuris*. If heated in vacuo, no sulphur dioxide is formed, so that that gas if present is produced by the action of air on sulphur. Just below the softening temp. of soda-lime-glass, the gas given off is nitrogen, some of the sulphur remains in the fused mass and is partly elemental, and partly thiosulphate ; a trace of ammonium sulphite sublimes; but the main reaction is represented: $2NaN(NaSO_3)_2=N_2+S+3Na_2SO_4$. Acids dissolve the trisodium salt, and if the right proportion of acid is added, the disodium salt is formed. Conc. sulphuric acid, not in excess, dissolves the crystals with a fall of temp., but if more than enough to form the disodium salt is present, heat is developed, and the neutralized soln. furnishes crystals of sodium sulphate and the disodium salt. Carbon dioxide decomposes a conc. soln. precipitating sodium hydrocarbonate ; conc. aq. ammonia precipitates the dodecahydrated trisodium salt free from ammonia; ammonium salts react by double decomposition, forming the triammonium salt which is partly decomposed by water giving off ammonia ; and potassium salts, say the nitrate, added to conc. soln. produce no change, but when neutralized with an acid, the sodium salt is deposited. Unlike the disodium salt, soln. of the trisodium salt give precipitates with metal salt soln.—in some cases hydroxides are formed, and with silver, mercury, lead, calcium, and barium nitrates yield imidosulphonates. There is no visible action with mercuric chloride ; and mercuric oxide dissolves to a limited extent in soln. of the trisodium salt.

E. Divers and T. Haga prepared **heptahydrated pentasodium ammonium imidosulphonate,** $Na_5NH_4N_2(SO_3)_4.7H_2O$, in small prisms, by cooling to 0°, a mixed soln. of the disodium salt and conc. ammonia. The dry salt is stable. If conc. ammonia be added to a soln. of the trisodium salt containing the eq. of 3 mols. of sodium nitrate, a crystalline precipitate of the **hemipentahydrate,** $Na_5NH_4N_2(SO_3)_4.2\frac{1}{2}H_2O$, is formed. It loses water and ammonia when heated.

E. Berglund noted that some **dilithium imidosulphonate,** $NH(LiSO_3)_2$, is formed when lithium amidosulphonate (*q.v.*) is heated to 160°–170°. E. Divers and T. Haga prepared **disodium imidosulphonate,** $NH(NaSO_3)_2.2H_2O$, by mixing 2 mols of sodium nitrate and 3 mols of sodium carbonate with twice their weight of water, and passing sulphur dioxide into the soln. The containing vessel is kept cool with cold water. When the liquid is almost neutral to lacmoid paper, the flow of gas is slackened, and stopped as soon as the liquid reddens the test-paper permanently. Neglecting intermediate stages, the main reaction at this stage may be symbolized: $2NaNO_2+3Na_2CO_3+8SO_2=2N(NaSO_3)_3+Na_2S_2O_5+3CO_2$. The excess of pyrosulphite is necessary to convert all the nitrite into the nitrilic salt; and its presence helps to preserve the imidosulphonate subsequently formed. The soln. also contains but very little sulphate. The soln. then becomes warm and gives off sulphur dioxide, owing to a partial hydrolysis of the nitrilic salt: $2N(NaSO_3)_3+Na_2S_2O_5+H_2O=2NH(NaSO_3)_2+2Na_2SO_4+2SO_2$, so that the soln. contains nothing but imidosulphonate, sulphate, and sulphur dioxide. The sulphur dioxide is removed by passing a current of air through the liquid for about 30 minutes; and sodium carbonate is added to render the liquid slightly alkaline. The liquid is concentrated by evaporation on the water-bath, and cooled to 0° so as to crystallize out the sulphate; a second evaporation and cooling may be necessary to eliminate more sulphate. Another evaporation and cooling to ordinary temp. causes the separation of dihydrated disodium imidosulphonate in well-formed crystals. The yield is about 80 per cent., and the main losses are due to the mixture of sodium sulphate and imidosulphonate in the mother-liquor. The salt can be purified by recrystallization from warm water made slightly alkaline to prevent hydrolysis. Instead of using sodium carbonate, fresh sodium sulphite or pyrosulphite can be used. The disodium salt can be made from the trisodium salt—the latter is the more stable salt. The trisodium salt is treated with dil. sulphuric acid until neutral to litmus, and the mixture kept for some hours at 0°. The clear liquor, on evaporation, yields good crystals of the dihydrated disodium salt.

Disodium imidosulphonate furnishes large rhombic prisms. It is very soluble in water; it has a slight acidic reaction, and is devoid of sulphurous taste. The crystals do not effloresce in air; but in air dried by conc. sulphuric acid, they slowly become opaque, and lose their water. They can be kept in a dry atm. indefinitely, but they are liable to hydrolyze into an acidic mixture of sulphate and amidosulphonate. The aq. soln. of the salt can be moderately heated for a short time, but is liable to hydrolysis. The crystals suffer some hydrolysis at 100°. The salt also decomposes when it is dehydrated. It decomposes when heated in a manner analogous to the dipotassium salt (*vide infra*). The disodium salt is more fusible than the potassium salt. The disodium salt does not give a precipitate with many of the common metal salts; but in moderately conc. soln., it gives a precipitate of the dipotassium salt, with potassium salts; of the trisodium salt, with sodium hydroxide; of the barium sodium salt, with barium hydroxide; and of the sodium ammonium salt, with ammonia: $5NH(NaSO_3)_2+5NH_3=2N_5(NH_4)N_2(SO_3)_4+NH_4N(NH_4SO_3)_2$; but if sodium nitrate, or chloride is added before the ammonia the reaction is: $NH(NaSO_3)_2+NH_3+NaNO_3=NH_4NO_3+NaN(NaSO_3)_2$. Basic lead acetate gives a copious precipitate, normal lead acetate a scanty precipitate, but lead nitrate no precipitate. The latter salt favours hydrolysis so that a little lead sulphate is soon precipitated. Both mercury nitrates give precipitates; precipitated mercuric oxide gives mercury disodium imidosulphonate; silver hydroxide forms the silver disodium salt; and cupric hydroxide has no visible action when evaporated on the water-bath; with sodium carbonate or acetate, some trisodium salt is formed, and carbon dioxide or acetic acid vapour escapes. In the latter case, a strong acid vapour rises from a highly alkaline liquid.

If a mixture of a soln. of the trisodium salt with a slight excess over an eq. proportion of ammonium nitrate be evaporated, ammonia escapes, and the acid soln. is neutralized with ammonia from time to time; water is also added if necessary to dissolve any crystals. During the cooling of the hot soln., crystals of **sodium ammonium nitratoimidodisulphonate**, $NH(NH_4SO_3)_2.NaNO_3$, are formed in small, flat, thick prisms, which are anhydrous, and stable in air. The salt cannot be washed with water, or recrystallized from water without hydrolysis. If too little ammonium nitrate is used the complex salt is contaminated with some disodium imidosulphonate. The constitution is represented with quinquevalent nitrogen:

$$\begin{matrix}H\\NO_3\end{matrix}>N<\begin{matrix}(NH_4SO_4)_2\\Na\end{matrix}$$

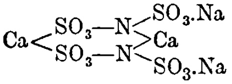
E. Berglund prepared **tripotassium imidodisulphonate**, $NK(KSO_3)_2.H_2O$, by dissolving the potassium salt in a soln. of potassium hydroxide, evaporating, and cooling. The salt can be purified by recrystallization from the smallest proportion of hot water. F. Raschig used this process. The well-formed, triclinic crystals were found by A. Fock to have the axial ratios $a:b:c=0.9796:1:0.8415$. The water of crystallization is given off at about 100°. E. Berglund found the salt can be heated to 200° without change, and it is also stable in aq. soln. The salt is not oxidized by permanganate, and with the heavy metals it forms sparingly soluble potassiferous precipitates.

E. Berglund obtained **dipotassium imidosulphonate,** $NH(KSO_3)_2$, by heating potassium amidosulphonate to 160°–170°. E. Divers and T. Haga worked at 350°, when the salt melts and decomposes: $2H_2N(KSO_3)=NH(KSO_3)_2+NH_3$. E. Frémy, A. Claus, and F. Raschig hydrolyzed potassium nitrilosulphonate with a little dil. sulphuric acid; and A. Claus and S. Koch observed that the dipotassium salt is formed by crystallization from soln. of potassium nitrilosulphonate in boiling water, or acidulated water. F. Raschig said that the yield is poor. M. Woronin made the dipotassium salt by decomposing the barium salt with potassium sulphate. E. Berglund, and E. Frémy added potassium chloride to a soln. of the diammonium salt, and recrystallized the dipotassium salt from luke-warm water, or dil. aq. ammonia; and E. Divers and T. Haga obtained the salt in a similar manner by double decomposition of the disodium salt with potassium salt. Dipotassium imidosulphonate furnishes small six-sided plates (E. Frémy); six-sided pyramids resembling augite (A. Claus and S. Koch); or long needles and granular aggregates (F. Raschig). L. Münzing said that the crystals belong to the monoclinic system, and have the axial ratios $a:b:c=1.6555:1:0.9573$, and $\beta=86°\ 31'$; while P. Friedlander said the crystals are rhombic with the hexagonal habit in consequence of trilling. E. Frémy said that the salt does not change in moist air; and, according to E. Divers and T. Haga, and A. Claus and S. Koch, not at 140°–150° in moist air. E. Divers and T. Haga found that at 170°–180°, the dipotassium salt slowly fixes water and hydrolyzes so that the imidosulphonate loses its crystalline lustre, cakes together, and become acid. If the salt be thoroughly dried, and in a dry atmosphere below the softening temp. of soda-lime-glass, no notable change occurs. If the air is not dried, the salt begins to increase in weight owing to the action of absorbed moisture. E. Frémy, and A. Claus and S. Koch reported that at about 200°, potassium sulphate, sulphur dioxide, ammonia, and a coloured sublimate are formed; but, according to E. Divers and T. Haga, they did not report the formation of a white sublimate as well, and also the evolution of nitrogen, which shows that the salt is not an addition compound of ammonia. In vacuo, the salt yields a slight sublimate between 360° and 440°; and at the temp. of decomposition the salt melts and boils: $3NH(KSO_3)_2=N_2+NH_3+3SO_2+3K_2SO_4$. The sublimates are a product of the union of sulphur dioxide and ammonia. There was no evidence of the intermediate formation of nitrilosulphonate: $3HN(KSO_3)_2=NH_3+2N(KSO_3)_3$. E. Berglund said that the dipotassium salt is less soluble than the other normal imidosulphonates, and E. Frémy added that 100 parts of water dissolve 1·56 parts of salt at 23°. Boiling water, said F. Raschig, transforms the salt into the amidosulphonate, and E. Frémy, and A. Claus and S. Koch showed that with acidulated water, sulphur dioxide, ammonium sulphate, and potassium sulphate are formed. E. Berglund found that the dipotassium salt dissolves in a soln. of potassium hydroxide, forming the more soluble tripotassium salt which, according to F. Raschig, can be precipitated by carbon dioxide. A. Claus said that sulphur dioxide does not decompose the cold aq. soln. E. Frémy, and A. Claus and S. Koch observed the slight action exercised by sulphuric and nitric acids on the dipotassium salt. E. Divers and T. Haga said that very little sulphuric acid is obtained by extracting the cold mass with ether or alcohol; and they add that there is no evidence of a reaction: $NH(KSO_3)_2+2H_2SO_4=2KHSO_4+NH(HSO_3)_2$. E. Divers and T. Haga studied the action of sulphuric acid; and they observed that a dry mixture of the dipotassium salt and potassium hydrosulphate may be fused without appreciable chemical action, but at 420°–450°, the imidosulphonate is decomposed the same as it is when heated alone—moisture must be excluded.

E. Frémy observed no apparent decomposition of the dipotassium salt by treatment with cold conc. nitric acid. A. Claus and S. Koch found that the dil. soln. gives a precipitate with lead acetate; while the hot conc. soln. gives a basic lead acetate; and E. Frémy obtained a crystalline double salt when the aq. soln. is treated with barium chloride. E. Divers and T. Haga observed that the dipotassium salt gives many of the reactions observed with the disodium salt (*q.v.*). E. Divers and T. Haga found that the sparingly soluble dipotassium salt is hardly affected by digestion with a cold dil. soln. of sodium nitrate; and if dissolved therein, it crystallizes out again almost unchanged. If a soln. containing 3 mols of sodium nitrate be allowed to stand in contact with a mol of powdered dipotassium imidosulphonate for some days, a granular mass of **potassium sodium dinitratoimidodisulphonate,** $NH(KSO_3)_2.NaNO_3.KNO_3$, is formed; it is decomposed by water. Neither the two potassium imidosulphonates nor the two sodium imidosulphonates form double salts. Disodium imidosulphonate and potassium nitrate suffer double decomposition, but the reaction is reversible. F. Raschig obtained **potassium chloroimidodisulphonate,** $NCl(SO_3K)_2$, in colourless, anhydrous crystals, when a hot soln. of sodium hypochlorite and potassium imidodisulphonate, $NH(SO_3K)_2$, is allowed to cool slowly to the ordinary temp. The substance is unstable and decomposes into nitrogen trichloride and potassium nitrilosulphonate, $N(SO_3K)_3$.

According to E. Divers and T. Haga, when silver nitrate is gradually added to a soln. of tripotassium or trisodium imidosulphonate, there is first formed a white precipitate which redissolves, there is then a separation of a felted mass of white crystals, which redissolve, with the subsequent separation of a granular mass of minute crystals. Silver nitrate and trisodium imidosulphonate yield three compounds in which 1, 2, and 3 atoms of, say, sodium are replaced by silver. If a limited amount of the trisodium salt be added to silver nitrate, a white precipitate of **trisilver imidodisulphonate,** $AgN(AgSO_3)_2$, is formed. E. Berglund first prepared this salt. E. Divers and T. Haga found that the trisilver salt is very slightly soluble in water, but is not decomposed by that liquid in washing, although after long washing it yields a turbid filtrate of the colloidal salt. The voluminous precipitate forms white, chalk-like masses when dried; the dried mass retains about 0·55 per cent. of water even after a protracted heating at 110°. At a high temp. the salt decomposes with or without fusion, giving, in an open tube, a little ammonia, and a slight sublimate, then sulphur dioxide, nitrogen, silver, and silver sulphide and sulphate. In vacuo, there is scarcely any sublimate, and no change occurs until the temp. attains 440°, when nitrogen and sulphur dioxide are evolved, and the residue blackens without fusion, and consists of silver sulphide and sulphate, and silver. The reactions are probably: $4AgN(AgSO_3)_2=2N_2+2SO_2+5Ag_2SO_4+Ag_2S$; and $4AgN(AgSO_3)_2=2N_2+4SO_2+4Ag_2SO_4+4Ag$, the latter being more pronounced the higher the temp. The granular precipitate indicated above is **disilver sodium imidodisulphonate,** $NaN(AgSO_3)_2$, and it is best made by adding the trisodium salt to a little less than two-thirds its eq. of silver nitrate. The faint, buff-coloured, granular mass is quickly washed, and dried on a porous tile. The salt consists of microcrystalline, hexagonal plates which act on polarized light. The salt is sparingly soluble in water, and is slightly decomposed by it, forming some silver hydroxide. The retention of water and the behaviour of heat resemble closely the results with the trisilver salt except that sodium sulphate forms one of the products of decomposition. The interlacing fibrous crystals, indicated above, consist of **silver disodium imidodisulphonate,** $AgN(NaSO_3)_2$; and the salt is prepared by adding the trisodium salt to less than one-third its eq. of silver nitrate, and the mixture agitated at once so as to redissolve the white silver salt first precipitated before the fibrous crystals begin to form. The salt is dried by press. in a calico filter, and between porous tiles. This is the most soluble of the three silver salts, but it is even then only sparingly so; the salt is gradually decomposed by water, forming silver hydroxide, disodium imidosulphonate, and the trisodium and sodium disilver salts. It is therefore difficult to obtain the salt pure. It retains water, and behaves when heated like the preceding salt. E. Berglund said that when silver nitrate is added to an excess of a soln. of the trisodium salt, the precipitate contains more silver than corresponds with the trisilver salt. This is due to the hydrolysis of the silver disodium salt in dil. soln. with which E. Berglund worked.

E. Berglund reported **tricalcium imidodisulphonate,** $Ca\{NCa(SO_3)_2\}_2.8H_2O$, to be formed by mixing soln. of the trisodium salt and calcium chloride. E. Divers and T. Haga showed that the product of this reaction is always sodium calcium imidosulphonate—*vide infra.* If the triammonium salt is used then no sparingly soluble salt is formed. The normal salt, tricalcium imidodisulphonate, is produced, when the trisilver salt is treated with an eq. amount of a soln. of calcium chloride, and evaporating the clear soln. for crystallization. E. Divers and T. Haga also made this salt by the less satisfactory process in which a soln. of diammonium imidosulphonate is treated with the calculated amount of calcium hydroxide, and the ammonia all expelled by two or three evaporations of the soln. to dryness. The salt is only sparingly soluble in water, from which it crystallizes in rectangular prisms and plates which are stable in air. They also made **calcium hydroimidodisulphonate,** $NHCa(SO_3)_2.3H_2O$, by decomposing the trisilver salt with two-thirds an eq. of calcium chloride, and a little less than one-third an eq. of hydrochloric acid; and also by the less satisfactory method of mixing the diammonium salt with the calculated proportion of calcium hydroxide, and repeatedly evaporating the soln. to expel all the ammonia. The evaporation of the aq. soln. furnishes a mass of radiating prisms, which, when dried on porous tiles, are permanent in air. When the calculated quantity of calcium hydroxide is dissolved in a soln. of the diammonium salt, a liquid is obtained which furnishes crystals of what are considered to be **ammonium calcium imidodisulphonate,** possibly $NH_4NCa(SO_3)_2.nH_2O$. They also made **sodium calcium imidodisulphonate,** $NaNCa(SO_3)_2.3H_2O$, by adding a soln. of calcium chloride to an eq. amount of trisodium imidosulphonate; on cooling, the double salt separates in prismatic crystals which can be recrystallized from water. The salt is sparingly soluble in cold water, and absorbs carbon dioxide from the atm. Remembering the uncertainty in the relative positions of sodium and calcium in the mol., the graphic formula can be written:

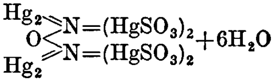


$$Ca<\begin{array}{l}SO_3{-}N<SO_3.Na\\ \qquad\qquad >Ca\\ SO_3{-}N<SO_3.Na\end{array}$$

According to E. Divers and T. Haga, E. Berglund seems to have made a mistake with respect to the strontium imidosulphonate similar to that he made with the normal calcium salt. They obtained **tristrontium imidodisulphonate,** $Sr\{NSr(SO_3)_2\}_2.12H_2O$, by dissolving the strontium sodium salt in dil. hydrochloric acid and filtering the soln. into a warm conc. soln. of strontium hydroxide, repeating the operation twice or until all the sodium is removed. The soln. deposits thin scaly crystals which can be dried on a porous tile. When freshly prepared the salt is a dodecahydrate, but after two weeks' exposure, it forms a heptahydrate. The strontium salt is more soluble than the barium salt, and is fairly soluble in hot water. When an ammoniacal soln. of the diammonium salt is mixed with a slight excess of a conc. soln. of strontium chloride, mixed with an excess of conc. aq. ammonia, and the soln. allowed to evaporate in a desiccator over potassium carbonate, a white powder is formed which is the normal tristrontium salt with a slight quantity of ammonia in addition, and not *ammonium strontium imidosulphonate.* If the normal strontium salt is boiled with water, a basic salt can be formed, **tristrontium trihydroxyimidodisulphonate,** $(SrOH)N\{(SrOH)SO_2\}_2.5H_2O$. E. Berglund made **strontium hydroimidodisulphonate,** $NHSr(SO_3)_2.nH_2O$, by a method analogous to that employed for the calcium salt, but found the product so soluble, and so difficult to crystallize, that he did not examine it further. E. Divers and T. Haga prepared **sodium strontium imidodisulphonate,** $NaNSr(SO_3)_2.3H_2O$, by mixing moderately conc. soln. of strontium chloride and the trisodium salt in the molar proportions 3 : 2. The precipitate first formed dissolves on shaking, and the soln. deposits small prismatic crystals of the double salt which is sparingly soluble in water, and which resembles the corresponding calcium salt. E. Berglund mixed soln. of strontium chloride and the tripotassium salt, and obtained a granular mass of **potassium strontium imidodisulphonate**; his analyses calculated by E. Divers and T. Haga agree with $Sr_{12}K_8H(NS_2O_6)_{11}.3H_2O$. The salt was probably impure.

The reports of M. Woronin, and V. A. Jacquelain on barium imidosulphonates refer in both cases to double salts. E. Berglund first made **tribarium imidodisulphonate,** $Ba\{NBa(SO_3)_2\}_2.5H_2O$. It was also prepared by E. Divers and T. Haga as a voluminous, coherent precipitate when the trisodium salt is gradually added to an excess of a soln. of barium chloride. The washed precipitate is dried on a porous tile in thin layers exposed to air. It is difficult to remove adherent water. The water is lost very slowly at 115°. Under the microscope, the white powder appears to consist of long, slender, interlacing needles. The salt is only slightly soluble in water, just enough to make the water give a slight opalescence with sulphuric acid. The soln. is alkaline to litmus, and is decomposed by alkali carbonates. The salt is soluble in dil. nitric acid, and reprecipitated from the soln. by barium hydroxide. This property enables the product to be purified from sodium salts. V. A. Jacquelain, E. Berglund, and E. Divers and T. Haga prepared **barium hydroimidodisulphonate,** $NHBa(SO_3)_2.H_2O$, by adding cautiously to the tribarium salt a little less than one-third the eq. of sulphuric acid; and evaporating the clear soln. in a desiccator. The minute, rhombic crystals are moderately soluble in water. The soln. is acid to litmus, but neutral to methyl orange. The salt is stable in a desiccator in a dry atm., but it soon hydrolyzes in ordinary air at 140°. If rapidly heated it decomposes suddenly, giving a cloud of barium sulphate. When treated with ammonia, the insoluble tribarium salt and ammonium imidosulphonate are formed. M. Woronin prepared this salt, but he assigned to it a mol of water more, and called it *barium sulphamate*, $Ba(H_2NSO_3)_2$, which is the same as $BaNH(SO_3)_2.H_2O$, when the water is regarded as constitutional. V. A. Jacquelain, M. Woronin, and E. Berglund made impure **ammonium barium imidodisulphonate**; and E. Divers and T. Haga added that the gelatinous precipitate obtained by treating the diammonium salt with barium hydroxide soon becomes granular, and consists of granular crystals interspersed with slender needles of the tribarium salt in insignificant amounts. Analyses agreed with the formula $Ba_5(NH_4)_2N_4(SO_3)_8.8H_2O$. The product may be a solid soln. of $Ba_3N_2(SO_3)_4$ and $NH_4NBa(SO_3)_2$ with water of crystallization. E. Frémy, E. Berglund, and E. Divers and T. Haga prepared **potassium barium imidodisulphonate** by the action of baryta-water on the dipotassium salt. E. Berglund, and E. Divers and T. Haga made **sodium barium imidodisulphonate,** $Ba_{11}Na_8N_{10}(SO_3)_{20}.13H_2O$, which may be a solid soln. of $NaNBa(SO_3)_2$ and $Ba_3N_2(SO_3)_4$ with water of crystallization. This salt is formed as a crystalline precipitate by slowly adding a dil. soln. of the barium chloride to an excess of the trisodium salt. The salt is alkaline to litmus; very sparingly soluble in water; readily soluble in nitric or hydrochloric acid; and decomposed incompletely by ammonium carbonate. It does not lose appreciable amounts of water below 120°, but when heated quickly to a higher temp., it is dissipated in a cloud of barium sulphate.

Normal *mercurous imidosulphonate* has not been isolated. The only mercurous imidosulphate known is the basic salt prepared by E. Divers and T. Haga by adding disodium imidosulphonate to an excess of powdered mercurous nitrate which has been stirred up with water until all has passed into soln. except a little basic nitrate: $8HgNO_3+H_2O+2NH(NaSO_3)_2=\{Hg_4N(SO_3)_2\}_2O+4NaNO_3+4HNO_3$. The resulting **mercurous oxyimidosulphonate,** $\{Hg_4N(SO_3)_2\}_2O.6H_2O$, or



is white and flocculent. It loses very little weight at 100°–120°, and part of that loss is due to the volatilization of mercury, for the salt becomes grey. At a higher temp. it becomes black, and then white again; at a red-heat, the salt fuses and effervesces, evolving nitrogen, but no sulphur dioxide. The dark red liquid is mainly a mixture of mercury sulphates. This salt is more soluble in dil. nitric acid than the basic mercuric salt; conc. hydrochloric acid, even in the cold. causes the formation of some mercury and mercuric chloride, and on heating the change is complete owing to the production of amidosulphonic acid. A soln. of sodium chloride becomes alkaline owing to the formation of trisodium imidosulphonate; a cold conc. soln. of potassium iodide dissolves it, leaving half its mercury as metal; and trisodium imidosulphonate converts it into mercury and sparingly soluble disodium mercuric imidosulphonate, hence the trisodium salt is not used in the preparation of the basic mercurous salt.

Normal *mercuric imidosulphonate* has not been isolated. According to E. Berglund, and E. Divers and T. Haga, when barium mercury imidosulphonate is treated with dil. sulphuric acid, in just sufficient quantity to remove the barium, it forms barium sulphate, and *mercury hydroimidosulphonate;* the latter begins to hydrolyze at once, and the soln. becomes turbid owing to the separation of **mercuric hydroimidodioxysulphonate,** $HN(SO_3)_2Hg_3O_2$, or

$$H{-}N{<}\begin{matrix}SO_3{-}Hg{-}O\\SO_3{-}Hg{-}O\end{matrix}{>}Hg$$

E. Berglund represented the formula $Hg\{N(HgSO_3)_2O\}_2$, but E. Divers and T. Haga think there is an error due to E. Berglund's product having been contaminated with potassium salt when prepared from dipotassium mercury imidosulphonate and mercuric nitrate; E. Divers and T. Haga's product was obtained from trisodium imidosulphonate and mercuric nitrate. Conc. soln. of mercuric nitrate, even when freed as much as possible from nitric acid, dissolve potassium or sodium imidosulphonates, forming clear, stable soln.; if these soln. are heated the imidosulphonate hydrolyzes into amidosulphonate, but if diluted without heating, they deposit the mercuric hydroimidodisulphonate. The same salt is precipitated on adding a cold soln. of one part trisodium imidosulphonate to a cold soln. of 5 parts of mercuric nitrate. Precipitation of the salt begins almost at once, and is finished in a few minutes. The mother-liquor still contains much mercuric nitrate and some imidodisulphonate, besides sodium nitrate and much nitric acid. The addition of a little more trisodium salt causes scarcely any further precipitation, but a larger quantity throws down the hydroimidodioxysulphonate. The brilliant white and voluminous hydroimidoxysulphonate hydrolyzes only very slowly in its acid mother-liquor, on account of the protective action of the mercuric nitrate. It should be repeatedly washed by subsidence and decantation with an abundance of cold water, and drained till dry on a tile or filter. If less mercuric nitrate has been used, and the precipitate contains sodium (as disodium mercuric imidodioxysulphonate), this may be converted into the pure hydroimidodioxysulphonate either by digestion for a day with conc. mercuric nitrate soln. and washing, or simply by continued and thorough washing with water. If digestion with mercury nitrate soln. is adopted, the water used for the first washing must contain a little nitric acid to guard against the formation of any oxynitrate. The reaction is symbolized $3Hg(NO_3)_2+Na_3N(SO_3)_2+2H_2O=HN(SO_3)_2Hg_3O_2+3NaNO_3+3HNO_3$, and it can be regarded as involving the formation of sodium mercury imido-oxysulphonate, $NaN(SO_3)_2Hg_2O$, which reacts with the mercuric nitrate: $Hg(NO_3)_2+NaN(SO_3)_2Hg_2O+H_2O=NH(SO_3)_2Hg_3O_2+NaNO_3+HNO_3$. This salt is anhydrous; it loses 0·7–0·8 per cent. of absorbed water at about 100°; and it may be heated to 180° without change, but at dull redness it decomposes, giving off water, nitrogen, and sulphur dioxide; at the softening temp. of hard glass, it melts to a red liquid and effervesces, yielding sublimates of mercury, mercurous and mercuric sulphates, etc. Even in vacuo, the salt does not decompose completely before the mercury sulphates themselves begin to decompose. The salt reacts with sodium hydroxide and chloride, and with trisodium imidosulphonate similar to sodium mercury imidoxysulphonate (*vide infra*). E. Berglund tried to make *ammonium mercuric imidodisulphonate* by the action of ammonium sulphate on barium mercury imidosulphonate, and E. Divers and T. Haga, by the action of ammonium hydrocarbonate on calcium mercury imidosulphonate. The precipitate consisted of calcium carbonate and *calcium mercuric imidotetraoxysulphonate*, $Ca(SO_3)_2N.Hg.N(SO_3HgO)_2Hg$. The ammonium mercuric salt thus appears incapable of continued existence. There are two sodium mercury imidosulphonates —one is the normal salt, the other is basic. E. Divers and T. Haga found that unless gradually added to the soln. of the trisodium salt, mercuric nitrate causes the immediate formation of a white, flocculent, crystalline precipitate which disappears on agitation so long as there is enough sodium salt present to keep the mixture neutral; when this point is just passed, the precipitate is permanent, and consists of sodium mercuric imidodioxysulphonate, $(NaSO_3)_2N.Hg.N(SO_3HgO)_2Hg$. If the nitrate is added until neutrality is just reached, or nearly reached, the soln. soon begins to deposit small, brilliant crystals, or does so after evaporation. These crystals are **disodium mercuric imidodisulphonate,** $Hg\{N(NaSO_3)_2\}_2.5H_2O$. The salt was first prepared by E. Berglund. The addition of a soln. of the trisodium salt to one of mercuric nitrate, free from any unnecessary excess of nitric acid, produces a flocculent precipitate of mercuric hydroimidosulphonate (*vide supra*). If there is too little nitrate, some sodium mercuric imidoxysulphonate will be deposited as well. Disodium mercuric imidosulphonate forms small prisms which are permanent in air, and sparingly soluble in cold water. Four mols of water are lost at ordinary temp. in vacuo, and most of the remaining water is lost at 100°. The residue slowly increases in weight at 130°, for it reacts with atm. moisture, and becomes hydrolyzed. When heated more strongly in an open tube, it yields a sublimate consisting mainly of ammonium sulphite, along with mercury, mercurous sulphate, sulphur dioxide, and nitrogen. The residue contains mercurous, mercuric, and sodium sulphates. In vacuo, no marked change occurs even at 440°, but just below red-heat, there is a steady decomposition: $2HgN_2(NaSO_3)_4=4Na_2SO_4+HgSO_4+HgS+2SO_2+2N_2$; and on further heating, $2HgN_2(NaSO_3)_4=4Na_2SO_4+2Hg+4SO_2+2N_2$. Soln. of ordinary metallic salts form a number of complex mercuric imidosulphonates studied by E. Berglund. Thus, barium chloride forms barium mercury imidosulphonate. Sodium hydroxide precipitates mercuric oxide incompletely from the pure salt soln., but not in the presence of sodium imidosulphonate. Ammonia, and ammonium chloride give white precipitates. Mercuric oxide dissolves slightly in an aq. soln. of disodium mercury imidosulphonate rendering the soln. alkaline. Both nitric and hydrochloric acids dissolve the salt freely, but the former acid does not decompose the salt immediately, while the latter does so completely, forming mercuric sodium chloride, sodium hydrosulphate, and amidosulphonic acid.

The formation of **disodium mercuric imidodioxysulphonate,**

$$\begin{matrix}NaSO_3\\NaSO_3\end{matrix}>N-Hg-N<\begin{matrix}SO_3.Hg.O\\SO_3.Hg.O\end{matrix}>Hg.3H_2O$$

has been discussed above. Two molar proportions of the trisodium salt are used for one of mercuric nitrate. It was first made by E. Berglund. E. Divers and T. Haga represent the reaction $4Hg(NO_3)_2+2NaN(NaSO_3)_2+2H_2O=4NaNO_3+4HNO_3+Hg(OHgSO_3)_2NHgN(NaSO_3)_2$.

When the attempt was made to prepare an intermediate salt, *disodium mercuric imidoxysulphonate*, $\{HgN(SO_3Na)_2\}O$, the reaction appeared to be $6NaN(NaSO_3)_2+6Hg(NO_3)_2+4NaOH=2HgN_2(NaSO_3)_4+Hg(OHgSO_3)_2N.Hg.N(NaSO_3)_2+12NaNO_3+2H_2O$.

Disodium mercuric imidodioxysulphonate contains water of crystallization, and appears to be slightly efflorescent. Protracted washing with water decomposes it, leaving a residue of the hydroimido-dioxysulphonate: $2Hg(OHgSO_3)_2N.Hg.N(NaSO_3)_2+H_2O=2NH(SO_3HgO)_2Hg+\{HgN(NaSO_3)_2\}_2O$. A similar result is obtained by the action of a conc. soln. of mercuric nitrate. At 135°, the colour changes permanently, and at a higher temp. the salt forms a reddish-brown liquid and effervesces. The decomposition resembles closely that with the normal disodium mercury salt. Gradual heating in a current of dry air at 170° does not expel all the water, presumably owing to hydrolysis. The salt is more readily dissolved by hydrochloric acid than by nitric or sulphuric acid; the salt is decomposed at once by the hydrochloric acid as it is in the case of the normal disodium mercury salt. Sodium hydroxide forms insoluble mercuric oxide, and disodium mercuric imidosulphonate which remains dissolved. A soln. of trisodium imidosulphonate dissolves a little disodium mercuric imidodioxysulphonate. E. Berglund prepared what was probably **dipotassium mercuric imidodisulphonate,** $Hg\{N(KSO_3)_2\}_2$, and reported that it is not affected by nitric acid; but E. Divers and T. Haga found that it is thus converted into mercuric nitrate and dipotassium imidosulphonate.

E. Berglund failed to make **calcium mercuric imidosulphonate** on account of the solubility of the salt; but E. Divers and T. Haga obtained it in small prismatic crystals by dissolving mercuric oxide in a warm soln. of calcium imidosulphonate, and evaporating the filtered soln. for crystallization. When mercuric hydroimidodioxysulphonate is digested with a soln. of calcium chloride, small crystals of **calcium mercuric imidochlorosulphonate,** $(NS_2O_6Ca)_3HgCl_2.12H_2O$, were found. E. Berglund also prepared **strontium mercuric imidodisulphonate,** $N_2Hg\{(SO_3)_2Sr\}_2.5H_2O$, by treating a conc. soln. of the potassium mercuric salt with strontium nitrate. The clear crystals are microscopic needles or rhombic plates. They are more soluble in water than the potassium salt. When suspended in water, and treated with hydrogen sulphide there is formed a soln. of *strontium hydroimidosulphonate,* $\{Sr(SO_3)_2\}NH$, which decomposes when the attempt is made to isolate the salt. E. Divers and T. Haga made crystals of **barium mercuric imidodisulphonate,** $N_2Hg\{(SO_3)_2Ba\}_2$, from sodium mercuric imidosulphonate. The salt is but sparingly soluble in water. E. Berglund made the *pentahydrate* by the process used for the analogous strontium salt; and also by the action of barium nitrate on mercuric imidosulphonate. The crystals resemble those of the strontium salt. The salt is fairly stable when heated; it is almost insoluble in water. It is not attacked by dil. nitric acid, but is soluble in conc. nitric acid. Conc. hydrochloric acid dissolves it freely; and with sulphuric acid it forms mercuric imidosulphonate. E. Berglund made **magnesium mercuric imidodisulphonate,** $HgN_2\{Mg(SO_3)_2\}_2.15H_2O$, as in the case of the sodium salt using as little water as possible. The temp. during evaporation must not exceed 30°, and radiating masses of crystals are formed. The salt is unstable, and cannot be crystallized without decomposition; it decomposes below 100°, passing into a sulphate; and it is easily soluble in water.

E. Berglund found that when potassium mercuric imidosulphonate is added to a soln. of mercurous nitrate, some mercuric hydroimidoxysulphonate is deposited only after long standing. E. Divers and T. Haga said that some nitric acid must have been present, because precipitation is immediate when that acid is absent. The composition varies within the limits expressed by *mercurosic imidoxysulphonate,* $O\{Hg''N(SO_3)_2Hg'_2\}_2.3H_2O$, and the more complex mercurosic salt:

$$O{<}\begin{matrix}Hg''{-}N{=}(SO_3)_2{=}Hg'_2\\ Hg''{-}N{=}(SO_3)_2{=}Hg'_2\end{matrix} + O{<}\begin{matrix}Hg''{-}N(SO_3)_2Hg'_2\\ Hg'_2{-}N(SO_3)_2Hg'_2\end{matrix}+6H_2O$$

The former is produced by adding disodium mercuric imidosulphonate to half its weight of normal mercurous nitrate; and the latter by using these two components in the proportion 2 : 5.

V. A. Jacquelain, and E. Berglund used a lead imidosulphonate in order to prepare the acid. E. Divers and T. Haga could not prepare the normal salt *trilead* *imidosulphonate*, $Pb_3N_2(SO_3)_4$. The first addition of lead acetate or nitrate to a soln. of trisodium imidosulphonate gives a basic salt; and when the basic salt is treated with a little nitric acid, most of it passes into soln., while the undissolved part remains unchanged. If one of the basic salts of lead imidosulphonate be treated with less than sufficient dil. sulphuric acid to make **lead hydroimidodisulphonate,** $HN(SO_3)_2Pb$, the clear decanted soln. contains this salt in soln., but attempts to isolate it lead to its decomposition. This unstable soln. was also made by E. Berglund. According to E. Divers and T. Haga, in the absence of acetates, the soln. can be preserved for only a short time; in a desiccator, the soln. decomposes into amidosulphonic acid and lead sulphate—slowly at first, but rapidly as the liquid becomes conc. A similar change occurs when the soln. is heated. The soln. is slightly acid to litmus, and it produces with alcohol a voluminous precipitate, which gradually becomes crystalline, and which appears to be lead sulphate.

According to E. Divers and T. Haga, if lead nitrate and trisodium imidosulphonate in soln. are mixed in widely varying proportions, **lead trihydroxyimidodisulphonate,** $HOPb.N(SO_3PbOH)_2$, is precipitated: $3Pb(NO_3)_2+3H_2O+4Na_3N(SO_3)_2=(HOPb)_3N(SO_3)_2+3HN(SO_3Na)_2+6NaNO_3$. The voluminous precipitate soon becomes dense and granular. The results are not so satisfactory with lead acetate in place of the nitrate. The disodium salt which is formed reacts with the excess of lead acetate: $3Pb(C_2H_3O_2)_2+3H_2O+HN(NaSO_3)_2=(PbOH)_3N(SO_3)_2+2NaC_2H_3O_2+4C_2H_4O_2$. The acetic acid so generated acts in reversing the reaction. This salt was also prepared by E. Berglund, and E. Divers and T. Haga said that it can be prepared in a high degree of purity by treating lead pentahydroxyimidosulphonate with but a little more nitric acid than is needed to remove the excess of lead. The reaction is said to occur in two stages: $(PbOH)_3N(SO_3)_2Pb(OH)_2+6HNO_3=HNPb(SO_3)_2+5H_2O+3Pb(NO_3)_2$; and the soln. then reacts with more of the basic salt: $2(PbOH)_3N(SO_3)_2Pb(OH)_2+HNPb(SO_3)_2=H_2O+3(PbOH)_3N(SO_3)_2$. The trihydroxyimidosulphonate has also been made by the action of disodium imidosulphonate on lead pentahydroxyimidosulphonate. The trihydroxyimidosulphonate forms microscopic, prismatic crystals which are anhydrous; they lose nothing at 100°; are insoluble in water; and give but a slight alkaline reaction in contact with moist litmus paper. E. Divers and T. Haga reported **lead pentahydroxyimidodisulphonate,** $Pb_4(OH)_5N(SO_3)_2$, or

$$HO—N\lessdot\begin{matrix}(SO_3PbOH)_2\\(PbOH)_2\end{matrix}$$

to be formed by adding trisodium imidosulphonate to a large excess of basic lead acetate: $Na_3N(SO_3)_2+5(HO)Pb(C_2H_3O_2)=3NaC_2H_3O_2+Pb(C_2H_3O_2)_2+(PbOH)_3N(SO_3)_2Pb(OH)_2$. This salt was made by E. Berglund by gradually adding aq. ammonia to a mixed soln. of the diammonium salt and lead acetate so long as the amorphous precipitate first produced gives place to a crystalline one. When the amorphous precipitate no longer changes, acetic acid is added until nothing but a crystalline precipitate is present. E. Berglund said that the precipitate has a variable composition; E. Divers and T. Haga found their product has a uniform composition. The precipitate is insoluble in water, readily soluble in dil. nitric acid (*vide supra*), has scarcely any action on moist red litmus; it is insoluble in soln. of the parent salts; it does not lose water at 130°, but at higher temp. it decomposes: $3(OH)_5Pb_4N(SO_3)_2=6PbO+3PbSO_3+3PbSO_4+NH_3+N_2+6H_2O$. The mass then blackens through the conversion of the lead sulphite to sulphate and to lead oxide and sulphur dioxide.

F. Ephraim and W. Flügel prepared sparingly soluble **cobalt hexammino-imidodisulphonate,** $[Co(NH_3)_6]_2.\{NH(SO_3)_2\}_3$; **cobalt aquopentamminoimidodisulphonate,** $[Co(NH_3)_5(H_2O)]_2\{NH(SO_3)_2\}_3$; and **cobalt nitritopentamminoimidodisulphonate,** $[Co(NH_3)_5(H_2O)]NH(SO_3)_2$.

H. Kirmreuther prepared **tetrapotassium trans-dichlorodiimidodisulphonatoplatinite,** $[Cl_2Pt(NH.SO_3)_2]K_4$, by dissolving potassium trans-dichloroimidosulphonatoplatinite in potassium hydroxide, and precipitating the soln. with alcohol. The yellow radiating clusters of prisms form a strongly alkaline soln. with water.

§ 54. Thionyl and Sulphuryl Amides, Imides, and Hydrazides

H. Schiff[1] thought that he had made **thionyl amide**, $SO(NH_2)_2$, by the action of thionyl chloride on ammonia, but A. Michaelis showed that the yellow product so obtained was only a mixture of nitrogen sulphide, and ammonium tri- and tetra-thionates. A. Mente obtained a similar product by the action of ammonium carbonate on thionyl chloride.

According to W. Traube,[2] when sulphuryl chloride in chloroform soln. is treated with ammonia, there is formed (i) sulphuryl amide, $SO_2Cl_2+4NH_3=2NH_4Cl+SO_2(NH_2)_2$; (ii) sulphuryl imide, $SO_2Cl_2+3NH_3=2NH_4Cl+SO_2(NH)$; and (iii) probably imidosulphuryl amide, $2SO_2Cl_2+7NH_3=4NH_4Cl+NH(SO_2.NH_2)_2$, because ammonium imidosulphonate was present in an aq. soln. of the products of the reaction. A. Hantzsch and co-workers also obtained several by-products when ligroin was used in place of chloroform as solvent. H. V. Regnault prepared **sulphuryl amide**, or *sulphamide*, $SO_2(NH_2)_2$, admixed with ammonium chloride, by the action of dry ammonia on a mixture of sulphuryl chloride and ethylene chloride in the cold. W. Traube recommended the following mode of preparation:

Well-cooled sulphuryl chloride, diluted with 15–20 vols. of chloroform, is sat. with dry ammonia, the precipitated product dissolved in water, the soln. acidified with nitric acid, and the whole of the chlorine precipitated with silver nitrate; the filtered soln. is neutralized with alkali, treated with silver nitrate, and the crystalline precipitate, which consists of silver sulphimide and some other silver derivative, separated by filtration. After adding a further quantity of silver nitrate, the clear soln. is treated with alkali, when silver sulphamide is obtained as a colourless, amorphous precipitate, which, however, is invariably mixed with some other silver compound, probably the same as that present in the silver sulphimide precipitate. In order to remove this impurity, the well-washed precipitate is treated with hydrochloric acid in quantity exactly sufficient to convert the silver into chloride, and the strongly acid soln. is neutralized with ammonia and mixed with silver nitrate, when only the silver compound of unknown composition is precipitated; pure silver sulphamide can now be precipitated by adding silver nitrate and excess of ammonia, and on decomposing this compound with the necessary quantity of hydrochloric acid, a neutral or feebly acid soln. of sulphamide is obtained. Sulphamide is deposited in large, colourless crystals when its aq. soln. is evaporated over sulphuric acid under reduced press.

A. Hantzsch and A. Holl recommended purifying the compound by crystallization from hot ethyl alcohol. A. Mente found it among the products of the action of ammonium carbonate on sulphuryl chloride; and F. Ephraim failed to obtain it during the action of urethane on sulphuryl chloride. E. Divers and M. Ogawa observed the formation of this compound in the spontaneous decomposition of ammonium sulphinate.

The ammonium sulphinate is prepared as indicated in connection with that salt, and, without removing the product from the flask in which it was made, a slow current of hydrogen was passed through the flask while immersed in a water-bath and gradually warmed to 70°. This temp. is maintained for 6–7 hrs. so as to drive off all the ammonia. The sulphuryl amide is formed at 30°–35°, and the higher temp. is used to destroy the thionic compounds as much as possible. If the temp. exceeds 70°, the sulphuryl amide is decomposed. The products of the reaction are then dissolved in enough ice-cold water to dissolve everything except the sulphur; and conc. barium hydroxide is added to the unfiltered soln. This precipitates the sulphates, imidosulphinates, and thiosulphates. The filtrate, which is more or less turbid, is treated with silver nitrate until precipitation no longer obtains. The filtrate is neutralized with ammonia, and the small precipitate removed. The filtrate contains sulphuryl amide and ammonium amidosulphonate. The former is precipitated by the addition of ammonia and silver nitrate, and the silver sulphamide treated as in W. Traube's process—*vide supra.*

F. Ephraim and M. Gurewitsch said that sulphamide of a high degree of purity is made by dissolving the product of the reaction between sulphuryl chloride and liquid ammonia in a small quantity of water and making the soln. just acid. After two or three days the hydrolysis is complete, the mixture is evaporated to dryness in a vacuum, and the residue extracted with ethyl acetate, which dissolves out the sulphamide, amidosulphonic acid and ammonium chloride being insoluble. After evaporating off the ethyl acetate, pure sulphamide, m.p. 93°, is left.

The colourless, rhombic, tabular crystals are quite tasteless and leave a cooling sensation on the tongue. W. Traube said that they sinter at 75°, and melt at 81°, while A. Hantzsch and A. Holl gave 91·5°, and F. Ephraim and M. Gurewitsch, 93°, for the m.p. W. Traube said that when heated above the m.p., sulphuryl amide begins to give off ammonia, and it decomposes completely with the evolution of acid vapours when heated above 250°. A. Hantzsch and B. C. Stuer found that when heated above its m.p., it forms sulphuryl imidodiamide, and not trisulphuryl imide. A. Hantzsch and A. Holl said that sulphuryl amide is not an electrolyte, and its aq. soln. conducts very badly. The lowering of the f.p. of water by sulphuryl amide agrees with the mol. wt. 96·8—theory for $SO_2(NH_2)_2$ requires 96·2. The compound is therefore unimolecular and built on the carbamide type. W. Sarow found the mol. electrical conductivity, μ, of a mol of sulphuryl amide in v litres of water at 25° to be:

v . . .	32	64	128	256	512	1024
μ . . .	17·0	18·8	20·1	21·1	22·9	30·2

He also measured the conductivity in soln. of hydrochloric acid, sodium hydroxide, and aq. ammonia, and inferred that the sulphuryl amide has the character of an acid—*vide supra,* amidosulphinic acid. Sulphuryl amide has a neutral reaction. It is readily soluble in water. Boiling acids decompose it, forming sulphuric acid and ammonia; but when treated with alkali-lye, amidosulphonic acid. It is decomposed by nitrous acid in the cold, forming sulphuric acid. E. C. Franklin and O. F. Stafford said that sulphuryl amide rapidly absorbs gaseous ammonia, and readily dissolves in liquid ammonia. The soln. so formed yields two potassium salts when treated with potassium. According to F. Ephraim and E. Lasocky, sulphamide readily dissolves in cold, conc. nitric acid, of sp. gr. 1·48, without being decomposed or nitrated. Nitration takes place immediately, however, if conc. sulphuric acid is added to the soln., the nitrito-compound thus formed precipitating in the solid form. It is necessary to avoid any rise in temp. during the reaction and to work with a small quantity only, since the **nitritosulphamide,** $NH_2.SO_2.NH(NO_2)$, formed very readily decomposes with explosive violence when present in large quantity. When dry, it is much more stable than when moist. As so prepared, it is fairly pure, and it may be further purified from ether. When heated carefully, it decomposes quietly at 95°–96°, but ordinarily it decomposes with a slight puff, without detonation, white vapours being evolved. The formula is confirmed by the analysis of the **silver nitritosulphamide,** $NHAg.SO_2.NAg.NO_2$, which is obtained as a flocculent, white precipitate when silver nitrate is added to the aq. soln. of the nitritosulphamide, and then ammonia until the precipitate no longer increases in vol. Hydrogen is evolved when zinc dust is added to the aq. soln. of nitrosulphamide, the zinc salt being formed. If the soln. is then acidified with sulphuric acid, complete reduction to **hydrazinesulphamide,** $NH_2.SO_2.NH.NH_2$, occurs. The reaction does not stop at this point, but proceeds further, forming amidosulphonic acid, and hydrazinosulphonic acid—*vide infra*—or their zinc salts. The zinc salt of the latter is much more soluble than the zinc salts of the former. If the nitric acid soln. of sulphamide is well cooled, the addition of a few drops of sulphuric acid may give a white, deliquescent precipitate, which is probably a **nitratosulphamide.** W. Traube found that the compound is insoluble in ethyl alcohol, ether, and some other organic liquids; but it is perceptibly soluble in cold and readily soluble in hot methyl or ethyl alcohol.

W. Traube and E. Reubke found that sulphuryl amide dissolves 1·4 mol. proportions of ammonia at 20°; 3·0, at 0°; and 5·4 at −20°. The product has an electrical conductivity 150 times that of a 4*N*-aq. soln. of sulphuryl amide; and the conductivity is 25 times that of a 4*N*-soln. of ammonia alone. It is therefore assumed that sulphuryl amide can exist in an *aci*-form:

$$SO_2{<}{}^{NH_2}_{NH_2} \rightleftharpoons H{-}N{=}SO{<}{}^{OH}_{NH_2}$$

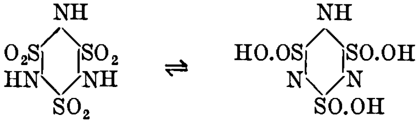
Sulphuryl amide. Sulphamidic acid.

as in the case of carbamide. **Sodium sulphamidate,** $HN : SO(NH_2)ONa$; **lithium, potassium, barium, and calcium sulphamidates** were prepared in colourless, non-hygroscopic crystals. Similarly, **copper tetramminosulphamidate,** $\{HN : SO(NH_2)O\}_2Cu.4NH_3$; and **copper ethylenediaminosulphamidate** were obtained as blue crystals. They also prepared *benzylidene sulphamide,* $NH_2.SO_2.N : CH.C_6H_5$.

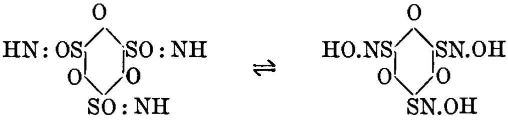
F. Ephraim and M. Gurewitsch made **amidosulphuryl chloride,** or **sulphuryl chloroamide,** $Cl\,SO_2.NH_2$, by the action of thionyl chloride on amidosulphonic acid—*vide supra;* they also found that amidosulphonic acid and phosphorus pentachloride, in the proportion of 1 : 5 by weight, readily interacted at 70-90°. After filtering the olive-green liquid so obtained through glass wool, it was distilled on the water-bath under diminished press. Phosphoryl chloride and phosphorus trichloride passed over, leaving a viscous, dark brown liquid, which deposited white crystals (m.p. 33°–34°)—after a long time at 0°. W. Traube and E. Reubke obtained it by the action of hypochlorous acid on sulphuryl amide, and gave its m.p. as 66° without decomposition. The analytical results were only in approximate agreement with the formula $NH_2.SO_2.Cl.PCl_3$, **amidosulphuryl phosphorous tetrachloride.** The compound is very sensitive to water vapour, hydrogen chloride, phosphorous acid, and amidosulphonic acid being formed. Boiling sodium hydroxide does not liberate ammonia, which is only produced on prolonged heating with fuming hydrochloric acid in a sealed tube. All attempts to decompose it into its components were unsuccessful.

W. Traube prepared **silver sulphamide,** $SO_2(NHAg)_2$, by digesting sulphuryl amide with ammonia and silver nitrate. The compound was also prepared by E. Divers and M. Ogawa, and A. Hantzsch and A. Holl. F. Ephraim and M. Gurewitsch found that dimethyl sulphate and ammonia, instead of giving sulphuryl amide, formed methylamine and ammonium methyl sulphate. They found that silver sulphimidodiamide is readily transformed with silver sulphamide by soln. in dil. acid, and precipitation from the warm soln. by ammonia: $NH(SO_2.NH_2)_2+H_2O=NH_2(HSO_3)+SO_2(NH_2)_2$. If ammonium chlorosulphonate be treated with liquid ammonia; and the residue after the evaporation of the ammonia be acidified with nitric acid; treated with silver nitrate; and the filtrate fractionally precipitated with ammonia, hot soln. yield silver sulphamide, and cold soln. silver sulphimidoamide. It is a colourless, amorphous powder, only slightly sensitive to light; it has an alkaline reaction, and dissolves freely in nitric acid and ammonium carbonate, but is sparingly soluble in cold water. It loses ammonia when heated, and decomposes completely at about 200° with evolution of sulphurous anhydride; it reacts with alkyl iodides and with acid chlorides, and its aq. soln. gives precipitates with mercuric nitrate—**mercury sulphamide**—and lead acetate—**lead sulphamide.** A. Hantzsch and A. Holl found that it is insoluble in pyridine, and forms unsymmetrical *dimethyl sulphamide* when treated with methyl iodide; W. Sarow also prepared a number of sulphamides.

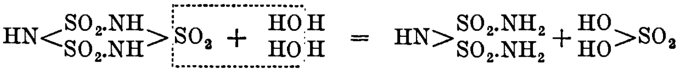
W. Traube described the formation of what he called *sulphimide*, along with ammonia and imidosulphonic acid, when sulphamide is heated at 200°–210°. The solid product is treated with water, the soln. mixed with silver nitrate, and the precipitated silver sulphimide, purified by recrystallization, is decomposed with dil. hydrochloric acid. The aq. soln. decomposes when the attempt is made to isolate the solid, for when the soln. is evaporated below 40°, only ammonium hydrosulphate remains. A. Hantzsch and A. Holl found the soln. in ethyl acetate has properties in accord with the trimolecular formula **sulphuryl triimide**, or *trisulphimide*, $(SO_2.NH)_3$—*e.g.* ebulliscopic determinations of the mol. wt.; and the electrical conductivities of the aq. soln. of trisulphimide and its salts. They were able to isolate a crystalline solid by crystallization from ethyl alcohol which they considered to be trisulphimide itself. A. Hantzsch and B. C. Stuer, however, showed that the alleged compound is extremely unstable, and that the soln. obtained by W. Traube, and the solid obtained by A. Hantzsch and A. Holl, was really sulphuryl imidodiamide, only indications of the transient formation of trisulphimide in non-aqueous solvents were obtained. Trisulphimide acts as an acid, and a few salts have been reported. A. Hantzsch and B. C. Stuer consider that the compound has tautomeric forms—a true imide and an acid:



analogous with cyanuric acid. Trisulphimide may possibly be constituted on the cyamelide type, with the tautomeric forms:



The resolution of sulphimide into the imidoamide and sulphuric acid is symbolized



$$HN{<}\begin{matrix}SO_2.NH\\SO_2.NH\end{matrix}{>}\boxed{SO_2+\begin{matrix}HO\,H\\HO\,H\end{matrix}}=HN{>}\begin{matrix}SO_2.NH_2\\SO_2.NH_2\end{matrix}+\begin{matrix}HO\\HO\end{matrix}{>}SO_2$$

A. Hantzsch and B. C. Stuer reported **ammonium trisulphimide,** $(SO_2.N.NH_4)_3$, to be formed by passing ammonia into a soln. of the acid in acetic ether. The salt reported by W. Traube by the action of ammonia on sulphimide must have been the sulphimidodiamide. Similar remarks apply to the product obtained by A. Hantzsch and A. Holl. According to A. Hantzsch and B. C. Stuer, the gelatinous substance obtained by these workers as a by-product in the preparation of sulphamide by the action of ammonia on a soln. of sulphuryl chloride in ligröin was a mixture of ammonium chloride and **ammonium sulphimide,** $(SON)_3(OHN_4)_3$, of the melide-type. The mixture is difficult to separate. The product is soluble in dil. acids from which it is precipitated by alkali; the acid soln. is gradually decomposed by water. The salt is completely decomposed by heating it with conc. hydrochloric acid in a sealed tube at 150°. According to W. Traube, when the silver derivative—*vide supra*—is treated with an eq. quantity of a hot soln. of potassium chloride, well-defined colourless crystals of **potassium sulphimide,** $SO_2 : NK$, or $(SO_2 : NK)_3$, are formed. The salt is soluble in water; the soln. has a neutral reaction and is quite stable, but it is slowly decomposed by boiling acids. The dry salt decomposes when heated, glowing vividly, and leaving a residue of potassium sulphate and sulphite with the evolution of nitrogen and sulphur dioxide. A crystalline powder of **sodium sulphimide,** say $(SO_2 : NNa)_3$, was similarly obtained. It is soluble in water, and its properties resemble those of the potassium salt. A green amorphous powder of **copper sulphimide,** say $\{(SO_2 : N)_3\}_2Cu_3$, was also prepared. W. Traube made **silver sulphimide,** SO_2NAg, as represented by A. Hantzsch and A. Holl, $(SO_2NAg)_3$, by treating a soln. of silver sulphamide with silver nitrate, and heating the precipitated salt at 170°–180° until ammonia is no longer given off. The powdered material is ground up with an indifferent substance by barium sulphate or ammonium chloride, and heated to at first between 140° and 150°, and later between 170° and 180°. The mass is extracted with hot dil. nitric acid, and on cooling, silver sulphimide is obtained in acicular crystals, which can be purified by re-crystallization from water. It is sparingly soluble in cold water, more soluble in hot water, and very soluble in water acidulated with nitric acid. It decomposes completely when heated, forming silver and silver sulphate. A. Hantzsch and A. Holl prepared complexes with pyridine, $(SO_2NAg)_3.6C_6H_5N$. W. Traube made **calcium sulphimide,** $\{(SO_2N)_3\}_2Ca_3$, soluble in water; and **barium sulphimide,** $\{(SO_2N_3\}_2Ba_3.2H_2O$, in lustrous needles, which lose water when heated. The salt is freely soluble in water, and decomposed by boiling hydrochloric acid, forming barium sulphate. Silver nitrate produces a sparingly soluble precipitate with the aq. soln. A. Hantzsch and B. C. Stuer obtained the melide-type of barium sulphimide, $\{(SO_2N)_3\}_2Ba.5H_2O$, by the action of barium chloride on the ammonium salt. W. Traube also prepared **lead sulphimide,** presumably $\{(SO_2N)_3\}_2Pb$, which crystallizes from hot dil. alcohol in long needles. A. Hantzsch and A. Holl also made *methyl sulphimide,* $(SO_2NCH_3)_3$; and *benzoyl sulphimide,* $(SO_2N.CO.C_6H_5)_3$.

A. Mente reported **sulphuryl imidodiamide,** or *sulphimidodiamide,* or *imidosulphamide,* $NH_2.SO_2.NH.SO_2.NH_2$, or $HN(SO_2.NH_2)_2$, to be formed when ammonia acts on pyrosulphuryl chloride. This has not been confirmed. The substance which A. Hantzsch and A. Holl described as trisulphimide was shown by A. Hantzsch and B. C. Stuer to be sulphuryl imidodiamide. M. Gurewitsch obtained this compound by the action of sulphuryl chloride on liquid ammonia: $2SO_2Cl_2+7NH_3=NH(SO_2.NH_2)_2+4NH_4Cl$; and likewise by the action of amidosulphuryl chloride on the same menstruum: $2(NH_2.SO_2.Cl)+3NH_3=2NH_4Cl+NH(SO_2.NH_2)_2$. In preparing sulphuryl imidoamide, A. Hantzsch and A. Holl decomposed silver trisulphimide with hydrogen sulphide and crystallized the product from methyl alcohol; and A. Hantzsch and B. C. Stuer preferred to decompose the silver compound with anhydrous hydrogen cyanide, and to use ethyl acetate as the crystallizing agent:

Fifteen to twenty c.c. of thoroughly dried hydrogen cyanide at −12° were treated with 3 to 5 grms. of dried and powdered silver trisulphimide in small quantities at a time, with frequent agitation. The filtrate was rapidly washed with hydrogen cyanide, and the solvent evaporated in vacuo. The crystalline residue, protected from the moisture of the atm., was treated with dried ethyl acetate at 50°, and the filtrate evaporated in vacuo. The residue was pressed on porous tiles to remove oleaginous matters, washed with a little ethyl acetate, and crystallized from its soln. in dried ethyl acetate. The operation should be conducted in desiccators. The yield is only 5 per cent. of the silver trisulphimide employed.

The needle-like crystals have no colour or smell, but have a strong acidic taste. They are not readily dissolved by water, they are not hygroscopic, and are fairly stable. The compound is at once decomposed by water at 0° into amidosulphonic acid and sulphuryl amide: $HN(SO_2.NH_2)_2+H_2O=SO_2(NH_2)_2+NH_2.HSO_3$. The mol. wt. determinations of the salt in aq. soln., and the electrical conductivity confirm this reaction. The electrical conductivity of aq. soln. gives values corresponding with those for amidosulphonic acid, since the sulphuryl amide also produced is not an electrolyte. The compound is insoluble in benzene, and chloroform;

sparingly soluble in ether, cold and hot ethyl acetate, and acetic acid. It is soluble in cold ethyl or methyl alcohol, and more so when heated.

Sulphuryl imidodiamide is moderately stable towards alkalies, and it acts as a monobasic acid, forming salts of the type $(NH_2.SO_2)_2NM$. It is not certain whether the metal is directly attached to the nitrogen. A. Hantzsch and B. C. Stuer found that when sulphuryl imidodiamide is mixed with finely divided glass, and exposed to dry ammonia, about 20 per cent. of gas is absorbed; if the product be kept in a desiccator until its weight is constant, **ammonium sulphimidodiamide,** $(NH_2.SO_2)_2N(NH_4)$, is formed. The same salt is produced when a soln. of sulphuryl imidodiamide in liquid ammonia is evaporated in vacuo. Its m.p. is 117°. When sulphuryl imidodiamide is gradually added towards an excess of an aq. soln. of potassium hydroxide, the **potassium sulphimidodiamide,** $(NH_2.SO_2)NK$, first formed gradually decomposes—one-third of the total nitrogen being evolved as ammonia, and an amidosulphonate is formed: $H_2O+KOH+(SO_2.NH_2)_2NK \rightarrow NH_3+2K(NH_2SO_3)$. Hence, alkali-lye does not hydrolyze sulphuryl imidodiamide to ammonium imidosulphonate as supposed by A. Mente. There are similar indications of the formation of *barium sulphimidodiamide*, by the action of baryta-water. It was also found that **silver imidodiamide,** $(NH_2.SO_2)_2NAg.1\frac{1}{2}H_2O$, obtained by adding sulphuryl imidodiamide, to an excess of silver carbonate or of silver oxide suspended in water, is not acted on by cold conc. aq. potassium hydroxide with the formation of ammonia; it separates from a mixture of ether and pyridine in stellate crystals. When acted on by acids, it forms mol. proportions of amidosulphonic acid and sulphonamide. It is formed in small amount during the preparation of silver trisulphimide. It is sometimes formed in rhombohedra. F. Ephraim and M. Gurewitsch found that silver sulphimidodiamide is obtained from ammonium chlorosulphonate as indicated above. When sulphuryl chloride is added drop by drop to liquid ammonia cooled by an ether-solid carbon dioxide freezing mixture, there is a violent reaction according to the equation: $2SO_2Cl_2+7NH_3 = NH(SO_2.NH_2)_2+4NH_4Cl$. No trisulphimide is formed, and, after evaporating off the excess of ammonia, silver imidosulphamide may be obtained from the residue in a manner similar to that already described. It is always contaminated with silver sulphamide, the sulphamide being formed from the sulphuryl imidodiamide according to the equation: $NH(SO_2.NH_2)_2+H_2O = NH_2.SO_3H+SO_2(NH_2)_2$. In fact, silver sulphimidodiamide may be readily transformed into silver sulphamide by soln. in dil. acid and precipitation from the warm soln. by ammonia. Pure silver sulphimidodiamide was prepared by extracting the product of the reaction between sulphuryl chloride and liquid ammonia with ethyl acetate in order to remove the sulphamide, and then working up the residue at the ordinary temp. to silver sulphimidodiamide in the manner already indicated.

Instead of working with an excess of sulphuryl chloride, F. Ephraim and F. Michel worked with an excess of ammonia, adding a soln. of sulphuryl chloride in ligröin to a soln. of ammonia in the same solvent, while a current of ammonia gas is passing so as to keep the ammonia in excess. The products of the reaction are different in this case; very little sulphuryl amide, or trisulphimide is formed. The chief products are sulphuryl imidoamide, and long chain products involving four SO_2-groups—*e.g.* $NH_2.SO_2.NH.SO_2.NH.SO_2.NH.SO_2.NH_2$—and these form sulphuryl imide only by secondary reactions. The different substances were isolated as silver salts. The product of reaction in the light petroleum was dissolved in water, and the soln. digested with freshly precipitated lead hydroxide to remove the ammonium chloride. After cooling and filtering, the filtrate was acidified with nitric acid, and the remaining chlorine precipitated with silver nitrate. After collecting the silver chloride, the filtrate was fractionally precipitated by ammonia. The first fraction was obtained by adding ammonia until the white, flocculent precipitate began to ball together, and then stirring for some minutes. The filtrate from this reacted acid; excess of ammonia was added, and the second and chief reaction was obtained. The filtrate was again acid, and gave a further precipitate of unimpure product (not further investigated) on neutralizing with ammonia. The silver salts were all amorphous, and contained irregularly varying amounts of water; they were very difficult to purify.

The first fraction furnished a white powder only slightly affected by light; and it corresponded with $Ag_2N.SO_2.NAgSO_2.NHSO_2.NAg.SO_2.NAg_2$, *i.e. hexasilver tetrasulphuryltrimidodiamide*, or $Ag_2N.SO_2.NH.SO_2.N(SO_2.NAg)_2$. The first fraction contained what was considered to be an equimolar mixture of silver sulphamide, and silver sulphimidamide. It gives an addition product with pyridine. By fractionation still more, the salts $(SO_2)_4N_5Ag_8H.2H_2O$, or $Ag_2N.SO_2.NAg.SO_2.NH.SO_2.NAg.SO_2.NAg_2$, *hexasilver tetrasulphuryltriimidodiamide*; $(SO_2)_4N_5Ag_78H_2O$, or $Ag_2N.SO_2.NAg.SO_2.NAgSO_2.NAg.SO_2.NAg_2$, *heptasilver tetrasulphuryltriimidodiamide*, $(SO_2)_3N_5H_6Ag_3.5\frac{1}{2}H_2O$, or $AgNH.SO_2.NAg.SO_2.NAg.SO_2.NH(NH_4)$, *ammonium trisilver trisulphuryldiimidodiamide*; and $(SO_2)_4N_7Ag_5H_8.4H_2O$, which may be a mixture of silver sulphamide and sulphimidamide, or $(NH_4)NAg.SO_2.NAg.SO_2.NAg.SO_2.NAg.SO_2.NAg(NH_4)$, *i.e. diammonium pentasilver tetrasulphuryltrimidodiamide.*

F. Ephraim and E. Lasocky found that sulphuryl chloride reacts with hydrazinecarboxylic acid, or preferably with hydrazine hydrazinecarboxylate, according to the equation: $SO_2Cl_2+2NH_2.NH.CO_2H,N_2H_4=SO_2(NH.NH_2)_2+2N_2H_4,HCl+2CO_2$, forming **sulphuryl hydrazide**, $SO_2(NH.NH_2)_2$. The hydrazine hydrazinecarboxylate is suspended in light petroleum or carbon tetrachloride, and the sulphuryl chloride gradually added, the mass obtained being well kneaded in order for the reaction to become complete. It was not found possible to obtain the pure sulpho-hydrazide, owing to the difficulty of separation from the accompanying hydrazine hydrochloride, but the **hydrazine sulphurylhydrazide**, $SO_2\{N(N_2H_5.NH_2)\}_2$, was obtained from the reaction product as follows: The reaction product was dissolved in water, and the soln. digested at 50° with freshly precipitated and washed lead hydroxide for several hours. The suspension of lead hydroxide is alkaline enough to prevent the decomposition of the sulphohydrazide, which is very sensitive towards acids. On evaporating the filtrate in vacuo an uncrystallizable syrup was obtained. The compound is stable in neutral or alkaline soln., but it readily decomposes in the presence of acids. It gives no precipitate with the salts of the heavy metals, except mercury. When the soln. is evaporated with lead nitrate ($\frac{1}{2}$ mol) a syrupy residue is left, from which hydrazine nitrate may be crystallized out by inoculation, leaving an oil corresponding with the formula of **lead hydrazine sulphurylhydrazide**, $Pb\{N(NH_2).SO_2.N(N_2H_5).NH_2\}_2$. A crystalline benzoyl derivative, **sodium dibenzoyl sulphurylhydrazide**, $SO_2(NNa.NHBz)_2$, was obtained by the action of benzoyl chloride on the alkaline soln. of hydrazine sulphohydrazide.

§ 55. Nitrosulphinic and Nitrilosulphonic Acids and their Salts

A. Claus[1] assumed that a series of substitution products are obtained in which the nitrogen is quinquevalent, thus, $N(HSO_3)_5$, *pentasulphammonic acid*; $NH(HSO_3)_4$, *tetrasulphammonic acid;* $NH_2(HSO_3)_3$, *trisulphammonic acid*; $NH_3(HSO_3)_2$, *disulphammonic acid;* and $NH_4(HSO_3)$, *monosulphammonic acid.* There is, however, very little support for the hypothesis, the first member is not known; the representative of the second member is based on what is now considered to have been a mixed product; the representative of the third member is dubious; the term disulphammic acid was applied to imidosulphonic acid which is now considered to have the constitution $H.N:(HSO_3)_2$; and the last member is represented by ammonium hydrosulphite, $(NH_4)(HSO_3)$. The replacement of the third hydrogen atom of ammonia by the sulphinic and sulphonic acid radicles furnishes the corresponding nitrilo-acids, in which the nitrogen nucleus is assumed to be tervalent. The first member, **nitrilosulphinic acid,** $N(HSO_2)_3$, has not been prepared. There is a possibility that H. Schumann produced **ammonium nitrilosulphinate,** $N(SO_2NH_4)_3$, with the ultimate composition $4NH_3.3SO_2$, by boiling a soln. of amidosulphinic with carbon disulphide in a reflux condenser with the careful exclusion of moisture; ammonia is given off, and a dark red crystalline sublimate of this compound is formed. It is very hygroscopic, and is decomposed by water with the evolution of ammonia. E. Divers considers the alleged compound to be a mixture of the decomposition products of ammonium amidosulphinate (*q.v.*).

E. Divers and T. Haga [2] have shown that there is an interesting list of compounds of ammonia with sulphur trioxide, namely:

[$NH_3.3SO_3$, *i.e.* $N(HSO_3)_3$	Nitrilotrisulphonic acid]
$NH_3.2SO_3$, *i.e.* $NH(HSO_3)_2$	Imidosulphonic acid
$NH_3.SO_3$, *i.e.* $NH_2(HSO_3)$	Amidosulphonic acid
$4NH_3.3SO_3$, *i.e.* $N(NH_4SO_3)_3$	Ammonium nitrilosulphonate
$3NH_3.2SO_3$, *i.e.* $HN(NH_4SO_3)_2$	Diammonium imidosulphonate
$4NH_3.2SO_3$, *i.e.* $(NH_4)N(NH_4SO_3)_2$	Triammonium imidosulphonate
$2NH_3.SO_3$, *i.e.* $H_2N.SO_3NH_4$	Ammonium amidosulphonate

The first member of the series, **nitrilotrisulphonic acid,** $N(HSO_3)_3$, has not been isolated in the free state, although its ammonium salt is fourth on the list. The remainder can be derived from one another backwards or forwards. The **nitrilosulphonates** were discovered by E. Frémy in 1845 and called by him *sulphammonates*; in 1869, their sulphonic nature was established by A. Claus and S. Koch; and in 1875, E. Berglund demonstrated their nitrilic constitution and called them nitrilosulphonates. This was confirmed by F. Raschig in 1888. E. Divers and T. Haga called them *nitrilosulphates,* and suggested as possible names, *aminotrisulphonates,* and *trisulphamates.* E. Frémy called the acid *sulphammonic acid;* A. Claus, *trisulphammonic acid;* and A. Claus and S. Koch, *tetrasulphammonic acid.*

The nitrilosulphonates cannot be obtained by the union of ammonia and sulphur trioxide since the imidosulphonate is formed which is not resolved by heat into ammonia and nitrilosulphate. These salts are made by the sulphonation of the hydroxylamidosulphonates which E. Frémy accomplished by adding a nitrite to an excess of, say, potassium pyrosulphite when the potassium nitrilosulphonate crystallizes out, or by treating a hydroxylamidosulphonate with sulphur dioxide in presence of a base, a process which, in practice, resolves itself into treating the corresponding nitrite in this way since the hydroxylamidosulphonate is formed by the sulphonation of a nitrite. E. Frémy prepared **ammonium nitrilotrisulphonate,** $N(NH_4SO_3)_3.2H_2O$, by passing sulphur dioxide into a conc. soln. of ammonium nitrite mixed with a large excess of ammonia until an abundant precipitation of crystals occurs in the soln. kept sufficiently cool. The crystals were washed and dried. E. Frémy represented the salt as a monohydrate, but E. Divers and T. Haga showed that it is really a dihydrate; E. Frémy's crystals had lost some water in the desiccator. Ammonium nitrilosulphonate separates in minute crystals which have only a slight taste, and are somewhat sparingly soluble in water, but so much more so than the potassium salt that E. Frémy suggested that its soln. might be used as a qualitative reagent for potassium salts. It is not volatilized by heat, but is decomposed into sulphate. It is a very unstable salt, being liable in the solid state to decompose (hydrolyze) suddenly with a hissing sound, charring paper in contact with it.

E. Frémy prepared **potassium nitrilotrisulphonate,** $N(KSO_3)_3.2H_2O$, either by mixing soln. of potassium nitrite and sulphite; by rapidly passing a soln. of sulphur dioxide into a dil. soln. of potassium nitrite; or by the action of potassium sulphite on one of the other nitrosulpho-acids salts. A. Claus, and E. Divers and T. Haga showed that E. Frémy must have worked with soln. made alkaline with potassium hydroxide. A. Claus and S. Koch thus describe the process: A soln. of 100 grms. of potassium hydroxide in 200 c.c. of water is neutralized with sulphur dioxide, and mixed with 25 grms. of potassium nitrite in 10 c.c. of water. The mixture very quickly forms a mush of crystals which is allowed to stand for an hour. The alkaline liquid is warmed with the addition of water necessary for the dissolution of the crystals, and allowed to cool. A. Claus and S. Koch believed that if the crystals are separated at once, they consist of *potassium tetrasulphammonate,* $HN(KSO_3)_4$, but this has not been confirmed, and his product is considered to be the impure nitrilotrisulphonate. The slender needles with a pearly lustre were shown by F. Raschig to belong to the rhombic system, and, according to A. Fock, have the axial ratios $a : b : c = 0{\cdot}8156 : 1 : —$. The crystals lose a part of their water over conc. sulphuric acid in vacuo, and all is lost at 100°–110°. At a higher temp., oxygen is given off as well, and potassium sulphate is formed. At a higher temp. still, E. Frémy said that sulphur dioxide, sulphuric acid, and ammonium and potassium sulphates, but no nitrogen oxides are given off. The salt in the course of a month decomposes into hydrosulphate, and imidosulphonate; but F. Raschig, and E. Frémy said that it does not appear to change when kept in an atm. of ammonia. A. Claus and S. Koch said that the salt is insoluble in cold water, and E. Frémy found that at 23°, 100 parts of water dissolve 2 parts of salt. A. Claus and S. Koch said that the salt is not affected by water at 40°, and E. Frémy crystallized the salt by cooling its aq. soln. from 40°–50°. F. Raschig showed that boiling water hydrolyzes the salt to potassium amidosulphonate, and also, if the action has been in progress only a short time, imidosulphonate. The presence of free alkali in the aq. soln. was found by A. Claus to retard the hydrolysis. Dil. acids act like water, but the salt is not decomposed by sulphur dioxide in a cold soln. According to E. Frémy, cold conc. sulphuric acid, and cold nitric acid act slowly, forming potassium and ammonium sulphates. The cold aq. soln. does not precipitate the metal salts, but with warm soln. complex, sparingly-soluble barium and lead salts may be formed. A. Claus and S. Koch said that the soln. in water at 30°–40° gives no precipitate with either baryta-water, or barium chloride; with lead acetate there is a dense, white precipitate of variable composition; mercurous nitrate soln. forms a black powder; and silver nitrate is not changed.

F. Raschig prepared an impure form of **sodium nitrilotrisulphonate,** $N(NaSO_3)_3.5H_2O$, by pouring a conc. soln. of 3 mols of sodium hydrosulphite or pyrosulphite on a mol of solid nitrite avoiding a rise of temp.: $NaNO_2+2Na_2S_2O_5=N(NaSO_3)_3+Na_2SO_3$, but the product also contained hydroxylamino-sulphate, sulphite, and unchanged nitrite were present. E. Divers and T. Haga showed that the soln. should be alkaline, and recommended the following procedure:

A soln. containing 2 mols of sodium nitrate and 3 mols of carbonate and water eq. to about twice the weight of the anhydrous carbonate, is treated with a rapid stream of sulphur dioxide while the soln. is being shaken. The flask is cooled by cold water; and owing to the temporary formation of hydrocarbonate, the shaking is maintained. The warm soln. is now at a temp. of 50°–60°, and the rate of passage of the gas is reduced as the quantity of hydrocarbonate suspended in the soln. lessens. As soon as the soln. reddens litmus, the current of gas is stopped, otherwise the nitrilosulphate will hydrolyze. During the final sulphonation crystals of the nitrilosulphonate separate; and the quantity increases as the soln. cools. It is best to work with the soln. made alkaline by a drop or two of a conc. soln. of sodium hydroxide. The mother-liquor can be evaporated over sulphuric acid for more crystals. The reaction is symbolized: $2NaNO_2+3Na_2CO_3+8SO_2=2N(NaSO_3)_3+Na_2S_2O_5+3CO_2$. The crystals are washed with a little conc. aq. ammonia, and dried on a tile. The excess of pyrosulphite beyond that shown in the equations is necessary for the prompt sulphonation. The crystals containing 21·8 per cent. H_2O lose 15·5 per cent. when dried in vacuo over sulphuric acid.

Sodium nitrilotrisulphate crystallizes in short, thick prisms which melt when heated and decompose in their water of crystallization into sulphates. A. Fock found for the hexagonal prisms the axial ratio $a : c = 1 : 1{\cdot}4413$. E. Divers and T. Haga showed that the crystals cannot be long preserved under any circumstances, soon suffering decomposition and becoming opaque and acid, even in their own liquor after it has been made alkaline. That is, the sodium salt is more unstable than the potassium salt. It is neutral to litmus, and must be soluble in about its own weight of water, to judge from the amount of it left in the mother-liquor in its preparation, although here, no doubt, the pyrosulphite also in soln. will affect its degree of solubility. F. Raschig also reported **sodium dipotassium nitrilotrisulphonate,** $N(SO_3)_3K_2Na$, to be formed by adding a soln. of potassium chloride gradually to a crude soln. of sodium nitrilosulphonate. E. Divers and T. Haga obtained the same salt, which is like the sodium salt in appearance and like the potassium salt in being nearly insoluble. According to F. Raschig, it is anhydrous, and occurs either as a sparkling sand or in hard crystals the size of pinheads and of adamantine lustre.

E. Frémy treated a soln. of barium nitrite with sulphur dioxide and obtained crystals of a salt—probably impure **barium nitrilotrisulphonate,** $\{N(SO_3)_3\}_3Ba_2.nH_2O$ —which gave off ammonia when heated, and which was too unstable to investigate further. E. Frémy also obtained a crystalline precipitate by adding ammonium nitrilosulphonate to a soln. of a barium salt. The composition approximated **ammonium barium nitrilotrisulphonate,** $N(SO_3)_3Ba(NH_4)$. It was sparingly soluble in water; **potassium barium nitrilotrisulphonate,** $N(SO_3)_3BaK.nH_2O$, was made in an analogous way. E. Divers prepared what was possibly **sodium barium nitrilotrisulphonate,** $N(SO_3)_3BaNa.nH_2O$, by adding the sodium salt to a conc. soln. of barium chloride rendered faintly alkaline with ammonia, a flocculent precipitate is obtained which becomes dense and crystalline on standing. It is sparingly soluble in water and very unstable. According to E. Frémy, impure *ammonium lead nitrilosulphonate,* and *potassium lead nitrilosulphonate* have been prepared. F. Ephraim and W. Flügel prepared sparingly soluble **cobalt hexamminonitrilotrisulphonate,** $[Co(NH_3)_6].N(SO_3)_3$; **cobalt aquopentamminonitrilotrisulphonate,** $[Co(NH_3)_5(H_2O)]N(SO_3)_3$; **cobalt cis-dinitritotetramminonitrilotrisulphonate,** $[Co(NH_3)_4(NO_2)_2]N(SO_3)_3$; and **cobalt trans-dinitritotetramminonitrilotrisulphonate,** $[Co(NH_3)_5(NO_2)_2](NSO_3)_3$.

§ 56. Hydronitrilomonosulphonic Acid and its Salts

The sulphazotized acids reported by E. Frémy in his memoir: *Sur une nouvelle série d'acides formés de oxygène, de soufre, d'hydrogène, et d'azote,* (1845), cannot all be identified; but A. Claus' memoir: *Beiträge zur Kenntniss der Schwefelstickstoffsäuren* (1871); F. Raschig's *Ueber das Verhalten der salpetrigen zur schwefligen Säure*

(1887); and E. Divers and T. Haga's *Identification and constitution of Frémy's sulphazotized salts of potassium*, agree more or less closely with the following:

E. Frémy's acids.	Possible equivalents.
Acide sulfazeux, $3SO_2.N_2O_3.3H_2O$	Hydroxynitrilodisulphonic acid
Acide sulfazique, $4SO_2.N_2O_3.3H_2O$	Hydroxynitrilodilsulphonic acid
Acide sulfazotique, $5SO_2.N_2O_3.3H_2O$	Nitritohydroxynitrilodisulphonates
Acide sulfazilique, $4SO_2.N_2O_3.H_2O$	Peroxyamidodisulphonic acid
Acide metasulfazilique, $4SO_2.2SO_3.N_2O_3.3H_2O$	Hydroxynitrilosulphonic acid
Acide sulfazidique, $SO_2.N_2O_3.3H_2O$	Hydroxynitrilomonosulphonic acid
Acide sulfammonique, $8SO_2.N_2O_3.3H_2O$	Nitrilosulphonic acid
Acide metalsulfamidique, $4SO_2.S_2O_2.N_2O_3.3H_2O$	(Transition form)
Acide sulfamidique, $2S_2O_2.N_2O_3.3H_2O$	Imidosulphonic acid

A series of acids can be derived from orthonitrous acid by the substitution of sulphinic, HSO'_2, or sulphonic, HSO'_3, radicles in place of the hydroxyl-groups. The result with the sulphonic radicles is:

$HO{-}N{<}^{OH}_{OH}$

Orthonitrous acid.

$HSO_3{-}N{<}^{OH}_{OH}$

Hydroxynitrilo-monosulphonic acid.

$HO{-}N{<}^{HSO_3}_{HSO_3}$

Hydroxynitrilodisulphonic acid.

$HSO_3{-}N{<}^{HSO_3}_{HSO_3}$

Nitrilotrisulphonic acid.

E. Divers and T. Haga [2] obtained no evidence of the existence of the second member of this series; and it was therefore suggested that the series is better regarded as being derived from hydroxylamine by the substitution of sulphonic radicles in place of hydrogen, thus:

$HO{-}N{<}^{H}_{H}$

Hydroxylamine.

$HO{-}N{<}^{HSO_3}_{H}$

Hydroxynitrilomono-sulphonic acid.

$HO{-}N{<}^{HSO_3}_{HSO_3}$

Hydroxynitrilodisulphonic acid.

$(HSO_3)O{-}N{<}^{HSO_3}_{HSO_3}$

Hydroxynitrilotrisulphonic acid.

In the case of these mono- and disulphonic acids, isomeric forms are possible.

$HO{-}N{<}^{HSO_3}_{H}$

Hydroxynitrilo-monosulphonic acid.

$(HSO_3)O.N{<}^{H}_{H}$

Hydroxynitrilo-iso-monosulphonic acid.

$HO{-}N{<}^{HSO_3}_{HSO_3}$

Hydroxynitrilodi sulphonic acid.

$(HSO_3)O{-}N{<}^{HSO_3}_{H}$

Hydroxynitrilo-iso-disulphonic acid.

According to F. Raschig, the **hydroxynitrilo-iso-monosulphonic acid** appears as a transient intermediate stage in the hydrolysis of the iso-forms of the disulphonates (*q.v.*). It differs from the ordinary form of the monosulphonates in possessing oxidizing properties—*e.g.* it liberates iodine from potassium iodide. He therefore considers this acid as the amide of Caro's acid, **amidopersulphonic acid**, $NH_2.O.HSO_3$. The disulphonic forms will be considered in the next section.

The other acid, **hydroxynitrilomonosulphonic acid**, $HO.NH.HSO_3$, was called *acide sulfazidique* by E. Frémy,[3] and *Sulfhydroxylaminsäure* by A. Claus. It is not known in the solid state; the aq. soln. are fairly stable. E. Frémy, and A. Claus obtained the soln. by decomposing the barium salt with dil. sulphuric acid. F. Raschig represented the reaction between sodium nitrite and hydrosulphite: $NaNO_2+NaHSO_3+SO_2=HO.N(NaSO_3)_2$, and when a soln. of the alkali hydroxynitrilodisulphonate is boiled it decomposes into alkali sulphate and the monosulphonic acid: $HO.N(NaSO_3)_2+H_2O=NaHSO_4+HO.NH.HSO_3$. The former can be precipitated by alcohol, and the evaporation of the filtrate gives a syrupy liquid containing the impure monosulphonic acid. F. Sommer and H. G. Templin obtained the acid of a high degree of purity by the action of chlorosulphonic acid on hydroxylamine hydrochloride at the ordinary temp. It separates from a mixture of ether and methyl alcohol in the form of a microcrystalline powder, liberates iodine from potassium iodide, and is hydrolyzed in acid soln. to hydroxylamine. A soln. of the acid is also obtained by gently warming hydroxylamine sulphate with fuming sulphuric acid. The acid can be purified by dissolving it in cold, dry methyl alcohol and precipitating it with dry chloroform. The hydrolysis of the aq. soln.

of the acid into hydroxylamine and sulphuric acid is accelerated by dil. hydrochloric acid, and by heat: $2(HO)NH(HSO_3)+2H_2O=H_2SO_4+2NH_2OH.H_2SO_4$; the change is completed after many hours' boiling a conc. aq. soln., but in the presence of hydrochloric acid, at 130°, the reaction occupies about an hour. A. Claus, and F. Raschig found the hydrolysis is very rapid in alkaline soln.: $HO.NH.KSO_3+KOH=K_2SO_4+NH_2OH$. Consequently, many of the reactions of the acid are those of hydroxylamine—*e.g.* decoloration with potassium permanganate, evolution of nitrous oxide with sodium nitrite, etc. E. Divers and T. Haga said that in an alkaline soln., the hydrolysis yields a hyponitrite, not hydroxylamine. For other properties, *vide infra* in connection with the salts. A. Angeli showed that with aldehydes, the acid splits into the sulphurous acid and the radicle NOH which immediately combines with the aldehyde to form R.COH : NOH. He therefore considers hydroxynitrilomonosulphonic acid to be related with nitrohydroxylamine, NOH : NO(OH), and he writes the formula $HO.N:SO(OH)_2$. F. Sommer and coworkers found that hydroxynitritomonosulphonic acid reacts with alcohols to form compounds of the type $RO.SO_2.OH,NH_2OH$. Aldehydes and ketones in alkaline soln. react to form salts of oxime acids, *e.g.* $CR_1R_2:NO.SO_2.OK$. On boiling with alkali, the acid is decomposed according to the equation $3NH_2O.SO_2.OH+6KOH=3K_2SO_4+6H_2O+NH_3+N_2$. The salts are very unstable and liable to explode. Many of the reactions of the acid suggest that it possesses the alternative structural formula $HN:O:SO(OH)_2$. On boiling aq. soln. of the acid with a considerable excess of ammonia, 50 per cent. yields of hydrazine are obtained. Amino-compounds yield the corresponding hydrazine derivatives. Alkaline soln. of ethylenediamine react to form *a-hydrazino-β-aminoethane*, which furnishes a number of salts. Benzylidene-hydrazino-β-aminoethane was also obtained.

According to A. P. Sabanéeff, **ammonium hydroxynitrilomonosulphonate,** $HO.NH.NH_4SO_3$, is obtained by boiling a soln. of the potassium salt for a few minutes, and adding barium hydroxide to the filtered liquid whereby barium hydroxynitrilomonosulphonate is precipitated. This salt is decomposed with ammonium sulphate. The crystals decompose on keeping. The salt is isomeric with hydroxylamine amidosulphonate, $NH_3OH.NH_2.SO_3$, and with hydrazine sulphate, $N_2H_4.H_2SO_4$. E. Frémy made **potassium hydroxynitrilomonosulphonate,** $HO.NH.KSO_3$, which he called *sulfazidate de potasse*, along with potassium hydrosulphate by boiling a soln. of the corresponding disulphonate in water, or allowing the soln. to stand for some time.

The aq. soln. of potassium hydroxynitrilodisulphonate is boiled for some minutes, neutralized with ammonia, treated with barium chloride, and filtered. The clear liquor is treated with baryta-water when barium hydroxynitrilomonosulphonate is precipitated. The product is treated with dil. sulphuric acid, and the aq. soln. of the acid neutralized with potassium hydroxide, and the soln. evaporated for crystallization.

The hexagonal plates so obtained have a neutral reaction. They decompose when heated, forming oxygen, ammonia, and potassium hydrosulphate, and the same products were reported by E. Frémy to be formed when the salt is boiled with alkali-lye, while, according to A. Claus, one-third to one-half the nitrogen is thus given off as ammonia, and the remainder as nitrous oxide. A. Claus said that the aq. soln. mixed with a cold soln. of potassium hydroxide has the characteristics of a soln. of hydroxylamine, but E. Divers and T. Haga showed that a sulphite and hyponitrite, not hydroxylamine, are produced: $HO.NH.KSO_3+2KOH=KO.NK.KSO_3+2H_2O$, followed by $2(KO.NK.KSO_3)=K_2N_2O_2+2K_2SO_3$. Ammonia is not formed, and very little sulphate or nitrogen appears. If the aq. soln. of the salt be evaporated with sodium carbonate, carbon dioxide is evolved, and sodium hyponitrite is formed. According to A. Claus, dil. acids or water decomposed the salt with prolonged boiling, the action is slow because the salt can be crystallized from boiling water, or by evaporating the aq. soln. The products of the decomposition by dil. acids are ammonia, sulphuric acid, oxygen, and nitrous oxide. E. Divers and T. Haga said that the aq. soln. reduces salts of silver and gold, while with copper salts, the decomposition can be symbolized: $2(HO.NH.KSO_3)+2CuO+2KOH=K_2SO_3+K_2SO_4+Cu_2O+N_2O+3H_2O$. E. Frémy said that the warm aq. soln. reacts with manganese dioxide giving off oxygen. The salt is not soluble in alcohol. According to F. Raschig, the salt is oxidized by iodine: $2(HO.NH.KSO_3)+2I_2+H_2O=N_2O+4HI+2KHSO_4$. The primary product of the oxidation in alkaline soln. is to form the residue, $(OH).N.KSO_3$, which, by condensation, forms $KSO_3.N(OH).N(OH).KSO_3$, a product which loses water, forming oxydiazodisulphonate:

$$O<\begin{matrix}N—KSO_3\\ \ddot{N}—KSO_3\end{matrix}$$

This is unstable and yields half its sulphur as sulphite and the remainder as a dinitrosulphonate, $K_2N_2O_2.SO_3$.

E. Frémy, and E. Divers and T. Haga prepared **sodium hydroxynitrilomonosulphonate** as a clear, gummy, viscid, neutral liquid, which did not solidify or show any signs of crystallization. E. Frémy reported **dibarium hydroxynitrilomonosulphate,** as *sulfazidate de baryte*, and A. Claus as *sulfhydroxylaminsaures Baryum*. The mode of preparation, used by E. Frémy, and by E. Divers and T. Haga, is indicated above in connection with the ammonium and potassium salts. The white crystalline precipitate is sparingly soluble in water; and the soln. has an alkaline reaction. It is soluble in hydrochloric acid, and when heated, it detonates with the production of ammonia and oxygen. E. Divers and T. Haga also made **barium hydroxynitrilomonosulphonate,** $(HO.NH.SO_3)_2Ba.H_2O$, by adding to the dibarium salt as much sulphuric acid as is necessary to precipitate half the barium as barium sulphate, and evaporating the neutral filtrate over conc. sulphuric acid. The crystals are tabular and prismatic and very soluble in water; they decompose on keeping; and when heated to 100°, decompose suddenly into gases and barium sulphate. W. Flügel prepared **cobalt hexamminodihydroxynitrilomonosulphonate,** $[Co(NH_3)_6]\{(HO)_2N(SO_3)\}_2$, freely soluble in water.

§ 57. Nitrilohydroxydisulphonic Acid and its Salts

As indicated in the preceding section, there are two isomeric forms of these acids:

$$HO—N<\begin{matrix}HSO_3\\ HSO_3\end{matrix}$$

Normal acid.

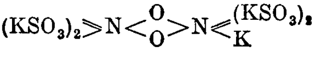
$$(HSO_3)O—N<\begin{matrix}HSO_3\\ H\end{matrix}$$

Iso-acid.

F. Raschig[1] prepared salts of what he called *hydroxylaminodisulphonic acid;* and E. Divers and T. Haga salts of what they called *oximidosulphonic acid*, which is here regarded as a nitrilosulphonic acid with one sulphonic radicle replaced by an hydroxyl-group. It is hence called **nitrilohydroxydisulphonic acid,** or **hydroxynitrilodisulphonic acid,** $N(OH)(HSO_3)_2$. E. Divers, and W. C. Reynolds and W. H. Taylor showed that the acid is formed as an intermediate stage in the reaction between nitrous and sulphurous acids because, working at 0°, if one mol. proportion of the former is mixed with two of the latter the reaction: $HNO_2+2H_2SO_3=H_2O+(HO)N(HSO_3)_2$, takes place, and if the product is neutralized and concentrated, alkali hydroxynitrilodisulphonate is formed. On the other hand, the product of the interaction of the two acids furnishes nitrous oxide if mixed with another mol of nitrous acid: $(HO)N(HSO_3)_2+HNO_2=N_2O+2H_2SO_4$—*vide infra*, nitrosyl sulphonic acid. The oxidation products of hydroxynitrilosulphonic acid in acid and alkaline soln. are the same: $2(HO)N(HSO_3)_2+O=2NO+2H_2SO_4+H_2O$, but in alkaline soln. the nitric oxide combines with the sulphite to form alkali hyponitritosulphate—*vide infra.* Hydroxynitrilodisulphonic acid itself has not been isolated, but numerous salts have been reported. In the so-called neutral salts, only the hydrogen atoms of the hydroxyl group of the acid radicle are replaced by a metal, M′, forming the series $HO.N(MSO_3)_2$; and in the so-called basic salts all the hydrogen atoms are displaced by the metal, forming $MO.N(MSO_3)_2$. There are also complex salts formed by the union of the basic and neutral salts. This makes the subject somewhat complex. The most important memoir on the subject is E. Divers and T. Haga's *Oximidosulphonates or Sulphazotates.* E. Frémy described a number of these salts, and the subject was also examined by A. Claus. F. Raschig said that hydroxynitrilodisulphonic acid in a cold acid soln. yields the monosulphonic acid; and when the alkali salt is oxidized with a dil. soln. of permanganate, what he called *sodium sulphazalinate*, $O:N:(NaSO_3)_2$, is formed, and this, when hydrolyzed with potassium hydroxide furnishes the di- and tri-sulphonates: $4NO(KSO_3)_2+KOH=KNO_2+2NO(KSO_3)_3+HO.N(KSO_3)_2$. F. Raschig said that **potassium iso-hydroxynitrilodisulphonate,** $NH(KSO_3).O.KSO_3$, is produced by the hydrolysis of the corresponding trisulphonate with a weak acid. In the presence of hydrochloric acid, the KSO_3-group attached to the nitrogen atom may be eliminated to form *iso*-hydroxynitrilomonosulphonic acid, $NH_2.O.HSO_3$. The reaction of the *iso*-disulphonate with hypochlorite is represented: $KSO_3.NH.O.KSO_3+3NaOCl+H_2O=HNO_3+2KHSO_4+3NaCl$; and with permanganate soln., the *iso*-monosulphonate is formed, then $NO.HSO_4$, and finally nitrous oxide and sulphate.

E. Divers and T. Haga prepared **triammonium hydroxynitrilodisulphonate,** $NH_4O.N(NH_4SO_3)_2$, by shaking the basic lead salt with a soln. of ammonium hydrocarbonate, or the barium salt with a soln. of normal ammonium carbonate. The salt could not be isolated, because, when the clear soln. is conc. by evaporation in air, it decomposes with the evolution of ammonia. If the soln. be mixed with conc. ammonia, and evaporated in an atm. of ammonia over potassium hydroxide, prismatic crystals form as a crust near the walls of the containing vessel. They slowly effloresce in dry air. The analytical results were not satisfactory; it is possibly a complex salt—*pentammonium hydroxybisnitrilodisulphonate*—or solid soln. of a mol each of $HO.N(SO_3NH_4)_2$ and $NH_4O.N(SO_3NH_4)_2$, If the aq. soln. of the triammonium salt be evaporated to a small volume keeping the soln. alkaline by adding a drop of ammonia from time to time, and finishing the evaporation rapidly over sulphuric acid, prismatic crystals of **diammonium hydroxynitrilodisulphonate,** $HO.N(NH_4SO_3)_2$, are formed. All three ammonium salts are decomposed when heated with the formation of ammonium hydrosulphate.

F. Raschig prepared **tripotassium hydroxynitrilodisulphonate,** $KO.N(KSO_3)_2.H_2O$, which he called *basic potassium sulphazotate*, by rapidly cooling a hot aq. soln. of the dipotassium salt and adding a cold soln. of potassium hydroxide until the liquid begins to appear turbid; or adding an excess of potassium hydroxide to a warm soln. of the pentapotassium salt, and then adding alcohol. E. Divers and T. Haga obtained the salt in an analogous way—the precipitate obtained with alcohol was the dihydrated salt. F. Raschig assumed that the salt is bimolecular and has the constitution:



$$(KSO_3)_2{\geqslant}N{<}{}^{O}_{O}{>}N{\leqslant}{}^{(KSO_3)}_{K},$$

It forms needle-like crystals, or a crystalline powder; when recrystallized from water, it forms the dipotassium salt. It decomposes when heated with explosive violence. It is freely soluble in cold water, and reacts towards salts of the heavy metals like free alkali, forming at the same time a soln. of the dipotassium salt. E. Divers and T. Haga reported a complex salt with potassium nitrite—**tripotassium nitritohydroxynitrilodisulphonate,** $2(KO)N(KSO_3)_2.KNO_2$, with $4{\cdot}4H_2O$, and $6H_2O$. The potassium metasulphazotinate of E. Frémy is supposed by F. Raschig to be the impure dipotassium salt, and by E. Divers and T. Haga to be a mixture of the normal tripotassium salt with the complex of that salt and potassium nitrite.

E. Frémy described what he called *sulfazotate de potasse basique;* A. Claus, *potassium sulphazotate;* and F. Raschig, *neutral potassium sulphazotate,* which E. Divers and T. Haga showed to be **pentapotassium hydroxybisnitrilodisulphonate,** $HO.N(KSO_3)_2.KO.N(KSO_3)_2.H_2O$. E. Divers and T. Haga showed that this is only one way of preparing this salt, namely, by dissolving the dipotassium salt in a soln. of enough potassium hydroxide or an eq. salt, and crystallizing. The dipotassium salt should not be put into cold water, or even into the alkali-lye, and then heated for its dissolution unless the mixture is continuously stirred; otherwise, undissolved salt lying on the bottom of the vessel is liable to hydrolysis. This method was used by A. Claus, and F. Raschig. In E. Frémy's process, the salt is apparently formed direct by sulphonating the nitrite, but in reality, the dipotassium salt is first formed, and then converted by the alkali-lye into the five-sixths salt. E. Frémy said the crystals are white, rhombic columns; A. Claus, rhombohedral crystals, which, when rapidly formed, furnish aggregates *en tremies.* They have an alkaline reaction and caustic taste. The crystals were said to lose no water at 120°, but E. Divers and T. Haga found that water is given off slowly at this temp., and that the water is restored by exposure to the atm. A. Claus said that the crystals can be preserved for months without change, but not if any of the dipotassium salt be present. E. Frémy showed that the crystals become matt at 140°–160°, give off red fumes, sulphur dioxide, and ammonium sulphite, leaving a residue of potassium sulphite; the salt decomposes slowly when boiled with water; and A. Claus said that it loses potassium when repeatedly crystallized from water. E. Frémy showed that the salt is not soluble in alcohol or ether; and found that red fumes are evolved when the salt is treated with nitric acid, and, added A. Claus, the whole of the sulphur is transformed into sulphuric acid. E. Frémy, and A. Claus showed that conc. sulphuric acid decomposes the salt with the evolution of nitric oxide. If the aq. soln. be warmed with silver oxide, lead dioxide, or chlorine, it acquires a violet colour, and is transformed into potassium nitroxysulphonate. A. Claus showed that one-third of the nitrogen is given off as ammonia when the salt is heated with admixed soda-lime. Almost all salts of the metals—excepting those of calcium and strontium—give precipitates of variable composition when their soln. are treated with this salt.

F. Raschig claimed to have made an isomeric form of this salt—which he called *potassium hydroxylamineisodisulphonate*—but E. Divers and T. Haga believed that the alleged isomer was a complex salt of potassium nitrite and the dipotassium salt. F. Raschig recommended the following process for making the potassium salt: sodium hydrosulphite soln. (5*N*-, 1200 c.c.) is added with continuous stirring to a mixture of ice (1000 grms.) and commercial sodium nitrite (150 grms.), whereby the temp. is not allowed to rise above 5°. One c.c. of the soln., when tested after the addition has been finished for ten minutes, should react with about 17 c.c. of 0·1*N*-iodine soln., and subsequently require 14–15 c.c. of 0·1*N*-sodium hydroxide for neutralization in the presence of methyl-orange. Any ice particles are removed and the soln. is treated whilst being vigorously shaken with lead dioxide (600 grms.). It is subsequently warmed on the water-bath, frequent agitation being required to prevent the oxidizing agent from becoming aggregated. The conclusion of the oxidation is reached when 1 c.c. of the soln. neutralizes about 9 c.c. of 0·1*N*-hydrochloric acid and subsequently does not react with more than 1 c.c. of 0·1*N*-iodine soln. The soln. is filtered and the residue washed with hot water (200 c.c.). The filtrate is warmed with commercial potassium chloride (800 grms.) until the precipitated lead chloride forms coarse particles, which are removed. The filtrate, after remaining for three days in an ice-chest, deposits potassium hydroxylaminetrisulphonate (790 grms.) in large mono-symmetric prisms. It is filtered, dried on porous earthenware, and subsequently over calcium chloride. The finely-divided, dry salt (423 grms.) is agitated with boiling water (800 c.c.) containing 1 c.c. of dil. hydrochloric acid until soln. is complete; the small amount of lead sulphate which separates is removed. The filtrate deposits potassium hydroxylamineisodisulphonate in colourless crystals, the yield being about 90 per cent. of that theoretically possible. E. Divers and T. Haga made three complex salts with potassium nitrate—pentapotassium nitritohydroxylnitrilodisulphonate—namely, $2K_5H(NS_2O_7).7KNO_2.3H_2O$; $K_5H(NS_2O_7).3K_2NO_2.H_2O$; and $3K_5H(NS_2O_7).7KNO_2$. E. Divers showed that the *sulfazinate de potasse* of E. Frémy, and A. Claus is a mixture of one of these complex salts with the tri- and di-potassium salts; and the *metasulfazate de potasse* of E. Frémy, a mixture of the tripotassium salt and one of the complex salts with potassium nitrite.

The sulfazotate de potasse neutre of E. Frémy, the *disulfhydroxyazosaures Kalium* of A. Claus, and the *potassium oximidosulphonate* of E. Divers and T. Haga, is **dipotassium hydroxynitrilodisulphonate,** $HO.N(KSO_3)_2.2H_2O$. E. Frémy prepared this salt by passing sulphur dioxide into a soln. of potassium nitrite and hydroxide. If the soln. be too conc., the tri-potassium salt is formed, in that case water is added to dissolve the salts and the current of gas continued. A. Claus always obtained some nitrilosulphonate when using this process, but by keeping the soln. cool during the passage of the gas, he obtained a soln. which gave crystals of the dipotassium salt on standing. F. Raschig did not obtain good results with this process. E. Divers and T. Haga speak very highly of this mode of preparing both the disodium and dipotassium salts. The former salt may be taken as a type for both:

Fifty grms. of sodium nitrite containing 96 per cent. $NaNO_2$ and 100 grms. of sodium carbonate (or 30·8 grms. of sodium hydroxide) are mixed with 150 c.c. of water in a 500 c.c. flask (if sodium hydroxide is used, 200 c.c. of water are needed). A piece of lacmoid paper is also placed in the flask. A rapid stream of sulphur dioxide is passed through the soln. while the containing flask is agitated, and cooled in a freezing mixture. In about 70 minutes, the soln. will be acidic to lacmoid paper. The nitrilosulphonate which is present is hydrolyzed into imidosulphonate and hydrosulphonate, and to make sure that this change is completed, the well-cooled soln. is left in its acidic condition for 10–15 minutes. The sulphur dioxide is removed by a stream of air. A conc. soln. of sodium carbonate is now added until the soln. is alkaline. This prevents the hydrolysis of the disodium salt. The soln. now contains about 150 grms. of the disodium salt, 15 grms. imidosulphonate, and 22 grms. of sodium sulphate in about 220 c.c. of water. The filtered soln. is evaporated either at a gentle heat in air, or in vacuo over sulphuric acid. When the soln. weighs about 300 grms., it is cooled in ice, and after some hours it is strained free from the crystals of sodium sulphate. When the soln. is further conc. in vacuo, a crop of crystals of the disodium salt appears, and when 90–100 grms. has separated, the soln. may be again cooled to crystallize out more sodium sulphate. Another evaporation gives another crop of crystals of the disodium salt. The salt may be recrystallized from a small quantity of hot water rendered alkaline with ammonia. The main reaction is represented $NaNO_2+NaOH+2SO_2=HO.N(NaSO_3)_2$.

F. Raschig mixed a mol of potassium nitrite dissolved in as little water as possible with a well-cooled soln. of 2 mols of potassium hydrosulphite, and added a cold sat. soln. of about 2 mols of potassium chloride. In 24 hrs., the needle-like crystals of nitrilosulphonate were separated from the crystalline crust of the nitrilodisulphonate by washing. The latter salt can be purified by crystallization from warm water rendered alkaline by ammonia or potassium hydroxide. A. Claus also made the salt by mixing 4 mols of potassium sulphite and one of potassium nitrite. The soln. is filtered from the crystals of nitrilosulphonate, and in about 10–12 hrs. it deposits crystals of dipotassium nitrilodisulphonate. He also made the same salt by crystallization from a soln. of potassium nitrosyl sulphonate in warm water.

The well-defined, colourless, prismatic crystals of dipotassium nitrilodisulphonate were found by A. Fock to belong to the monoclinic system, and to have the axial ratios $a:b:c=1·5490:1:0·9208$, and $\beta=74°$. The crystals, said E. Frémy, are neutral and nearly tasteless. A. Claus said that the crystals are stable only when in the presence of free alkali; if treated with water free from alkali, the crystals decomposed in half an hour when confined over sulphuric acid in vacuo. F. Raschig also said that the salt decomposes in a few days when confined in an atm. of ammonia, forming nitrilomonosulphonate and sulphate. The hydrolysis occurs very rapidly in acidic soln. The crystals detonate when heated rapidly to about 85°, and when slowly heated, water is given off. E. Divers and T. Haga found that when heated to 170°–180° in moist air, water is absorbed and hydrolyzes the salt. When the dehydrated crystals are heated above 100°, acid vapours are given off along with sulphur dioxides; the salt melts and forms ammonium and potassium sulphates and free sulphuric acid. Conc. nitric acid acts on the crystals, giving off red fumes and transforming the sulphur into sulphuric acid. A. Claus said that when heated with soda-lime, one-third of the total nitrogen is given off as ammonia. Barium salts with warm soln. give a precipitate of barium sulphate; while lead and silver salts give no precipitation. According to E. Divers and T. Haga, when boiled with a soln. of copper sulphate, a copper salt is formed which is partly oxidized and partly reduced, forming nitrous oxide, water, sulphuric acid, and copper sulphate. They also prepared a complex salt with potassium nitrate, **dipotassium nitratohydroxynitrilodisulphonate,** $HO.N(KSO_3)_2.KNO_3.H_2O$; with sodium chloride, **decapotassium octosodium chlorohydroxynitrilodisulphonate,** $5(HO)N(KSO_3)_2.8NaCl.3H_2O$; and with potassium nitrite, **dipotassium nitritohydroxynitrilosulphonate,** $HO.N(KSO_3)_2.KNO_2$; they say that F. Raschig's *sulfazinsaure Kalium* is the same as the complex salt with potassium nitrate; and similarly also with his *basisch dihydroxylaminsulfosaure Kalium.* This is also the case with E. Frémy's *sulfazite de potasse.*

E. Divers and T. Haga prepared **trisodium hydroxynitrilodisulphonate,** by adding the calculated quantity of sodium hydroxide to a soln. of the disodium salt and evaporating for crystallization; or it is precipitated from a conc. soln. of the disodium salt by adding an excess of sodium hydroxide. The rhombic, prismatic crystals begin to decompose when heated in air to 100°, owing to the action of the absorbed moisture; if moist air be excluded, they decompose at 182°–183°, forming a residue of sodium sulphate and thiosulphate, a little sublimate of sulphur and an ammonium salt, and the gases sulphur dioxide and nitrogen: $2NaO.N(NaSO_3)_2=3Na_2SO_4+N_2+SO_2$. At 20°, 100 parts of water dissolve 77 parts of the salt; the soln. is strongly acidic, and inclined to supersaturation. The soln. reacts towards metal salt soln. like free alkali-lye, and the disodium salt passes into soln. If a soln. of the disodium salt be mixed with some sodium hydroxide, or the trisodium salt; or a soln. with the theoretical proportions of the component salts be evaporated in a desiccator, prismatic or tabular crystals of what is probably the *pentasodium hydroxybisnitrilodisulphonate* are formed; but on filtration the crystals are those of **octosodium hydroxytrisnitrilodisulphonate,** $HO.N(NaSO_3)_2.2(NaO)N(NaSO_3)_2.3H_2O$. When recrystallized from water, microscopic crystals are formed without decomposition. At 14°, 100 parts of water dissolve 66 parts of the salt. The aq. soln. is easily supersaturated. E. Divers and T. Haga also prepared **disodium hydroxynitrilodisulphonate,** $HO.N(NaSO_3)_2$, by the process indicated above. The salt appears in thick prismatic crystals which can be recrystallized without chemical change from ammoniacal water. The salt is decomposed by the moisture in atm. air, but in dry air it can be heated slowly to 140°, and rapidly to 171°, whereby the salt fuses and decomposes with intumescence. The residue consists of sodium hydrosulphate, and the gases which are formed consist of sulphur dioxide and nitrogen. No nitrous fumes were observed; but some nitrous fumes are given off when the salt is treated with sulphuric acid. The salt is soluble in rather more than its own weight of water, and the soln. reddens blue litmus. The trisodium salt is formed when the aq. soln. is evaporated with sodium acetate or carbonate. 100 c.c. of a sat. soln. of sodium chloride dissolve 25 grms. of the salt, and from the soln. a complex salt is precipitated. It forms complex salts with potassium nitrate, but not with potassium chloride, or sodium nitrate or sulphate. It also forms a complex salt with sodium nitrite, **disodium nitritohydroxynitrilodisulphonate,** $HO.N(NaSO_3)_2.NaNO_2$, which on account of its free solubility was not investigated closely.

E. Divers and T. Haga prepared a number of complexes, **potassium sodium hydroxynitrilodisulphonates.** There is nothing to show which of the complexes in the following list are chemical individuals: $3K_3(NS_2O_7).2Na_3(NS_2O_7).1\frac{1}{2}H_2O$; $6K_3(NS_2O_7).Na_3(NS_2O_7).H_3(NS_2O_7).20H_2O$; $K_2H(NS_2O_7).2Na_2H(NS_2O_7).4Na_3(NS_2O_7).5H_2O$; $KNaH(NS_2O_7).Na_3(NS_2O_7)$; $K_{1\cdot4}Na_{1\cdot6}(NS_2O_7).H_2O$; $5K_3(NS_2O_7).Na_3(NS_2O_7).Na_2H(N_2O_7).H_3(NS_2O_7).9H_2O$; $K_{2\cdot1}Na_{0\cdot3}H_{0\cdot6}(NS_2O_7).0\cdot72H_2O$; $K_{3\cdot75}NaH_{1\cdot25}(NS_2O_7)_2.18H_2O$; $K_3(NS_2O_7).KNaH(NS_2O_7)$; $2K_3(NS_2O_7).NaH_2(NS_2O_7).2H_2O$; $KNaH(NS_2O_7).3H_2O$.

Barium chloride does not give a precipitate with a soln. of the dipotassium or disodium salt, but the mixed soln. are very unstable, and, as shown by A. Claus, rapidly hydrolyze, forming the sulphate and hydroxynitrilosulphonate. E. Divers and T. Haga prepared **tribarium hydroxynitrilodisulphonate,** $Ba_3(NS_2O_7)_2.4H_2O$ (and $8H_2O$), by the action of barium chloride or hydroxide on an excess of a soln. of the trisodium salt; the washed precipitate is nearly all dissolved in dil. hydrochloric acid until a neutral soln. or one slightly alkaline to litmus is formed; the turbid soln. is rapidly filtered into an excess of warm baryta-water; and the precipitate washed with well-boiled hot or cold water. The voluminous, curdy precipitate generally changes to a chalk-like powder consisting of crystalline particles. It is practically insoluble in water, but soluble in a soln. of ammonium chloride. It is decomposed in the cold by soln. of ammonium or sodium carbonate. If heated dry, it suddenly decomposes into barium sulphate and gases; it loses water at ordinary temp., in dry air, and nearly all at 110°. A soln. of **barium hydroxynitrilodisulphonate,** $HO.N(SO_3)_2Ba$, can be obtained by adding just enough sulphuric acid to the tribarium salt, and filtering. The soln. is acid to litmus, and hydrolyzes too quickly to permit the isolation of the salt. A compound $(HOBa)_2HNS_2O_7$, or $(HOBa)Ba.NS_2O_7$, is known only in combination.

E. Divers and T. Haga prepared a series of **potassium barium hydroxynitrilodisulphonates;** *e.g.* $4KBa(NS_2O_7).(HOBa)_2H(NS_2O_7).H_2O$; $K_2H(NS_2O_7)K_3(NS_2O_7)$; $3Ba(OH)_2.K_3(NS_2O_7).3Ba_3(NS_2O_7)$; $KBa(NS_2O_7).H_2O$; $K_3(NS_2O_7).3Ba_3(NS_2O_7)_2.14H_2O$; and $Ba_3(NS_2O_7)_2.4K_2H(NS_2O_7).9H_2O$; as well as $BaCl_2.2Ba(OH)_2.4Ba_3(NS_2O_7)_2.2K_3(NS_2O_7).14H_2O$. They also prepared a series of **sodium barium hydroxynitrilodisulphonates,** *e.g.* $5Na(NS_2O_7).6Ba_3(NS_2O_7)_2.24H_2O$; $Na_3(NS_2O_7).2Ba_3(NS_2O_7)_2.7H_2O$; and $Na_3(NS_2O_7).3Ba_3(NS_2O_7)_2.7H_2O$.

Neither E. Frémy, nor A. Claus obtained a precipitate on adding an alkali hydroxynitrilodisulphonate to a strontium salt, but E. Divers and T. Haga showed that the soln. remains clear for a moment, then forms a voluminous silky precipitate; while with the ammonium or potassium salts, the soln. deposits silky crystals in a few hours. The **potassium strontium hydroxynitrilodisulphonate** had the composition $(HOSr)_3(NS_2O_7).8SrK(NS_2O_7).16H_2O$; while the **sodium strontium hydroxynitrilodisulphonate** and the **ammonium strontium hydroxynitrilodisulphonate** were not analyzed. E. Frémy obtained needle-like crystals by the action of sulphur dioxide on a soln. of calcium nitrite; they gave off ammonia when heated, but were not further examined. According to E. Divers and T. Haga, calcium salts give no precipitate with soln. of the alkali hydroxynitrilodisulphonates, but the hydroxide forms salts by reacting with ammonium hydroxynitrilodisulphonate, mol for mol. The evaporation of the soln. on the water-bath gives off ammonia and forms a crystalline residue, probably **ammonium calcium hydroxynitrilodisulphonate,** $Ca(NH_4)(NS_2O_7)$, or **calcium hydroxynitrilodisulphonate,** $CaHNS_2O_7$. If this is treated with water, some nearly insoluble calcium hydroxynitrilodisulphonate is left, but the greater part dissolves as the calcium ammonium salt. If after dissolving 2 mols of calcium hydroxide in 2 mols of the ammonium salt, a third mol of the softest moist calcium hydroxide be stirred in, it is converted into a voluminous precipitate, which most probably is normal **calcium hydroxynitrilodisulphonate;** this precipitate is only sparingly soluble in water, and is so free from ammonia as to evolve none when mixed with calcium hydroxide, a test, however, which is not quite conclusive.

According to E. Divers and T. Haga, the reactions of the alkali hydroxynitrilodisulphonates with lead salts are complex; the disodium and dipotassium salts give no precipitates with normal lead acetate, but they do so with soln. of basic lead acetate. Trisodium hydroxynitrilodisulphonate and normal lead acetate give no precipitate unless the soln. are dil., but with basic lead acetate there is no precipitate unless the lead salt is in excess. The tripotassium salt gives an immediate precipitate with normal lead acetate, but with conc. soln. and basic lead acetate the clear soln. deposits a flocculent precipitate, which dissolves on heating and re-deposits on cooling. If basic lead acetate in excess be treated with the trisodium salt, the voluminous flocculent precipitate, when washed and dried, is **triplumbhydroxyl hydroxynitrilodisulphonate,** $(PbOH)_3NS_2O_7.3H_2O$. The reaction is symbolized $Na_3(NS_2O_7)+3(PbOH)C_2H_3O_2=(PbOH)_3(NS_2O_7)+3NaC_2H_3O_2$; the same salt is formed by adding the disodium salt to an excess of highly basic lead acetate, $Na_2H(NS_2O_7)+Pb_3(OH)_4(C_2H_3O_2)_2=2NaC_2H_3O_2+H_2O+(PbOH)_3(NS_2O_7)$. The salt decomposes when heated to a moderate temp.: $(PbOH)_3(NS_2O_7)=HO.PbNO_2+2PbSO_3+H_2O$; and the residue, when heated still more, gives off red fumes; and if moistened with hydrochloric or sulphuric acid, evolves sulphur dioxide. The salt is insoluble in acetic and other acids, and in soln. of ammonium chloride or other ammonium salts, and sodium hydroxide. It is immediately and completely dissolved by cold soln. of sodium, potassium, or ammonium hydrocarbonate. When the salt is stirred with enough sulphuric acid to deprive it of two-thirds of its lead, the slightly acid mother-liquid, on evaporation in a desiccator, gives a crust of minute crystals which, under the microscope, appear as transparent prisms. The salt was not analyzed, but was thought to be **lead hydroxynitrilodisulphonate,** $PbH(NS_2O_7)$. If basic lead acetate be added to a slight excess of the dipotassium salt, **diplumbhydroxyl hydroxynitrilodisulphonate,** $(PbOH)_2H(NS_2O_7).H_2O$, is formed as a voluminous flocculent precipitate, $K_2H(NS_2O_7)+2(PbOH)C_2H_3O_2=2KC_2H_3O_2+(PbOH)_2H(NS_2O_7)$.

A complex salt with lead acetate was also prepared, *viz.*, **tetraplumbhydroxyl acetobishydroxynitrilodisulphonate,** $(PbC_2H_3O_2)(PbOH)_4H(NS_2O_7)_2.2\frac{1}{2}H_2O$; and a couple of **potassium lead hydroxynitrilosulphonates**: $(PbOH)_5K_5H_2(NS_2O_7)_4$; and $(PbOH)PbK_6(NS_2O_7)_3$. A salt similar to the latter was reported by F. Frémy. E. Divers and T. Haga also reported **sodium lead hydroxynitrilosulphonate,** $(PbOH)_2Na_6H(NS_2O_7)_3.14H_2O$; and **ammonium lead hydroxynitrilosulphonate,** $(PbOH)NH_4(NS_2O_7)$. The disodium and dipotassium hydroxy-lead salts cannot be prepared in a similar way, but a soln. of either of these salts, or of the diammonium salt, along with acetate, seems to be obtained on mixing conc. soln. containing basic lead acetate and the trisodium, tripotassium, or triammonium salts in mol. proportion. The soln. dries up to a vitreous mass, with a little crystalline matter, and is precipitated on dilution with water.

T. Haga[2] discovered salts of **hydroxynitrilo-iso-disulphonic acid,** $HSO_3.O:NH.HSO_3$, which F. Raschig called *Hydroxylamin-iso-disulfonsäure*, and T. Haga, *hydroxylamin-αβ-disulphonic acid*. The acid is dibasic, and forms a series of salts, the **hydroxynitrilo-iso-disulphonates.** Unlike the hydroxylnitrilodisulphonates, T. Haga showed that (i) the iso-salts furnish the sulphate and the amidosulphonate: $H_2O+2Na+(NaSO_3)O.NH.NaSO_3=Na_2SO_4+NaOH+(NH_2)SO_3Na$, while the ordinary salt is unaffected; (ii) while the ordinary salt reverts to nitrite and sulphite when it is left, even in the cold, in a conc. soln. of potassium hydroxide: $HO.N(KSO_3)_2+3KOH=KNO_2+2H_2O+2K_2SO_3$, the iso-salt is incompletely decomposed into sulphate, amidosulphonate, and nitrogen after many hours' digestion at 100°–125°: $3\{(KSO_3)O.NH.KSO_3\}+5KOH=5K_2SO_4+N_2+3H_2O+NH_2.KSO_3$; and (iii) the aq. soln. of the iso-salt is not coloured bluish-violet when treated with lead dioxide, or silver oxide, whereas the aq. soln. of the ordinary salt gives a coloration. F. Raschig also showed that (iv) the iso-salt is not hydrolyzed so readily as the ordinary salt; and (v) whilst the potassium iso-salt separates from hot acidified soln. in anhydrous crystals, those of the ordinary salt are dihydrated.

T. Haga prepared **diammonium hydroxynitrilo-iso-disulphonate,**

$NH_4SO_3O.NH.NH_4SO_3$, by crystallizing ammonium hydroxynitrilotrisulphonate from its soln. in hot water, acidified with a drop of sulphuric acid. The trisulphonate is hydrolyzed into a sulphate and the iso-sulphonate: $2\{(NH_4SO_3)O.N(NH_4SO_3)_2\} + 2H_2O = 2\{(NH_4SO_3)O.NH.NH_4SO_3\} + 2NH_4(HSO_4)$. The hydrosulphate is eliminated by adding just enough baryta-water, filtering, and evaporating, at first at a gentle heat and then in the cold, over sulphuric acid under reduced press. It occurs as small, thick plates, which are somewhat hard, and as nodules composed of minute, tabular crystals. It is very soluble salt, three parts dissolving normally in just two parts of water at 18°, but it is very apt to form supersaturated soln. It is a more stable salt than the ordinary salt. Its crystals are probably anhydrous, but those analyzed showed the presence of $0{\cdot}25H_2O$ per mol.

T. Haga precipitated **tripotassium hydroxynitrilo-iso-disulphonate,** $(KSO_3)O.NK(KSO_3).2H_2O$, as an oily liquid by adding alcohol to a conc. hot aq. soln. of the disulphonate and the calculated quantity of potassium hydroxide. The oily liquid slowly forms masses of microscopic tabular crystals. The salt is very soluble in water; its soln. is not precipitated by barium chloride, and it thus differs from a soln. of the ordinary salt. It has a caustic taste; and the salt explodes when heated. T. Haga, and F. Raschig observed that **dipotassium hydroxynitrilo-iso-disulphonate,** $(KSO_3)O.NH.KSO_3$, is obtained by the hydrolysis of the aq. soln. of potassium hydroxynitrilosulphonate, as in the case of the diammonium salt just described. The hydrolysis occupies about four days. The monoclinic prismatic crystals may appear as thick prisms, thin plates, or slender needles. The salt is not dimorphous. The iso-salt is about twice as soluble in water as the ordinary salt; thus, 100 parts of water at 16·4° dissolve 6·44 parts of salt; at 17·8°, 17·18 parts; and at 20°, 8·05 parts. The soln. is neutral to litmus, methyl-orange, and phenolphthalein. F. Raschig said that the salt is stable at 100°; and an excess of hydrochloric acid hydrolyzes the alkali iso-salt into sulphuric acid and hydroxylamine: $(NaSO_3)O.NH(NaSO_3)+2H_2O=NH_2OH.H_2SO_4+Na_2SO_4$, with the possible intermediate formation of *iso-monosulphonic acid.* T. Haga prepared **trisodium hydroxynitrilo-iso-disulphonate,** $(NaSO_3)O.NNa(NaSO_3)_2.2H_2O$, by the same method as that used for the tripotassium salt. The mol. magnitudes of the anhydrous ordinary and iso-salts are related as 233, and 256·4. T. Haga prepared **disodium hydroxynitrilo-iso-disulphonate,** $(NaSO_3)O.NH(NaSO_3)$, which, like the ordinary salt, is anhydrous. Thus, a soln. of sodium hydroxynitrilotrisulphonate in five times its weight of water and acidified with dil. sulphuric acid, will be completely hydrolyzed in two or three days at the ordinary temp.; the soln. is then to be neutralized with sodium carbonate; and on exposure for a night in the ice-chamber, almost all the sodium sulphate will crystallize out, and the mother-liquor can be evaporated to obtain the required salt. Like the ordinary iso-salt, it forms hard masses firmly adhering to the sides of the vessel. These masses are stellar or warty groups of microscopic, thick, rhombic plates. The salt is exceedingly soluble in water, from which it can be nearly all precipitated by alcohol. The hydrolysis of the salt at 95° is represented by $3\{(NaSO_3)O.NH(NaSO_3)\}+3H_2O=N_2+NH_4(HSO_4)+4Na(HSO_4)+Na_2SO_4$.

T. Haga did not obtain **barium hydroxynitrilo-iso-disulphonate** in a state suited for a satisfactory determination of the nature of the salt. The evaporation of a soln. of the ammonium salt with excess of barium hydroxide in a vacuum over sulphuric acid to a small volume removed all ammonia. After removal of the excess of barium hydroxide by carbon dioxide, the filtered soln. was further evaporated in the desiccator. First a viscid and then a bulky, friable, porous mass, devoid of crystalline character, were obtained. The latter was not quantitatively analyzed, but it yielded, when hydrolyzed, barium sulphate and hydroxylamine sulphate in crystals, which were further identified by a very satisfactory acid determination. The product was therefore undoubtedly a barium iso-salt. By using less barium hydroxide, crystallized **ammonium barium hydroxynitrilo-iso-disulphonate,** $6\{(NH_4SO_3)O.NH(NH_4SO_3)\}.Ba(SO_3)_2ONH$, was formed.

W. Flügel prepared the following sparingly soluble salts: **cobalt nitritopentamminohydroxynitrilodisulphonate,** $[Co(NH_3)_5(NO_2)]HO.N(SO_3)_2$; **cobalt iso-nitritopentamminohydroxynitrilodisulphonate,** $[Co(NH_3)_5(NO_2)]HO.N(SO_3)_2$; **cobalt iso-hexamminohydroxynitrilodisulphonate,** $[Co(NH_3)_6]HO.N:(SO_3)_2$; **cobalt iso-chloropentamminohydroxynitrilodisulphonate,** $[Co(NH_3)_5Cl]HO.N:(SO_3)_2$; **cobalt-cis-isodinitrotetramminohydroxynitrilodisulphonate,** $[Co(NH_3)_4(NO_2)_2]_2HO.N:(SO_3)_2$; and **cobalt trans-iso-dinitritotetramminohydroxynitrilodisulphonate,** $[Co(NH_3)_4(NO_2)_2]_2HO.N.(SO_3)_2$.

§ 58. Nitrilotrisulphonic Acid and its Salts

Among the sulphazotized salts discovered by E. Frémy,[1] there are two which result from the oxidation of one of the potassium hydroxynitrilodisulphonates in aq. soln. of either silver oxide or lead dioxide. One of these is the unstable salt, which crystallizes from the violet-blue aq. soln. in golden yellow needles, which he called *sulphazite de potasse*; and the other, which he called *metasulphazilate de potasse*, crystallizes in colourless rhombic prisms which are so well defined that he said: *Je considère ce sel comme le plus beau de tous les sels sulfazotés.* E. Frémy's analysis of the metasulphazilate was correct, $H_6O_{23}N_2S_6K_6$, which F. Raschig regards as being constituted:

$$(KSO_3)_3N<\substack{O\\O}>N(KSO_3)_3.2H_2O$$

A. Claus called this salt *trisulphoxyazoate*, and represented it by the formula $O:N(KSO_3)_3.H_2O$. In both formulæ, the nitrogen is considered to be quinquevalent. A. Hantzsch and W. Semple rejected F. Raschig's formula, and adopted that of A. Claus. F. Raschig doubled the empirical formula because the salt is not formed by the oxidation of potassium nitritotrisulphonate, but A. Hantzsch and W. Semple said that this argument has little weight when it is known that the oxidation of the tertiary ammonium derivatives does not yield amine oxides, ONR_3. The determination of the mol. wt. of the potassium sat. by cryoscopic and electrical conductivity methods is unsatisfactory. The monomolecular formula is preferred by analogy with dibenzyl nitrilotrisulphonate, $(C_6H_5SO_3)O.N(C_6H_5SO_3)_2$. T. Haga's cryoscopic observations agree with the simple formula, although the hemihydrated character of the ammonium and potassium salts suggests the doubled formula. T. Haga argued that the metasulphazilate is a triacylated hydroxylamine, $(KSO_3)_2:N.O(KSO_3)$, in which the nitrogen is tervalent. All other compounds of this type appear to have a more complex constitution—*e.g.*, W. Lossen's formula for dibenzhydroxamic acid. This view is in agreement with the scheme in which the metasulphazilates are considered to be **nitrilotrisulphonates,** $(KSO_3)(ON)(KSO_3)_2$. The free acid—**nitrilotrisulphonic acid,** $(HSO_3)(ON)(HSO_3)_2$—has not been isolated. A. Claus, and E. Frémy found that when the potassium salt is treated with hydrofluosilicic acid, the free acid is formed as potassium fluosilicate is precipitated, but the acid immediately decomposes into sulphuric acid, ammonia, and nitrogen. According to T. Haga, when the soln. of a salt is acidified, it forms hydroxynitrilo-iso-disulphonate (*q.v.*);

sulphites have no action on the salts; and sodium amalgam, or a warm copper-zinc couple, reduces the acid to imidosulphonic acid: $(HSO_3)O.N(HSO_3)_2+H_2=H_2SO_4+NH(HSO_3)_2$.

T. Haga prepared **ammonium nitrilotrisulphonate,** $(NH_4SO_3)(ON)(NH_4SO_3)_2.\frac{1}{2}H_2O$, by digesting the basic lead salt with ammonium carbonate, evaporating the soln. on a water-bath until it has almost lost its alkalinity, and concentrating it under reduced press. over solid potassium hydroxide. The thick, rhombic plates and prisms are probably isomorphous with those of the potassium salt. The salt is neutral to litmus and methyl-orange, and closely resembles the potassium salt in its properties. It is very soluble, 100 parts of water dissolving nearly 164 parts of salt. E. Frémy, A. Claus, F. Raschig, and T. Haga prepared **potassium nitrilotrisulphonate,** $(KSO_3)O.N(NH_4SO_3)_2.\frac{1}{2}H_2O$, by gently boiling the somewhat alkaline soln. of potassium hydroxynitrilodisulphonate with silver oxide or lead dioxide until the violet soln. just loses its colour. The evaporation of the filtered soln. furnishes crystals of the salt. The main reaction is: $2PbO_2+3\{HO.N(KSO_3)_2\}+KOH=2Pb(OH)_2+KNO_2+2\{(KSO_3)(ON)(KSO_3)_2\}$, along with a little sulphate, amidosulphonate, nitrogen, and nitrous oxide. Yields as high as 87·8 per cent. have been obtained. F. Raschig also obtained the salt by allowing the yellow pernitrosyldisulphonate to stand for some days in contact with water, and recrystallized the colourless residue from water. The crystals are flattened monoclinic prisms which, according to A. Fock, have the axial ratios $a:b:c=3\cdot7602:1:2\cdot0763$, and $\beta=87°\ 42'$. A. Claus said that the salt dissolves freely in water, and that the soln. can be boiled without decomposition; and F. Raschig added that it can be repeatedly crystallized from alkaline liquids without change. According to T. Haga, 100 parts of water at 18° dissolve 3·9 parts of the salt. The soln. is neutral to litmus, phenolphthalein, methyl-orange, and other indicators. When slowly heated to 100°–120° in air, it loses some water of crystallization, and is then hydrolyzed by the remainder acting together with the moisture of the atm. Hence there is first a loss of weight and then a gain. The residue is strongly acid owing to the presence of hydrosulphate. It has not been found possible to obtain the anhydrous salt because of the hydrolytic action which occurs even in a current of dry air. A. Claus found that when heated with soda-lime, one-third of the nitrogen is given off as ammonia: $3\{(KSO_3)O.N(KSO_3)_2\}+9KOH=9K_2SO_4+N_2+3H_2O+NH_3$. E. Frémy, and A. Claus found that the salt is not decomposed by nitric acid or other dil. acids; but F. Raschig, and T. Haga found that when the salt is boiled in dil. hydrochloric acid, hydroxynitrilo-monosulphonic acid is formed. F. Raschig said that an acidic soln. of permanganate is reduced by the salt, and A. Claus obtained no precipitation with soln. of the metal salts, although with lead salts a complex salt is formed which is decomposed by water. The inactivity of the sulphites towards the hydroxynitrilotrisulphonates, and the reducing action of sodium amalgam and the copper-zinc couple has been already indicated. T. Haga prepared **sodium nitrilotrisulphonate,** $(NaSO_3)(ON)(NaSO_3)_2.2H_2O$, by boiling a soln. of the disulphonate with the eq. amount of sodium hydroxide, and lead dioxide. It is more difficult than the potassium salt to purify, but by the cautious addition of sulphuric acid, the impurities can be converted into sulphates which can be removed from the soln. by freezing. It crystallizes in aggregates of small, tabular, monoclinic crystals. The solubility of the salt is considerable, 100 parts of water at 21·5° dissolve 35 parts of salt. Like the potassium salt, it is neutral to indicators, and when heated, it hydrolyzes in its water of crystallization. The mol. wt. of the salt by the cryoscopic method agrees with the simple formula. T. Haga also found that **lead hydroxynitrilotrisulphonate,** $(PbOH.PbO.SO_3)(ON)(PbOH.PbO.SO_3)_2.3H_2O$, is the only insoluble compound formed when a warm soln. of the potassium salt is poured into a soln. of basic lead acetate. The chalky white powder is readily decomposed by a soln. of an alkali carbonate. F. Ephraim and W. Flügel added different cobaltic ammines to a soln. of the potassium salt and obtained **cobaltic hexamminonitrilotrisulphonate,** $[Co(NH_3)_6]SO_3.ON:(SO_3)_2$; **cobaltic aquopentam-**

minonitrilotrisulphonate, $[Co(NH_3)_5(H_2O)]SO_3.ON:(SO_3)_2$; **cobaltic cis-dinitritotetramminonitrilotrisulphonate,** $[Co(NH_3)_4(NO_2)]\{SO_3.ON:(SO_3)_2\}_2$, as well as **cobaltic trans-dinitritotetramminonitrilotrisulphonate** ; and **cobaltic nitritopentamminonitrilotrisulphonate,** $[Co(NH_3)_5(NO_2)]SO_3.ON:(SO_3)_2$.

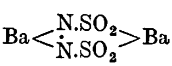
§ 59. Hydrazinosulphinic and Hydrazinosulphonic Acids

According to F. Ephraim and H. Piotrowsky,[1] when sulphur dioxide is slowly passed into a cooled soln. of hydrazine in absolute alcohol, a white crystalline precipitate of **hydrazine hydrazinodisulphinate,** $N_2H_2(HSO_2.N_2H_4)_2$, is formed. It sinters at 50°, and gives a cloudy liquid at 70°–80°, which decomposes with the evolution of gas. The aq. soln. is weakly acid, and smells slightly of sulphur dioxide; when treated with a soln. of a barium salt, it furnishes a precipitate of **barium hydrazinodisulphinate,**



$$Ba<\begin{array}{l}N.SO_2\\ N.SO_2\end{array}>Ba$$

in which the hydrogen atoms of hydrazine as well as those of the sulphinic radicle are replaced by barium. The salt gradually decomposes with the loss of nitrogen. Impure **silver hydrazinodisulphinate** was similarly obtained, as well as **calcium hydrazinodisulphinate,** and **lead hydrazinodisulphinate.** The parent acid, **hydrazinodisulphinic acid,**

$$\begin{array}{l}H-N-SO_2-N_2H_5\\ H-N-SO_2-N_2H_5\end{array}$$

has not been isolated. For the action of hydrazine on sulphur, hydrogen sulphide, sulphur trioxide, and thionyl chloride, see the chemical properties of these substances. In the case of thionyl chloride, there are indications of the formation of a hydrazine of sulphurous acid.

There are derivatives of hydrazine in which one or more of the hydrogen atoms are replaced by the sulphonic radicle. R. Stollé and K. A. Hoffmann passed carbon dioxide into a well-cooled, conc. aq. soln. of hydrazine and obtained **hydrazinocarboxylic acid,** $NH_2.NH.COOH$, as a white powder which can be dried over sulphuric acid in an atm. of carbon dioxide. When heated to 90°, it decomposes into carbon dioxide and **hydrazine hydrazinocarboxylate,** $N_2H_4.NH_2.COOH$, which distils at 140° under ordinary press., forming a clear, viscous liquid which when kept over sulphuric acid forms a crystalline mass, melting at 70°. It forms an alkaline soln. with water ; and it is rapidly decomposed by acids ; when heated to 140° in a closed tube, it forms some carbohydrazide ; and when treated with ethyl chlorosulphonate, it yields **hydrazinodisulphonic acid,** $NH_2.N(HSO_3)_2$, or $HSO_3.NH.NH.HSO_3.H_2O$, which can be isolated in the form of **potassium hydrazinodisulphonate,** $N_2H_2(KSO_3)_2.H_2O$, which crystallizes from water in transparent prisms. The acid does not yield a condensation product with benzaldehyde. F. Raschig prepared the potassium salt by the action of chlorosulphonic acid on a mixture of hydrazine sulphate and pyridine ; and the potassium salt is decomposed by alkali hydroxide : $N_2H_2(KSO_3)_2+2KOH=N_2+2K_2SO_3+2H_2O$. F. Raschig suggested that dihydroxyimide, or **dihydroxyhydrazine,**

$$\begin{array}{l}H-N-OH\\ H-N-OH\end{array}$$

is formed as an intermediate product because no nitrogen and no sulphite are formed when the alkali hydrazinodisulphonate is treated with alkali-lye cooled by ice; only when the temp. rises to, say 15°, is nitrogen evolved and alkali sulphite formed.

E. Konrad and L. Pellens prepared **pyridine hydrazinodisulphonate** by the action of chlorosulphonic acid on a suspension of hydrazine sulphate in cold pyridine and subsequently precipitating the salt with ethyl alcohol. The corresponding *ammonium, sodium, and barium hydrazinodisulphonates* were prepared respectively with 1, 2, and 3 mols of water of crystallization.

W. Traube and O. Vockerodt found that when dry air is slowly drawn through a flask containing fuming sulphuric acid rich in sulphur trioxide, and then through a flask containing anhydrous hydrazine, a considerable quantity of **hydrazine hydrazinomonosulphonate,** $N_2H_2.H_2N.NH.HSO_3$, is formed, and when the aq. soln. of this product is dissolved in water, and the soln. heated with an excess of barium hydroxide, to drive off the free hydrazine, the excess of barium precipitated by carbon dioxide, and the filtrate evaporated in vacuo, **barium hydrazinomonosulphonate,** $Ba(N_2H_3.SO_3)_2.2H_2O$, is formed. When the aq. soln. is precipitated with alcohol, the salt is obtained in glistening needles. By treating the barium salt with sulphuric acid, free **hydrazinomonosulphonic acid,** $N_2H_3.HSO_3$, is formed; and the white needles of the acid melt with decomposition at 217°. By treating the barium salt with ammonium carbonate, **ammonium hydrazinomonosulphonate,** $N_2H_3(NH_4SO_3)$, is formed as a deliquescent, crystalline mass. A. P. Sabanéeff noted that this ammonium salt is isomeric with hydrazine amidosulphonate. By treating the barium salt with a suitable alkali sulphate, acicular crystals of **potassium hydrazinomonosulphonate,** $N_2H_3(KSO_3)$, and monoclinic plates of **sodium hydrazinomonosulphonate,** $N_2H_3(NaSO_3).H_2O$, were produced. The salts are stable in alkaline and neutral soln., but are decomposed by acids into sulphuric acid and hydrazine. F. Raschig said that the salt reacts with iodine in acetic acid soln.: $N_2H_3.KSO_3+2I_2+H_2O=N_2+4HI+KHSO_4$; and when treated with potassium permanganate, nitrogen gas is evolved, and two hydrogen atoms are removed, forming potassium diazomonosulphonate, $NH:N(KSO_3)$, which then breaks down into nitrogen and potassium hydrosulphite. Ammoniacal silver nitrate is rapidly reduced by these salts, but the barium salt and silver nitrate furnishes acicular crystals of **silver hydrazinomonosulphonate,** $N_2H_3.AgSO_3$. By applying the method used for the barium salt to the other alkaline earths, **calcium hydrazinomonosulphonate,** $Ca(N_2H_3.SO_3)_2.H_2O$, and **strontium hydrazinomonosulphonate,** $Sr(N_2H_3.SO_3)_2.2H_2O$, were formed.

When the barium salt is treated with an aldehyde, *e.g.* salicylaldehyde or benzaldehyde, *barium hydroxybenzylidenehydrazinomonosulphonate,* $(OH.C_6H_4.CH:N.NH.SO_3)_2Ba.2H_2O$, and *barium benzylidenehydrazinomonosulphonate,* $(CH.C_6H_5:N.NH.SO_3)_2Ba.2H_2O$, were formed. If ethylenediamine be sulphonated like hydrazine, *barium ethylenediaminomonosulphonate,* $(NH_2.CH_2.CH_2.NH.SO_3)_2Ba$, is formed; and when this is treated for the free acid, there are formed colourless leaflets of *ethylenediaminomonosulphonic acid,* $NH_2.CH_2.CH_2.NH.HSO_3$. or

$$\begin{array}{l}CH_2.NH.SO_2\\ CH_2.NH_2.O\end{array}$$

E. Konrad and L. Pellens found that if pyridine hydrazinodisulphonate be oxidized by sodium hypochlorite in the presence of water at —20°, and the liquid treated with potassium chloride, **potassium diazodisulphonate,** $N_2(KSO_3)_2$, or $KSO_3.N:N.KSO_3$, is formed. The parent acid, diazodisulphonic acid, $HSO_3.N:N.HSO_3$, has not been isolated. F. Raschig said that **potassium diazomonosulphonate,** $H.N:N.KSO_3$, which he called *potassium diimidomonosulphonate,* is formed as an unstable intermediate product in the oxidation of potassium hydrazinomonosulphonate by potassium permanganate. The parent acid, **diazomonosulphonic acid,** $H.N:N.HSO_3$, has not been isolated.

W. Traube and O. Vockerodt observed that a well-cooled, conc., aq. soln. of potassium nitrite when treated with finely powdered hydrazine monosulphonate, reacts: $NH_2.NH.HSO_3+KNO_2=2H_2O+N_3.KSO_3$, and the resulting **potassium triazomonosulphonate**, $N_3.KSO_3$, is obtained in an impure state by spontaneous evaporation. When purified, it furnishes long, flat prisms which explode on heating. The parent acid, **triazomonosulphonic acid**, $N_3.HSO_3$,

$$\genfrac{}{}{0pt}{}{N}{\ddot{N}}{>}N{-}HSO_3$$

has not been isolated. They obtained, in a similar manner, **sodium triazomonosulphonate**, $N_3.NaSO_3$; **ammonium triazomonosulphonate**, $N_3.NH_4SO_3$; and **barium triazomonosulphonate**, $(N_3.SO_3)_2Ba$.

§ 60. Peroxyamidodisulphonic Acid and its Salts

The soln. of the *sulphazites* of E. Frémy[1] prepared by oxidizing a potassium hydroxynitrilodisulphonate with silver oxide or lead dioxide have an intense violet-blue colour, and furnish golden-yellow crystals. He represented the composition of the potassium salt by $HO_7NS_2K_2$, which, said A. Claus, would agree with the formula at present employed if the hydrogen be omitted. T. Haga showed that other oxidizing agents produce the violet coloration—*e.g.*, ozone, nitrous fumes, and acidified soln. of a nitrite—but hydrogen dioxide, potassium ferricyanide, potassium permanganate, alkaline cupric soln., and mercuric oxide have no perceptible action. A. Claus showed that the production of the coloured salt is not necessarily accompanied by a sulphate; that it is a product of oxidation; and that it passes spontaneously into the colourless trisulphonate, a little sulphate, and gaseous nitrous oxide. He recognized the sulphonic character of the coloured salt, and named it *oxysulphazotate* to which he assigned the formula:

$$(KSO_3)_3{\equiv}N{<}\underline{\overset{O}{\quad}}{>}NO{-}KSO_3$$

A. Claus's formula.

$$(KSO_3)_2{=}N\genfrac{}{}{0pt}{}{\lessdot O \gtrdot}{\lessdot O \gtrdot}N{=}(KSO_3)_2$$

F. Raschig's formula.

where the nitrogen is quinquevalent. F. Raschig modified this formula into that just indicated. A. Hantzsch and W. Semple regarded the coloured salt as sulphonated nitrogen peroxide, and called it *nitroxyldisulphonate*, $O.N:(KSO_3)_2$, in which the nitrogen is tervalent, and oxygen univalent. The yellow crystals are supposed to have twice the mol. magnitude of the dissolved violet form by analogy with the two forms which nitrogen peroxide itself assumes. P. Sabatier investigated the violet soln. produced by the action of reducing agents—say, sulphur dioxide—on a soln. of hydroxynitrosylsulphuric acid, $NO(HO)SO_3$, in monohydrated sulphuric acid. The similarity of the colours led him to assume that the coloration is due to the presence of the acid of E. Frémy's potassium salt, constituted $O:N(HSO_3)_2$. T. Haga raised the objections that there are striking chemical contrasts in the nature of the two soln.

(i) E. Frémy's violet salt is produced by the action of lead dioxide and is not attacked by it, whereas P. Sabatier's violet acid is at once attacked by lead dioxide; (ii) The violet acid is produced by and is indifferent towards sulphur dioxide, whereas the violet salt is at once changed by this reagent; (iii) S. Sekiguchi was unable to convert E. Frémy's violet salt into P. Sabatier's violet acid, or conversely.

The sulphonic character of the violet salt was established by the work of A. Claus, and by the fact that it can be produced by the dehydrogenation of hydroxylamine disulphonate. T. Haga defended the thesis that the nitroxy-residue in the violet salt of E. Frémy's salt of **peroxylamidodisulphonic acid,** $(HSO_3)_2N.O.O.N(HSO_3)_2$—a derivative of *peroxylamine,* $H_2N.O.O.NH_2$. It is maintained that the mode of formation of the potassium salt proves that the constitution is that of a peroxide, and therefore of a peroxamide. For example, the disodium hydroxynitrilodisulphonate loses two hydrogen atoms at ordinary temp., when oxidized by ozone, silver oxide, or lead dioxide, but not by oxygen itself: $(KSO_3)_2N.O\boxed{H+H}O.N(KSO_3)_2+O\rightleftharpoons(KSO_3)_2N.O.O.N(KSO_3)_2+H_2O$. The reversion, at ordinary temp., by a reducing agent occurs so that the peroxylamidodisulphonate forms hydroxynitrilodisulphonic acid. Again, the reaction between the peroxylamidosulphonic acid and normal alkali sulphite is most probably effected through the oxygen atoms of the peroxyl-group: $(KSO_3)_2N.O.O.N(KSO_3)_2+K_2SO_3=KO.N(KSO_3)_2+(KSO_3)ON(KSO_3)_2$. T. Haga then discusses the improbability that the nitrogen atom is more than tervalent. E. Divers favours T. Haga's view of the constitution of this salt because of the reactions with potassium sulphite resulting in the formation of hydroxylinitrilotrisulphonate and disulphonates; and with water resulting in the formation of nitrous acid and hydroxynitrilo-trisulphonate and disulphonate.

When the attempt is made to isolate **peroxylamidosulphonic acid,** $N_2O_2(KSO_3)_4$, by acidifying an aq. soln. of the potassium salt, brown fumes are evolved owing to the decomposition of the peroxylamidosulphonic acid. A. Rose possibly obtained a soln. of the acid by the action of nitric oxide on sulphuric acid: $3NO+4H_2SO_4=2H_2O+NO(HSO_3)_2+2(NO)HSO_4$. The blue liquid obtained by P. Sabatier by the action of sulphur dioxide on a soln. of hydroxynitrosylsulphonic acid in sulphuric acid may also contain this acid. As indicated below, the identity of P. Sabatier's blue acid with peroxylamidosulphonic acid has not been established. Both A. Rose's and P. Sabatier's products may be hydroxynitrosylsulphonic acid (*q.v.*).

In preparing **potassium peroxylamidosulphonate,** $N_2O_2(KSO_3)_4$, E. Frémy prepared the dipotassium or pentapotassium hydroxynitrilodisulphonates; A. Claus used the latter, F. Raschig the former. T. Haga said that the penta-salt is the better because the product is more stable in presence of the more alkaline salt, and there is consequently less loss, and the salt is more easily purified. E. Frémy preferred silver oxide as the oxidizing agent; A. Claus, lead dioxide. T. Haga found that the silver oxide gives the better yield, but lead dioxide is the more convenient oxidizing agent. The lead which contaminated the product is easily removed.

E. Frémy called this salt *sulfazilate de potasse;* A. Claus, *oxysulfazotinsäure Kalium;* and T. Haga, *potassium peroxylaminosulphonate.* T. Haga said that the unstable salt should be prepared just when it is wanted, and recommended the following process:

Mix 5 grms. of pentapotassium hydroxynitrilodisulphonate—or the dipotassium salt with a little potassium hydroxide—and a little more than the same weight of lead dioxide or silver oxide, and make up with water to 25 c.c. Agitate the mixture for 15 minutes at a temp. near to but not exceeding 40°. Decant the soln. at once, remove any lead by a current of carbon dioxide, and filter the warm soln. before crystallization sets in. Allow the mixture to stand in an ice-box for some hours when the whole of the desired salt will have separated as a crust of minute yellow needles. These can be recrystallized with a slight loss from hot water made alkaline with potassium hydroxide. If any salt has escaped oxidation, it will contaminate the yellow crystals, colouring them violet, owing, as A. Hantzsch and W. Semple observed, to hydroxynitrilodisulphonate retaining 1 to 4 per cent. of the violet soln. in solid soln.

There are some discrepant observations by E. Frémy, A. Claus, F. Raschig, and T. Haga on the properties of the potassium salt. The following are mainly from T. Haga's revision in his memoir: *Peroxylamine Sulphonates and Hydroxylamine Trisulphonates.* Solid potassium peroxylamidosulphonate is too unstable when dry and free from alkali to exist many minutes without rapidly and almost explosively decomposing. In this decomposition, slight white fumes of ammonium salt (probably pyrosulphite and pyrosulphate), nitrogen and nitrous oxide, and a small quantity of sulphur dioxide are given off, whilst the residue, when the mass of the salt has been at all considerable, becomes very hot (above 300°) and melts. This residue consists of potassium sulphate (principally pyrosulphate) with a very little ammonium salt. Sometimes a trace of amido-monosulphonate can be detected by the mercuric nitrate test; also a trace of hydroxylamine (or other substance reducing alkaline cupric soln.), but none of the other sulphonates, the temp. having been too high to leave these substances undecomposed. The true products of the spontaneous decomposition of a peroxylamidosulphonate are only found (in company with small quantities of apparently secondary products) when the salt is heated to boiling with enough water to dissolve it, and in presence of sufficient alkali to prevent both the acidification of the soln. during the decomposition of the salt and also the secondary changes which would result from acidification. The alkali does not appear to modify the nature of the primary change, although it distinctly increases the stability of the salt, as already mentioned. When carried out in the foregoing manner, the decomposition of a peroxylaminosulphonate proceeds largely in such a way that not only do three-fourths of the sulphur of the salt, as suggested by A. Claus, and by F. Raschig, together with one-half of its nitrogen, come out as hydroxylnitrilotrisulphonate, but the rest of the sulphur and one-fourth of the nitrogen become hydroxynitrilodisulphonate again, whilst the remaining one-fourth of the nitrogen appears as nitrite,

$$2(SO_3K)_4N_2O_2+H_2O=2(SO_3K)_3NO+(SO_3K)_2NOH+NO_2H,$$

although some nitrous oxide and sulphate, besides minute and uncertain quantities of other substances, are always produced. This result explains the production of the large quantities of acid sulphate and nitrous oxide observed by A. Claus, and F. Raschig, for the nitrous acid when not neutralized by alkali interacts with the hydroxynitrilodisulphonate and yields acid sulphate and nitrous oxide. The regeneration of hydroxynitrilodisulphonate in the spontaneous decomposition of a peroxylamidosulphonate accounts for the fact, met with in the present investigation, that much more hydroxynitrilotrisulphonate is obtainable by heating hydroxynitrilodisulphonate in soln. with excess of lead peroxide than can be derived from the decomposition (out of contact with lead peroxide) of the peroxylamidesulphonate equivalent to that quantity of hydroxynitrilodisulphonate.

E. Frémy was mistaken in saying that when the salt is left in a closed bottle it furnishes nitric oxide. According to T. Haga, the general character of the decomposition of the salt is as follows: the mol of peroxylamidosulphonate is halved by the hydrolysis, and converted into hydroxynitrilodisulphonate, and probably an unstable **potassium hydroxyperoxylamidosulphonate,** $HO.O.N(KSO_3)_2$, which has not been isolated: $(KSO_3)_2N.O.O.N(KSO_3)_2=HO.O.N(KSO_3)_2+HO.N(KSO_3)_2$. The unstable hydroxyperoxylamidosulphonate reacts with the original salt $N_2O_2(KSO_3)_4+HO.O.N(KSO_3)_2=HO.NO+2\{(KSO_3)O.N(KSO_3)_2\}$; and, neglecting intermediate products, this gives as a resultant equation (i): $2N_2O_2(KSO_3)_4+H_2O=HNO_2+2ON(KSO_3)_3+HO.N(KSO_3)_2$. The hydroxynitrilodisulphonate may also react with the original salt: $2N_2O_2(KSO_3)_4+2HON(KSO_3)_2=4\{(KSO_3)O.N(KSO_3)_2\}+H_2N_2O_2$, which gives the resultant equation (ii): $6N_2O_2(KSO_3)_4+H_2O=N_2O+2HNO_2+8\{(KSO_3)O.N(KSO_3)_2\}$. The sulphate found among the products of the decomposition in varying amounts does not come from the hydrolysis of the salt itself or from the reaction products hydroxynitrilotrisulphonate and disulphonate. The trisulphonate is stable in the presence of alkali, and the disulphonate yields sulphite not sulphate. T. Haga assumed that it came from the decomposition of the unstable hydroxyperoxylamidosulphonate, where it fails to react with the peroxylamidosulphonate. It may hydrolyze either according to $2\{HO.O.N(KSO_3)_2\}+H_2O=HO.N(KSO_3)_2+HNO_2+2KHSO_4$, or according to $2\{HO.O.N(KSO_3)_2\}+H_2O=N_2O+4KHSO_4$, which may be combined with the primary equation. The nitrogen which is formed may be produced in the reaction: $N_2O_2(KSO_3)_4+2H_2O=N_2+4KHSO_4$, and the potassium amidosulphonate by: $N_2O_2(KSO_3)_4+3H_2O=3KHSO_4+HNO_2+NH_2.KSO_3$. Part of the instability of the peroxylamidosulphonates is to be attributed to the presence of oxidizable impurities. Thus, E. Frémy noticed the decomposing action of atm. dust; while nitrites, liable to be present as an impurity, greatly increase its instability, and acids hasten while alkalies retard the decomposition of the salt. Potassium peroxylamidosulphonate is very unstable in water and very slightly soluble in the cold. In $\frac{1}{10}N$-KOH, which fairly represents its usual mother-liquor, it is more stable, but still not very soluble; 100 parts at 3° dissolve only 0·62 part of the salt, and, at 29°, only 6·6 parts. It interacts in soln. with normal potassium sulphite and then produces hydroxynitrilotrisulphonate and hydroxynitrilodisulphonate, evidently in mol. proportions, this change being a fact of great theoretical importance. Its chemical activity is manifested in oxidizing certain easily oxidizable substances, and being thereby reduced to its parent salt, hydroxynitrilodisulphonate. Although it liberates iodine from hydriodic acid, it fails to oxidize hydrochloric acid. When the latter acid in conc. soln. is poured on the solid salt, it sets up the same decomposition as that which occurs spontaneously. But here, as the rise of temp. is moderated, definite although minute quantities of amidomonosulphonate and of hydroxylamine (not its sulphonate) can be found. The salt has practically no action on alcohol; nitrous and sulphurous acids rapidy reduce it, so also does sodium amalgam, first to hydroxynitrilodisulphonate, as observed by P. Schatzmann, and then this salt passes slowly but completely into imidodisulphonate. Clean granulated zinc slowly reduces the salt, but copper does not. The spontaneous decomposition of the salt may, however, easily be mistaken for its slow reduction by a reducing agent, since in this case also hydroxynitrilodisulphonate is produced. The difference is readily detected by testing for nitrite, which is produced only in the spontaneous decomposition of the salt. Manganese dioxide very slowly decomposes it, causing a minute effervescence; lead peroxide is inactive. Potassium permanganate is reduced to green manganate. Clean filter-paper, unlike the paper in use in E. Frémy's time, does not affect it.

§ 61. Hyponitritosulphuric Acid and its Salts

In 1835, J. Pelouze,[1] in his *Mémoire sur quelques combinaisons d'un nouvel acide formé d'azote, de soufre, et d'oxigène*, described what he called *l'acide nitrosulfurique*, or *les sels nitrosulfates*, by bringing nitric oxide in contact with alkali sulphites, or a mixture of nitric oxide and sulphur dioxide in contact with an alkali at ordinary temp. An excess of alkali promotes the formation of the compound. He added that the alkali absorbs two vols. of nitric oxide for every vol. of sulphur dioxide. If the nitric oxide predominates the excess remains unabsorbed, while if the sulphur dioxide predominates, an alkali sulphite is formed as well as the nitrosulphate. E. Divers and T. Haga emphasized the fact that these salts are formed from sulphites by a process analogous to that by which sulphates and thiosulphates are formed from sulphites, namely, by leaving a soln. of a normal sulphite in contact with nitric oxide, oxygen, or sulphur as the case requires. The nitrosulphates of

J. Pelouze also revert to nitric oxide and sulphite. Hence, as in the case of, say, calcium thiosulphate, $CaS_2O_3 \rightleftharpoons CaSO_3+S$, so in the case of the nitrosulphates, $K(N_2O_2).SO_2.OK \rightleftharpoons K.SO_2OK+N_2O_2$; and in the case of sulphates, $KO.SO_2.OK \rightleftharpoons K.SO_2.OK+O$. Again, sodium amalgam acts on a thiosulphate, forming sulphite and sulphur, so on a nitrosulphate it forms sulphite and hyponitrite. The sulphonate constitution was advocated by F. Raschig, W. Traube, A. Hantzsch, and P. Duden, but other formulæ have been suggested:

$$O<\genfrac{}{}{0pt}{}{N:N.OK}{SO_2.OK}$$

E. Divers' formula.

$$O<\genfrac{}{}{0pt}{}{\dot{N}.OK}{\dot{N}.KSO_3}$$

A. Hantzsch's formula.

$$ON-N<\genfrac{}{}{0pt}{}{OK}{KSO_3}$$

F. Raschig's formula.

F. Raschig said that the potassium salt is best obtained by the action of nitric oxide on a 40 per cent. soln. of potassium sulphite as indicated below. E. Divers showed that the ordinary nitrogen-sulphonic compounds give a precipitate of barium sulphate with an acidified soln. of barium chloride only after standing an appreciable time, while the nitrosulphates give a precipitate immediately. Again, alone in aq. soln. the potassium salt slowly decomposes into normal sulphate and nitrous oxide, whereas in the presence of a little alcohol, potassium ethyl sulphate, potassium hydroxide, and nitric oxide are formed: $KO.SO_2.O.N:NOK+C_2H_5OH=(C_2H_5)KSO_4+KOH+N_2O$; it is extremely probable that the nitrous oxide is formed by the decomposition of the potassium hydrohyponitrite, $KO.N_2.OH$, of W. Zorn, so that the reaction is formulated: $KON_2.KSO_4+C_2H_5OH=(C_2H_5)KSO_4+KO.N_2OH$. F. Raschig's formula is well suited to explain the decomposition of the salt into sulphate and nitrous oxide, but it does not account very well for the action of sodium amalgam in harmony with that of other sulphonates; similarly, P. Duden's explanation of the action of potassium hydroxide by means of F. Raschig's formula does not make it clear why a sulphate is formed when other sulphonates under similar conditions yield sulphites. P. Duden's synthesis of hydrazine by the reduction of the nitrosulphate does not agree with the sulphonic character of these salts. A. Lachman and J. Thiele also showed that while all undoubted sulphonates give nitrous oxide, and sometimes a little nitramide, when mixed in the cold with nitric and sulphuric acids, potassium nitrosulphate does not do so. E. Divers and T. Haga also found that while the amidosulphonates, oxygenated or not, resist the action of sodium amalgam, the nitrosulphates are at once reduced, showing that the latter are probably not sulphonates. In conclusion, it is urged that the hyponitrite-sulphate formula explains every known chemical action of these salts while the sulphonic formula explains only some of them and suggests others they do not possess. The dibasic acid is therefore named **hyponitritosulphuric acid,** $HO.N:N.HSO_4$, and the salts **hyponitritosulphates.**

J. Pelouze prepared crystals of **ammonium hyponitritosulphate,** $(NH_4)_2SO_3N_2O_2$, by allowing a soln. of ammonium sulphite, cooled by a freezing mixture, to absorb nitric oxide. At 0° and upwards, the soln. decomposes into nitrous oxide and ammonium sulphite, but the reaction is retarded if the soln. be mixed with three times its vol. of aq. ammonia. The crystals were washed with aq. ammonia and dried between bibulous paper. The clear, rhombic prismatic crystals have a slightly bitter taste, and a neutral reaction. The crystals can be heated to 110°, but above that temp., they decompose with an explosion, forming nitrous oxide. They decompose with sparking when thrown on red-hot coals. They can be dissolved in water, but the salt in aq. soln. soon decomposes: $N_2O_2.(NH_4)_2SO_3=N_2O+(NH_4)_2SO_4$. The decomposition at 0° is slow, but very rapid at 40°; the speed of the reaction is accelerated by the presence of carbon, pyrolusite, silver oxide, and platinum sponge. The salt does not reduce manganic sulphate or indigo soln.; it is decomposed by acids and metal salts. It is insoluble in hot alcohol, and is precipitated by alcohol from its aq. soln. J. Pelouze prepared **potassium hyponitritosulphate,** $K_2SO_3.N_2O_2$, as indicated above. The salt was also prepared by A. Claus. F. Raschig reported another modification. He said that one isomer gives a precipitate with barium chloride which is insoluble in water, but which dissolves in hydrochloric acid to form a soln. which remains clear for a short time and then deposits barium sulphate; the other isomer, obtained only once, gives no precipitate with barium chloride, though on adding hydrochloric acid, barium sulphate is immediately precipitated. This was not confirmed by A. Hantzsch, E. Divers and T. Haga, and C. M. Luxmore.

A. Hantzsch prepared the salt by dissolving one-fourth of a weighed quantity of potassium hydroxide in a little water, and sat. the soln. with sulphur dioxide so as to form hydrosulphite; the remainder of the potassium hydroxido was added, and mixod with the necessary amount of water for its dissolution. The air was displaced by a fast current of nitric oxide, and the liquid sat. with the gas. The alkaline liquor was thon decanted from the crystals, which were washed twice with iced-water. E. Divers and T. Haga displaced the air by a stream of hydrogen; and recommended using vessels which exposed a large surface of liquid to the nitric oxide gas. They used a soln. containing 40 per cent. of potassium sulphite, and 5 per cent. of potassium hydroxide. The crystals wcro purified, if necessary, by dissolving them quickly, at 50°–60°, in 4 to 5 times their weight of water containing 1 to 1½ per cent. of potassium hydroxide. The recrystallization involves considerable loss.

F. Raschig said that that salt is not attacked by potassium permanganate in acidic soln.; but it is oxidized by sodium hypochlorite in the presence of a little water. The usual products of decomposition are nitrous oxide and potassium sulphate; nitric oxide and potassium sulphite can be obtained from it by boiling with potassium hydroxide soln., or by fusion; and hydrazinosulphonic acid, by alkaline reduction. He said that the formation of the hyponitritosulphate can be explained by assuming, with A. Hantzsch, that before the combination, nitric oxide forms double mols, and also that both potassium atoms in potassium sulphite are joined to the sulphur atom. When nitric oxide reacts with potassium hydrosulphite, the first product probably has the constitution $NO.N(OK)SO_3K$, which then undergoes rearrangement. When nitric oxide is passed into a soln. of potassium hydrosulphite, potassium nitrilosulphonate, $N(SO_3K)_3,2H_2O$, is formed, which decomposes on boiling, yielding potassium hydrogen sulphate and potassium amidosulphonate. The reaction between nitric oxide and potassium hydrosulphite may be explained by assuming the formation of potassium nitroxylsulphonate, $OH.N.SO_3K$, which combines further with nitric oxide, yielding potassium nitrosohydroxylaminosulphonate, $ON.N(OH)SO_3K$, from which the potassium nitrososulphite, $ON.N(OK)SO_3K$, is formed in alkaline soln. In the absence of alkali, potassium nitrosoamidodisulphonate is obtained. In the decomposition of potassium nitroxysulphonate, $OH.N.SO_3K$, hyponitrous acid and the residue, SO_3K, are first produced. From the latter by simple association potassium dithionate results.

A. Hantzsch said that the colourless needle-like crystals are stable in dry air, but in moist air they slowly form potassium sulphate. J. Pelouze said that the crystals are irregular, six-sided columns which resemble potassium nitrate. The crystals have no smell, a slightly bitter taste, and a neutral reaction. E. Divers and T. Haga found that the drier the atm. the more slowly does the salt lose weight when heated. C. M. Luxmore observed a loss of 2·5 per cent. in five minutes a little below 105°; J. Pelouze said the salt did not lose weight at 115°. The different results are due to differences in the humidity of air and salt. J. Pelouze added that the salt decomposes at 130° into nitric oxide and potassium sulphite. A. Hantzsch, however, said that the decomposition is quantitative at 90°, and nitrous oxide is the gaseous product. E. Divers and T. Haga said that if the gas observed by J. Pelouze was nitric oxide, it must have arisen from some impurities. They added that the crystals exploded in a current of air at 91°, in an oil-bath, and at 108° in an air-bath. C. M. Luxmore found that with a thermometer immersed in the salt, explosive decomposition occurs at 127°–148°. The difference in these results is due to the spontaneous heating of the salt to about 130° before it explodes. E. Divers and T. Haga reported that 100 parts of water at 14·5° dissolve 12·5 parts of salt.

J. Pelouze showed that the salt is insoluble in alcohol, but easily soluble in water, and that the aq. soln. is fairly stable; as indicated above, E. Divers and T. Haga found the salt is decomposed by absolute alcohol, and by water. With warm water, A. Hantzsch said that the soln. gives off nitrous oxide, and effervesces, but no nitric oxide is formed. The soln. in dil. alkali-lye was found by F. Raschig to yield crystals of hydroxynitrilodisulphonate. E. Divers and T. Haga said that alkaline soln. are reduced by sodium amalgam: $KO.N_2.KSO_4+H_2=H_2SO_3+K_2N_2O_2$, forming at the same time some ammonia, nitrogen, nitrous oxide, sulphate, sulphite, amidosulphonate, but no hydroxylamine; and P. Duden found that in the cold, reduction by sodium amalgam, or by zinc-dust and ammonia or soda-lye, furnishes some hydrazine. J. Pelouze said that even the feeblest of acids decomposes potassium hyponitritosulphate; and contact with barium chloride, copper oxide, silver oxide, zinc oxide, manganese sulphate, lead acetate, and platinum-sponge decomposes the salt. As indicated above, barium chloride acts only slowly on the aq. soln., precipitating barium sulphate. A. Hantzsch said that the salt forms complex salts with the salts of the heavy metals—thus, **potassium silver hyponitritosulphate** is formed as a white mass, which decomposes at 25° with the evolution of red fumes, when soln. of the salt are treated with silver nitrate; and **potassium barium hyponitritosulphate,** when treated with barium chloride; the complex barium salt is soluble in a large proportion of water.

J. Pelouze obtained a soln. of **sodium hyponitritosulphate,** $NaO.N_2.NaSO_4$, and found it to possess properties like those of the potassium salt, and to be so soluble in water that he did not isolate it. E. Divers and T. Haga prepared the salt by exposing to an atm. of nitric oxide at ordinary temp., a conc. soln. of normal sodium sulphite mixed with $\frac{1}{40}$th of its weight of sodium hydroxide as a preservative. At the end of five days, the soln. was effervescing, and nearly all the sulphate was crystallized out by keeping the soln. for some time at a temp. a little below zero. The clear soln. was quickly evaporated in vacuo, when it deposited minute crystals. These were drained and dried on a porous tile. The crystalline powder was anhydrous, but contained about 1·4 per cent. absorbed water. The crystals tasted like common salt; they were slightly alkaline to litmus, and were free from sulphate and sulphite. Sodium hyponitritosulphate is, therefore, an anhydrous salt, like the potassium salt. Like the potassium salt also, although it continuously decomposes into sulphate and nitrous oxide when in neutral soln., it can be heated moderately with very little change, if some sodium hydroxide is present; when, however, such an alkaline and somewhat conc. soln. is boiled, it rapidly decomposes into sulphite and nitric oxide, and this the potassium salt does not do. It thus seems that the reversion of hyponitritosulphates into nitric oxide and sulphite is dependent on temp. alone, and is not prevented by the presence of water. It is otherwise with their decomposition into nitrous oxide and sulphate, which is caused either by water alone, or by elevation of temp. alone; for at the common temp. they can be kept for an apparently indefinite time when dry, but decompose in damp air or in soln.; on the other hand, when heated, even in dry air, they generally decompose much more in this way than into nitric oxide and sulphate. One exception to this is the potassium silver salt, which, when heated, gives only nitric oxide and sulphite (A. Hantzsch). This fact points to the latter decomposition as the primary effect of heat in all cases, and to the production of sulphate and nitrous oxide as the result of the interaction of nitric oxide and sulphite. Potassium silver sulphite not being readily oxidizable, this interaction does not occur when potassium silver hyponitritosulphate decomposes.

§ 62. Nitratosulphuric Acid and its Salts

According to C. F. Schönbein,[1] a mixture of nitric and sulphuric acids acts as a more vigorous oxidizing agent than nitric acid alone, and produces different products. If only a small proportion of nitric acid is present, and in the cold, sulphur dioxide with very little nitrogen peroxide is evolved; if more nitric acid is present, nitric oxide is given off—*vide* the action of sulphuric acid on sulphur. The soln. dissolves selenium, and phosphorus at 0° without evolution of gas, forming selenium dioxide in the one case, and phosphorous and phosphoric acids in the other; and iodine is converted into iodic acid. A. Cahours found a mixture of hydrated sulphuric acid and fuming nitric acid converts many organic substances into nitro-compounds; and M. Dietzenbacher, that it oxidizes sulphur, and arsenic in the cold; and it inflames phosphorus, and carbon. A. Rose showed that by distilling the mixed acids some nitroxylsulphonic acid is formed. Free **nitratosulphuric acid,** $HNO_3.H_2SO_4$, or $(HO)_2NO.O.HSO_3$, has not been isolated. J. Kendall, and A. V. Saposhnikoff said that conc. nitric does not form with sulphuric acid the compound supposed to exist by W. B. Markownikoff, but the mixed soln. may contain a little free nitrogen pentoxide. W. C. Holmes reported that there is a maximum on the f.p. curves of mixtures of sulphuric and nitric acid corresponding with *nitratopentasulphuric acid,* $HNO_3.5H_2SO_4$, but C. D. Carpenter and A. Lehrman showed that the compound is really a complex **dinitratosulphato-octosulphuric acid,** $2HNO_3.8H_2SO_4.SO_3$, or $10SO_3.N_2O_5.9H_2O$; and it belongs rather to the ternary system: SO_3–N_2O_5–H_2O, although it is responsible for a maximum on the f.p. curve of the binary system—Fig. 102. The solid phases in the ternary system are illustrated by Fig. 103.

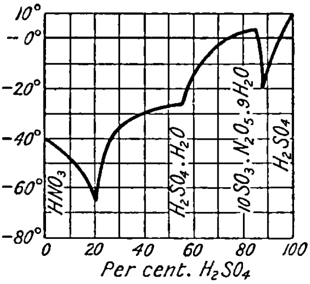

FIG. 102.—Freezing Points of the Binary System: HNO_3–H_2SO_4.

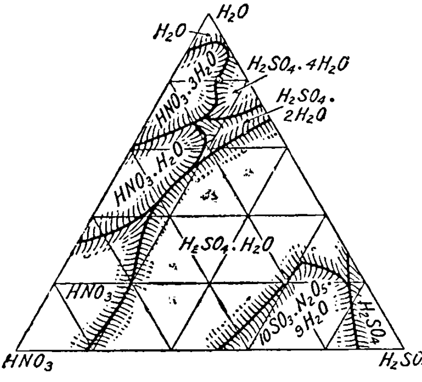

FIG. 103.—Solid Phases in the Ternary System: H_2SO_4–HNO_3–H_2O.

In the **sodium nitratosulphates** discussed in a previous volume—**2.** 20, 26, and 36—and in the potassium and ammonium nitratosulphates indicated below, C. Friedheim and J. Mozkin hold that ordinary double salts are not involved, but rather mols. with definite and atomic structures. Thus, with the potassium salt, $KNO_3.KHSO_4$, or $HNO_3.K_2SO_4$, it is argued that since no free nitric acid is given off at 140°, and water is evolved at 180°, a pyrosalt must be involved, and they express the change: $2\{KSO_3.O.NO:(OK)OH\} = KSO_3.O.NO:(OK).O(KO):ON.O.KSO_3+H_2O$. The action of a mol of sulphuric acid on two mols of ammonium nitrate in dil. soln.. followed by slow evaporation, furnished C. Friedheim and J. Mozkin with deliquescent crystals of **ammonium nitratosulphate,** $NH_4.NO_3.(NH_4)HSO_4$, or $HNO_3.(NH_4)_2SO_4$; the constitution resembles that of the potassium salt, $HO.NO(ONH_4).O.SO_2.ONH_4$. V. A. Jacquelain obtained a crop of crystals of **potassium nitratosulphate,** $KHSO_4.KNO_3$, or $K_2SO_4.HNO_3$, from a soln. of potassium sulphate in warm sulphuric acid after some crystals of potassium nitrate and hydrosulphate had separated out. The sp. gr. is 2·381, and the m.p. 150°. C. Friedheim and J. Mozkin also obtained the same salt from a soln. containing one mol of sulphuric acid and two mols of nitric acid. As indicated above, they represent the constitution $HO.NO(OK).O.SO_2.OK$.

§ 63. Nitrosylsulphonic Acid, and Hydroxynitrosylsulphonic Acid

F. Raschig[1] considered that **nitrosylsulphonic acid,** $O:N.SO_2.OH$, is formed as a transient intermediate compound in the lead-chamber process for the oxidation of sulphur dioxide by nitrous acid: $HNO_2+SO_2=NO.HSO_3$ but this reacting with more nitrous acid forms hydroxynitrosylsulphonic acid: $NO.HSO_3+HNO_2=NO+ON(OH)HSO_3$. The hypothesis was discussed by G. Lunge and E. Berl, W. Manchot, F. Raschig, and O. Wentzky. F. Raschig said that nitrosylsulphonic acid decomposes in accord with the scheme: $NO.HSO_3+H_2O=NOH+H_2SO_4$, and the hyponitrous acid breaks down into nitrous oxide and water. W. C. Reynolds and W. H. Taylor said that the alleged nitrosylsulphonic acid does not exist; dil. soln. of nitrous and sulphurous acids mutually decompose one another, giving off nitrous oxide. E. Divers said that the reaction probably proceeds in two stages: $HNO_2+2H_2SO_3=HO.N(HSO_3)_2+H_2O$, and the hydroxynitrilodisulphonic acid then decomposes $HO.N(HSO_3)_2+HNO_2=2H_2SO_4+N_2O$. If, at 0°, a dil. soln. of nitrous acid is added to two mol. proportions of sulphurous acid, no gas is evolved and the intermediate hydroxynitrilodisulphonic acid is formed—if the soln. is neutralized and concentrated, the acid can be isolated—the addition of another mol. proportion of nitrous acid furnishes nitrous oxide and sulphuric acid.

W. Manchot argued that since the absorption spectrum of the blue acid does not resemble the absorption spectra of the ferrous and cupric nitrosyl salts, it is not constituted as F. Raschig supposed. F. Raschig replied:

> A soln. of sodium nitrate in conc. sulphuric acid in the absence of air acquires under the action of mercury, copper, or silver an intense blue colour, which gradually fades; the colourless soln. contains nitrous oxide. Nitrosulphonic acid forms with a soln. of sulphur dioxide in sulphuric acid a blue soln. from which nitric oxide is quantitatively evolved, $2NO_2.SO_3H+SO_2+2H_2O=2NO+3H_2SO_4$. Nitric oxide is absorbed by copper sulphate dissolved in conc. sulphuric acid in the mol. ratio 1 : 1 at atm. temp. and press.; the conception that the dark blue soln. contains the copper salt of nitrosisulphonic acid is strengthened by the observation that hydroxylaminesulphonic acid is oxidized by monopersulphuric acid in presence of sulphuric acid and a trace of copper to a dark blue compound, whereas hydroxylamine is not similarly affected.

The *blue acid* obtained by the reduction of nitroxylsulphonic acid was assumed by P. Sabatier to be a variety of peroxylamidosulphonic acid, but T. Haga, and F. Raschig did not accept this hypothesis. F. Raschig called this acid *Nitrosisulfonsäure*, and G. Lunge and E. Berl, *Sulfonitronsäure.* M. Trautz showed that it may be regarded as an intermediate stage in the reduction of nitroxylsulphonic acid. F. Raschig showed that it is produced by reducing nitroxylsulphonic acid, $O_2N.SO_2.OH$, and consequently that it is hydroxynitrosylsulphonic acid, $ON(OH)HSO_3$, *i.e.* $O{=}N(OH).SO_2.OH$, where the nitrogen has the same valency as in nitrogen peroxide. O. Wentzky represented the acid by the constitutional formula:

$$O<\begin{matrix}N.O.HSO_3\\N.O.HSO_3\end{matrix}$$

and called it *nitrosylous sulphuric acid.* He assumed that P. Sabatier's blue acid is formed by the reaction: $2NO_2.HSO_3+H_2SO_3=H_2SO_4+O(NO.HSO_3)_2$, by the removal of an atom of oxygen from two mols of nitroxylsulphonic acid, and not, as F. Raschig supposed, by adding an atom of hydrogen to a mol of nitroxylsulphonic acid. Both E. Divers, and O. Wentzky showed that only sulphur dioxide is evolved by the action of mercury on sulphuric acid, and that magnesium, which does furnish hydrogen, does not produce the blue acid when it acts on a soln. of nitroxylsulphonic acid in sulphuric acid. As shown by W. C. Reynolds and W. H. Taylor, P. Sabatier's blue acid can be formed only in soln. containing the nitroxylsulphonic acid. The acid has not been isolated, but G. Lunge and E. Berl synthesized it in conc. sulphuric acid soln. by mixing liquid sulphur dioxide, and liquid nitrogen peroxide and water at —15°, $NO_2+SO_2+H_2O=NO(HO)HSO_3$. F. Raschig said that hydroxynitrosylsulphonic acid is stable in sulphuric acid soln. It is also formed by reducing nitrosylsulphonic acid with copper or mercury in sulphonic acid soln. The soln. is very unstable, for it quickly decomposes into nitric oxide and sulphuric acid. Hydroxynitrosylsulphonic acid forms a blue soln. with conc. sulphuric acid; with more dil. sulphuric acid, it forms a red coloration, which becomes violet when copper sulphate is added; it is very unstable, the products of its decomposition being nitric oxide and sulphuric acid. With copper and iron respectively, it forms compounds of the nature of salts, the soln. of which in conc. sulphuric acid do not give off nitric oxide on being agitated. According to F. Raschig, nitric oxide is evolved when nitrous and sulphurous acids react in the presence of a great excess of sulphuric acid; and if sulphuric acid be absent, nitrous oxide is evolved. In both cases, potassium iodide was added to show if an excess of nitrous acid was present. W. C. Reynolds and W. H. Taylor said that instead of assuming the formation of F. Raschig's nitrosisulphonic acid, the phenomena are better explained from the fact that nitrous acid and potassium iodide in the presence of a mineral acid react: $2HNO_2+2HI=2NO+I_2+2H_2O$; and if sulphurous acid be also present, it is oxidized by the iodine: $H_2SO_3+H_2O+I_2=H_2SO_4+2HI$, and the cycle is repeated. A trace of potassium iodide thus acts as a catalyst converting sulphurous into sulphuric acid at the expense of the nitrous acid. The reactions indicated above by E. Divers proceed simultaneously with these changes; and thus the gaseous product is a mixture of nitrous and nitric oxides.

In F. Raschig's theory of the lead-chamber process, nitrosylsulphonic acid is supposed to react with nitrous acid, forming this acid: $NO.SO_2.OH+HNO_2=NO+NO(OH)HSO_3$. He also made the blue acid by dissolving 10 grms. of powdered sodium nitrite in 100 c.c. of conc. sulphuric acid, and after shaking to dissolve as much of the nitrite as possible, adding 10 grms. of sodium hydrosulphite, when the yellow soln. becomes blue. If the blue colour does not soon appear, add 10 c.c. of cold water. The blue acid soln. was also made by passing nitric oxide into a mixture of 10 c.c. of a sat. soln. of copper sulphate and 200 c.c. of conc. sulphuric acid. The reaction does not occur in the absence of the cupric sulphate, although ferrous sulphate does quite well. The blue acid soln. was obtained by F. Raschig by the oxidation of a soln. of 1·35 grms. of sodium hydroxynitrilomonosulphonate in 2 c.c. of water by mixing it with 10 c.c. of N-$CuSO_4$ and 100 c.c. of conc. sulphuric acid. The blue colour soon vanishes because the oxidation continues until nitroxylsulphonic acid is formed. E. Scandola said that the blue acid is best obtained by mixing conc. sulphuric acid with a few drops of nitric acid and some drops of alcohol; and then with a cold conc. soln. of copper sulphate, and heating. A. Guremann obtained the violet soln. about the cathode during the electrolytic reduction of a soln. of 0·00316 grm. nitrogen trioxide per c.c. of sulphuric acid of sp. gr. 1·837 using a current 0·1 amp. and 4 volts. The possible part played by hydroxynitrosylsulphonic acid in the lead-chamber process for sulphuric acid has been discussed by G. Lunge and E. Berl, and S. Littmann. J. W. Döbereiner observed a violet-blue coloration is produced during the reduction of nitroxylsulphonic acid by the metals, and F. Raschig said that a soln. of nitrosylsulphonic acid in sulphuric acid, or sodium nitrite in a great excess of conc. sulphuric acid is coloured violet-blue, and a little nitric oxide is evolved, when treated with numerous organic and inorganic reducing agents—*e.g.* sulphurous acid, hypophosphorous acid, mercury, etc.

Cuprous oxide, chloride, bromide, iodide, or thiosulphate, or cuprosic salts, or reduced copper effect the reduction in a decisive manner. The reaction is very slow with copper foil. F. Raschig agitated a soln. of 69 grms. of sodium nitrite in a litre of conc. sulphuric acid, with much copper-foil for 15 minutes, and obtained the violet-blue acid; he also added nitroxylsulphonic acid to a mixture of 10 c.c. of a sat. soln. of copper sulphate with 200 c.c. of conc. sulphuric acid, and agitated the mixture after the addition of mercury. This soln. of hydroxynitrosylsulphonic acid is fairly stable; it is oxidized by potassium permanganate to nitroxylsulphonic acid without the evolution of gas; it is likewise oxidized by a $\frac{1}{10}N$-soln. of nitric acid in conc. sulphuric acid. G. Lunge and E. Berl said that hydroxynitrosylsulphonic acid is not oxidized by oxygen alone, but it is instantly oxidized by nitrogen peroxide at −15°. F. Raschig found that the blue coloration is produced in a soln. of nitroxylsulphonic acid in sulphuric acid by silver, cadmium, mercury, aluminium, tin, lead, and antimony. The blue produced with cobalt is very unstable, while zinc, phosphorus, bismuth, sulphur, chromium, and uranium produce no blue coloration. Magnesium, thallium, arsenic, and reduced nickel are very active chemically, but give no blue coloration. Selenium and tellurium react as with sulphonic acid alone. No positive results were obtained with arsenic and antimony trioxides; mercurous and chromous chlorides; manganous and stannous oxides; carbon disulphide; zinc, tin, arsenic, and bismuth sulphides; potassium ferrocyanide; urea; oxalic, tartaric, and citric acids and their salts. A blue coloration is produced by zinc and arsenic phosphides, and barium hypophosphite, and less marked blue colorations are obtained with lead sulphide or stannous chloride. A vigorous reaction attended by the development of a blue ring occurs with alcohol, ether, glycerol, and acetic acid. Iron and the ferrous compounds are very effective—*e.g.* iron, ferrous chloride, sulphate, oxalate, and sulphide—while the ferric compounds are inactive. The coloration which nitric oxide produces with cupric salts was observed by E. Desbassayns de Richemont, and that with ferrous salts by V. A. Jacquelain—*vide supra,* nitric oxide. O. Wentzky considers that the acid is strong enough to displace sulphuric acid from copper sulphate, forming **copper hydroxynitrosylsulphonic acid,** $O:(N.O.SO_3)_2:Cu$. The copper and ferrous compounds have been discussed in connection with the solubility of nitric oxide in ferrous and cupric salt soln. E. Scandola found that hydroxynitrosylsulphonic acid in contact with methyl, ethyl, propyl, isobutyl, or isoamyl alcohol gives a positive reaction; octyl alcohol gives an uncertain reaction, but at a higher temp. a blue coloration is formed, whilst cetyl alcohol does not react. Isopropyl and secondary butyl alcohols both give the reaction, but methyl alcohol forms a resin. Tertiary butyl and tertiary amyl alcohols react easily at the ordinary temp. without the formation of blue compounds, which seem to appear on heating the alcohols with amyl alcohol at 140°–150°. Glycerol, mannitol, erythritol, and many carbohydrates give the reaction; allyl alcohol forms only a brown resin. Lactic, malic, and tartaric acids react easily, citric acid with difficulty, whilst benzyl and cinnamyl alcohols become resinous. Nitroethane and butane give a positive, nitromethane a negative result; in the same way, nitrobenzene, nitrotoluene, and trinitrophenol do not react. The ethers behave like the alcohols; of the aldehydes only formaldehyde gives the reaction; others become resinous without turning blue. Chloral neither becomes resinous nor gives the reaction; acetone immediately gives a brown resin; the results were negative in the case of benzaldehyde and salicylaldehyde, also with formic, acetic, oxalic, benzoic, and cinnamic acids, but positive with the esters of the acids. Carbamide and uric acid give no reaction; phenol gives a reddish-brown to a bluish-green coloration, which is different from the lustrous colour of copper hydroxynitrosylsulphonate. Anisic acid gives the reaction. The mechanism of the formation of nitrosylsulphonic acid by the decomposition of alkyl nitrates and nitrites can be explained by a reaction between the ester and the acid which leads to the formation of alkyl sulphuric acids; these form addition or condensation products of nitric acid with the sulphonic acid.

P. Sabatier found that when nitric acid or nitrogen oxides are dissolved in sulphuric acid containing sulphur dioxide, and the soln. is exposed to moist air, there are indications of the formation of a dark blue compound. If a mixture corresponding with $4NO+O_2$ is passed into sulphuric acid, sat. with sulphur dioxide, and cooled at 0°, the liquid remains colourless, but when water is added very slowly, a dark blue soln. is formed. Similarly, when a mixture of air and nitric oxide is passed into monohydrated sulphuric acid, sat. with sulphur dioxide, and cooled to 0°, the bluish-violet soln. is formed at once with vigorous effervescence. With more conc. sulphuric acid, the liquid is at first colourless, and slowly develops the bluish-violet colour. It was thought by P. Sabatier that peroxylamidosulphonic acid was formed, but there is no real evidence of this. The blue acid decomposes spontaneously into sulphuric acid, sulphur dioxide, and nitric oxide, but it is more stable than E. Frémy's potassium peroxylamidodisulphonate, and does not decompose rapidly even at 100°.

When agitated with air or mixed with hydrogen dioxide, persulphuric acid, nitric acid, chlorine, or potassium chlorate, hydroxynitrosylsulphonic acid is rapidly decolorized. Potassium perchlorate and bromine act more slowly. Alkali chlorides are immediately decomposed with evolution of hydrogen chloride and chlorine; potassium iodide at once decolorizes the liquid, and iodine is liberated. Sulphurous acid is without action; water at once decomposes the blue compound. Most metallic oxides and carbonates decompose the soln. of nitrosodisulphonic acid, and are converted into sulphates. Ferric oxide, however, gives a wine-red soln., and the same compound is formed by placing metallic iron or a conc. soln. of ferrous chloride or sulphate, or some particles of ferrous oxalate into the acid. Ferric salts do not give this coloration. Cupric carbonate, oxide, or hydroxide, metallic copper, or any cuprous salt yields an intense blue-violet coloration. With copper or cuprous salts, nitric oxide is liberated. Chromic hydroxide also yields a very deep blue-violet soln., but chromium and chromous salts have no action. In all these cases, the colour of the soln. of the salts is very much more intense than that of the acid, and the soln. themselves are more stable. A soln. of nitrososulphonic acid or sodium nitrite in sulphuric acid is reduced not only by cuprous and ferrous salts, but also by a large number of other substances, with production of the blue nitrosodisulphonic acid. Mercury acts very rapidly, but also readily decomposes the nitrosodisulphonic acid. Finely divided silver, tin, and aluminium behave in the same way, and so also do cadmium, antimony, and lead, although much more slowly. Zinc, even in powder-form, bismuth, chromium, uranium, sulphur, phosphorus, nickel, arsenic, thallium, and magnesium react more or less readily, but do not produce the blue compound. Selenium and tellurium behave as with sulphuric acid alone. Arsenious anhydride, antimonous, manganous, and stannous oxides, mercurous and chromous chlorides, carbon bisulphide, and arsenic, bismuth, tin, and zinc sulphides, potassium ferrocyanide, carbamide, and oxalic, tartaric, and citric acids give no distinct result. On the other hand, the blue product is readily produced by zinc phosphide or arsenide, and by barium hypophosphite, less readily by lead sulphide and stannous chloride. Alcohol, ether, glycerol, and even acetic acid will produce a blue ring if added to the hydroxynitrosylsulphonic acid soln. The salts are more stable than the acid, and if a cupric salt or a ferric salt is dissolved in the nitrososulphonic acid soln. and the reducing agents are then allowed to act, the colour produced is much more intense, and it is observed with substances such as arsenic and zinc sulphides, bismuth, zinc powder, etc., which do not seem to act under ordinary conditions. Sulphur dioxide reduces the hydroxynitrosylsulphonic acid only in presence of water. The blue compound is formed, for instance, if sulphur dioxide is dissolved in sulphuric acid dil. with one-third of its vol. of water, and this liquid is added to an equal vol. of the hydroxynitrosylsulphonic acid soln. The copper salt is formed by adding copper nitrite to a soln. of sulphur dioxide in sulphuric acid containing a small quantity of water. P. Sabatier obtained unstable **lead nitrosylsulphonate,** $Pb(ON)(SO_3)_2$, by adding lead oxide, hydroxide, or carbonate to a blue soln. of the acid $NO(HSO_3)_2$. Much lead sulphate is precipitated. The salt is not stable in the presence of conc. sulphuric acid.

F. Raschig tried to prove that P. Sabatier's blue acid is the same as hydroxynitrosylsulphonic acid, and that when nitric oxide is passed into a soln. of copper sulphate, in conc. sulphuric acid, the product is

$$O{=}N<\begin{matrix}O\\SO_2\end{matrix}>Cu$$

He said that hydroxynitrosylsulphonic acid is produced by the action of sulphur dioxide on nitrous acid in 70 per cent. sulphuric acid as a direct product of the interaction of nitrous and sulphurous acids, and not by the reduction of chamber crystals—nitroxylsulphonic acid—because he supposed that the latter cannot exist in less than 80 per cent. sulphuric acid. This assumption was shown, by W. C. Reynolds and W. H. Taylor, to be unfounded; nitroxylsulphonic acid can exist in the presence of even 60 per cent. sulphuric acid. Further, the blue colour produced by the action of sulphurous acid, or other reducing agent, on a nitrite in the presence of a conc. sulphuric acid soln. of a copper salt, was supposed by F. Raschig to be the copper salt of P. Sabatier's acid, whereas, according to W. C. Reynolds and W. H. Taylor, the product is the complex which nitric acid forms with copper sulphate, and studied by W. Manchot, V. Kohlschütter, etc.—*vide supra*. The existence of F. Raschig's nitrosylsulphonic acid may therefore be questioned, and the same remark applies to his statement of the identity of P. Sabatier's blue acid with the product of the reaction of nitrous and sulphurous acids in the presence of a copper salt.

§ 64. Nitroxylsulphonic Acid or Nitrosylsulphuric Acid

This compound was was first reported by F. Clément and C. B. Désormes[1] to be formed in the lead-chamber during the manufacture of sulphuric acid, and hence it is called *chamber-crystals* or *lead-chamber crystals*. F. Raschig called the compound *Nitrosulfosäure*, and it has also been called **nitrosylsulphuric acid,** regarded as constituted $NO.O(HSO_3)$; it can also be called **nitroxylsulphonic acid,** if it be constituted $HO.SO_2.NO_2$, or $NO_2(HSO_3)$. The former hypothesis is fashionable because it is the more probable one. The compound was synthesized by H. Davy, and was described by J. Dalton. V. Lenher and J. H. Mathews could not prepare **nitrosylselenic acid,** $HO.SeO_2.O.NO$; but they did get **dinitroxylselenyl,** $NO_2.SeO_2.NO_2$, or $SeO_2(O.NO)_2$, by the action of nitrogen peroxide on conc. selenic acid cooled by solid carbon dioxide. The dark blue solid melts at —13°, and decomposes above this temp. into nitrogen peroxide and selenic acid. J. Meyer and co-workers, however, prepared nitrosylselenic acid, $NO.O.SeO_2.OH$, by the action of a large excess of liquid nitrogen trioxide on ice-cold, anhydrous selenic acid. The colourless, snow-like mass melts with decomposition at 80°. It is somewhat unstable at atm. temp., and is decomposed by water.

Preparation of nitroxylsulphonic acid from sulphuric acid and nitrogen oxides.—G. Aimé, H. Rose, and F. Kuhlmann showed that anhydrous sulphuric acid absorbs nitric oxide. Nitroxylsulphonic acid is produced when conc. sulphuric acid is treated with one of the nitrogen oxides other than nitrous oxide. Thus, A. Bussy, F. H. de la Provostaye, O. Henry and A. A. Plisson, and C. A. Winkler used nitric oxide, or a mixture of nitric oxide and oxygen—but, according to J. J. Berzelius, and J. L. Gay Lussac, nitric oxide is not absorbed by the acid; C. Weltzien, dry nitrogen trioxide; J. L. Gay Lussac, A. Rose, and R. Weber, nitrogen peroxide: $N_2O_4+H_2SO_4=HNO_3+NO_2HSO_3$, and, added H. G. de Claubry, the formation of crystals is much accelerated if the vessel be filled with nitric oxide. A. Rose distilled a mixture of conc. nitric and sulphuric acids and obtained as a residue a soln. of nitrosylsulphonic acid in sulphuric acid, and M. Scanlan distilled a mixture of potassium nitrate in conc. sulphuric acid and obtained a crystalline mass towards the end of the operation. This was thought to be a potassium salt by the acid. He also found that if potassium nitrite be dissolved in sulphuric acid, the soln. has all the reactions of a soln. of nitroxylsulphonic acid in sulphuric acid. G. B. Taylor and co-workers represent the reaction: $2NO_2+H_2SO_4=HNO_3+NOHSO_4$. According to A. Sanfourche, a mixture of equimolar proportions of nitric oxide and nitrogen peroxide behaves towards sulphuric acid like nitrogen trioxide. Although the proportion of the trioxide actually formed is small, yet it serves as an intermediate compound in the soln.: $NO+NO_2=N_2O_3$; and $N_2O_3+2H_2SO_4=H_2O+2(NO.HSO_4)$.

Preparation from sulphur trioxide, nitrogen oxides, and water.—J. W. Döbereiner obtained nitroxylsulphonic acid by bringing the vap. of sulphur trioxide in contact with fuming nitric acid; H. G. de Claubry obtained it from a mixture of sulphur trioxide, nitrogen peroxide, and a little water; and F. Kuhlmann, by allowing monohydrated nitric acid, cooled by a freezing mixture, to absorb the vap. of sulphur dioxide. When the liquid thus obtained is distilled, it first evolves oxygen and nitrogen peroxide, and afterwards a sublimate of white needles collects, and the residue is a soln. of nitroxylsulphonic acid in sulphuric acid.

Preparation from a mixture of sulphur dioxide, nitrogen oxides with or without oxygen, and a little water.—G. Lunge found that nitric oxide and sulphur dioxide do not react at 100°, and that the two gases react in the presence of water and in the absence of oxygen, so that in a few hours the nitric oxide is all reduced to nitrous oxide, but not to nitrogen; but if dil. sulphuric acid, sp. gr. 1·32, is employed instead of water, the reduction does not occur; instead, the nitric oxide, sulphur dioxide, and water react to form nitroxylsulphonic acid. According to H. Davy, a mixture of sulphur dioxide, nitrogen peroxide, and water produces crystals of nitroxylsulphonic acid; but sulphur dioxide has no action on nitric oxide, nor on nitrogen peroxide vap. so long as water is not present—the admission of a trace of water then leads to the formation of the crystals of nitroxylsulphonic acid. C. A. Winkler also said that nitrogen peroxide and sulphur dioxide in an atm. of carbon dioxide react only in the presence of moisture. H. Reinsch observed the formation of crystals of nitroxylsulphonic acid when a mixture of sulphur and potassium nitrate (1 : 3) is inflamed under a large bell-jar. According to H. G. de Claubry, liquid sulphur dioxide mixes, but does not react with liquid nitrogen peroxide at —20°, but on the addition of a single drop of water, there is a violent disengagement of gas attended by the formation of crystals of nitroxylsulphonic acid. The crystals can be washed with liquid nitrogen peroxide, and dried in vacuo or in a stream of air at 20°–30°. The reaction was also studied by F. H. de la Provostaye, R. Müller, and G. Lunge and E. Berl. If a mixture of dried nitrogen peroxide and sulphur dioxide be passed into a large flask whose interior is moistened with a layer of conc. sulphuric acid, crystals of this acid are formed. F. Sestini also noticed that if sulphur dioxide be dropped into nitric acid, red fumes are evolved and crystals of nitroxylsulphonic acid are formed; and R. Weber prepared the acid by passing sulphur dioxide into well-cooled fuming nitric acid until a mush of crystals is formed, but not until the nitric acid is all decomposed. The crystals are dried on porous tiles over conc. sulphuric acid. W. A. Tilden made nitroxylsulphonic acid by leading nitrosylchloride (by heating aqua regia) into conc. sulphuric acid.

Analyses in agreement with the empirical formula $NO_2.HSO_3$ were made by W. Henry, H. G. de Claubry, T. Thomson, C. Weltzien, R. Müller, and R. Weber. The products obtained by several different methods of preparation were found by G. A. Elliott and fellow-workers to furnish a substance with the same crystalline form, and m.p. Fractional crystallization from sulphuric acid did not effect any change. Hence, the existence of non-dynamic isomerides is improbable, although the acid may be tautomeric. F. Raschig preferred the formula *nitrosylsulphuric acid*, $O:N.O.SO_2.OH$, to *nitroxylsulphonic acid*, $HO.SO_2.NO_2$, since, as C. A. Michaelis and O. Schumann showed, it reacts with phosphorus pentachloride: $NO.O.HSO_3+PCl_5=H(Cl)SO_3+NOCl+POCl_3$; and, according to C. A. Girard and J. A. Pabst, with sodium chloride, or bromide, forming the respective nitrosyl halide. The analogies with $NH_2OH+HO.HSO_2=NH_2.SO_2.OH+H_2O$, and $HO.NO_2+HO.HSO_2=H_2O+NO_2.HSO_3$, also favour the $NO.O.HSO_3$ formula. He also cited as evidence in favour of this formula the oxidation of hydroxyimidomonosulphonic acid by Caro's acid to form hydroxynitrosylsulphonic acid (*q.v.*). According to L. H. Milligan and G. R. Gillette, nitroxylsulphonic acid made from nitrous and sulphuric acids: $HNO_2+H_2SO_4\rightleftharpoons NOHSO_4+H_2O$, may be regarded as nitrous acid stabilized by soln. in conc. sulphuric acid; for when solid nitrosylsulphuric acid crystallizes from the soln., it is simply that the system has become supersaturated with respect to this particular compound, under the conditions of the experiment. The dilution of the sulphuric acid with water decreases the stability of the nitrosylsulphuric acid; nitrous acid is re-formed, and is decomposed at least partially into nitric oxide and nitric acid. G. Lunge and E. Berl said that the formation of the acid from sulphur dioxide and nitric acid favours the nitroxyl formula; while its formation from sulphuric acid and nitrogen trioxide favours the nitrosyl formula. In many of its reactions, the acid behaves like a nitrosyl-compound. W. A. Tilden showed that the crystallized acid furnishes nitrosyl chloride and sulphuric acid when treated with hydrogen chloride at ordinary temp. The reaction is reversible. This agrees with the assumption that the acid contains the nitrosyl-group, and this is more definitely suggested by the reaction between the acid and benzoyl chloride, producing according to G. A. Elliott and co-workers, dibenzoylsulphuric acid, $SO_2(O.CO.C_6H_5)_2$, the formation of which can be explained only on the assumption that the acid contains both a hydroxyl and nitrosyl group. The first stage of the reaction can be symbolized: $HO.SO_2.O.NO+C_6H_5CO.Cl=NOCl+HO.SO_2.O.CO.C_6H_5$, and the second stage: $C_6H_5CO.Cl+HO.SO_2.O.CO.C_6H_5=HCl+C_6H_5.CO.O.SO_2.O.CO.C_6H_5$. The action of acetyl chloride, and of acetic anhydride investigated by A. J. van Peski, yielded similar evidence. G. A. Elliott found that nitroxylsulphonic acid reacts with ether, producing ethyl nitrate, and hydrosulphate: $(C_2H_5)_2O+HO.SO_2.O.NO=C_2H_5.HSO_4+C_2H_5.O.NO$; ethyl hydrosulphate and soln. of nitroxylsulphonic acid gave no nitroethane as would be expected to result if the acid had the NO_2-structure. G. A. Elliott and co-workers agree with J. Biehringer and W. Borsum that both *p*-nitro- and *p*-nitrosodimethylaniline are produced by the action of a sulphuric acid soln. of dimethylaniline on solid sodium nitrite; and they observed in addition that (i) the percentage yield of the *p*-nitro-derivative increases with the excess of nitroxylsulphuric acid used in the reaction mixture. (ii) If an excess of dimethylaniline is used, no oxides of nitrogen are produced by pouring the mixture on ice and no *p*-nitro-derivative is obtained. (iii) When an excess of nitroxylsulphuric acid is present, and the mixture is poured into absolute alcohol or dry ether, no *p*-nitro-derivative is obtained. Both these solvents rapidly decompose nitroxylsulphuric acid, forming ethyl nitrite and ethyl hydrogen sulphate.

(iv) When crystalline nitroxylsulphuric acid is added to a soln. of dimethylaniline in dil. sulphuric acid (2*N*-), in which the former acid is immediately decomposed, both the *p*-nitro- and the *p*-nitroso-derivative are obtained. (v) If a soln. of dimethylaniline in conc. sulphuric acid is added to a dil. soln. of nitric acid (10 per cent.) or of potassium nitrite (5 per cent.), the *p*-nitro-derivative is formed. (vi) No sulphur dioxide could be detected in any of the experiments. All these facts are in accord with the view that the *p*-nitrodimethylaniline is not produced by the action of a presumed nitrosulphonic acid, but is a secondary product obtained by pouring the reaction mixture on ice, and is produced either by secondary oxidation of the nitroso-compound or by direct nitration of the dimethylaniline. The results of J. Biehringer and W. Borsum do not establish, therefore, the existence of nitroxylsulphonic acid or the possibility of tautomerism.

The fact that no salts—**nitroxylsulphonates**—have been prepared from nitroxylsulphonic acid might serve as an argument that it is not an acid at all. C. Schultz-Sellack obtained what can be regarded as **potassium nitroxylsulphonate,** $KSO_3.NO_2$, or $KO.SO_2.O.NO$, so far as mere composition goes, by the action of dry liquid sulphur dioxide on potassium nitrate; it is decomposed by a trace of water. There is no definite evidence of the conversion of the acid into **nitroxylsulphonic anhydride,** $(NO.O.SO_2)_2O$, although E. Berl said that it is formed by the action of nitric oxide on sulphur trioxide, or of sulphur dioxide on well-cooled nitrogen pentoxide.

While favouring the formula $HO.SO_2.O.NO$ rather than $HO.SO_2.NO_2$, G. A. Elliott and co-workers said that the structure

$$SO_2<^{O}_{O}>N.OH$$

merits consideration, because (i) an acid of this type would lose water on heating to give an anhydride of the structure $SO_2=O_2=N.O.N=O_2=SO_2$, a change which is parallel to the conversion of nitric acid into nitrogen pentoxide. (ii) It offers an explanation of the great difficulty of replacing both the hydroxyl groups of sulphuric acid by the nitroso-group. (iii) The structure is in accord with the methods of synthesis of the acid. (iv) The behaviour of the acid on reduction is more in accord with this structure than with the nitroso-structure. (v) The synthesis of the anhydride from sulphur dioxide and nitrogen pentoxide, observed by E. Berl, is readily explicable in terms of the above formula:

$$SO_2+{}^{O}_{O}\geqslant N.O.N\leqslant^{O}_{O}+SO_2=O_2S<^{O}_{O}>N.O.N<^{O}_{O}>SO_2 \quad \text{(iii)}$$

and so is the production of the anhydride from nitrogen tetroxide and sulphur dioxide observed by F. G. de la Provostaye, in which reaction nitrogen trioxide is a by-product:

$$SO_2+{}^{O}_{O}\geqslant N.O.N:O+O:N.O.N\leqslant^{O}_{O}+SO_2=O_2S<^{O}_{O}>N.O.N<^{O}_{O}>SO_2+N_2O_3$$

J. Biehringer and W. Borsum suggested that nitrosylsulphuric acid exists in two tautomeric forms, $HO.SO_2.O.NO \rightleftharpoons HO.SO_2.NO_2$, which are in equilibrium in conc. sulphuric acid soln. and in the molten state. In support of this, they found that in some cases it can react simultaneously as two different acids, for, when a soln. of dimethylaniline in conc. sulphuric acid is slowly treated with the requisite amount of sodium nitrite, both *p*-nitrodimethylaniline and *p*-nitrosodimethylaniline are produced, the former represents the nitrosyl-acid and the latter the nitroxyl-acid. At 10° to 15°, the yields are respectively 8·33 and 7·45 per cent., and at 28° to 30°, 42·85 and 39·33 per cent. This shows that the nitrosyl-form of the acid is favoured at the higher temp.

J. L. Gay Lussac described the crystals as four-sided prisms; G. A. Elliott and co-workers, and R. Müller, as rhombic prisms; and F. H. de la Provostaye, as colourless, transparent, laminated, feathery, or granular masses of crystals. C. Weltzien said the acid melts at 73° giving off red vapours; and G. A. Elliott and co-workers said that the rhombic prisms melt at 73·5°; while W. A. Tilden gave 85°–87° for the m.p. F. H. de la Provostaye found that an oily liquid is produced when the acid is heated, and the more the crystals are contaminated with sulphuric acid the lower the m.p. Fusion occurs at 60°, and the liquid may be under-cooled to 10°, and it then solidifies when shaken, and much heat is evolved, which, according to W. Henry, T. Thomson, and H. G. de Claubry, causes the acid to decompose. The last-named also found that at 50°, the crystals begin to give off nitric oxide and nitrogen peroxide; the remaining solid softens at 100° and fuses between 120° and 130°, disengaging at the same time much nitrogen peroxide; at 200° a little nitric acid is also given off; at 280°, nitric acid is still evolved and the yellowish-red liquid is transparent; and at 357°, nearly colourless sulphuric acid collects as a distillate which gives off nitric oxide when treated with water. W. Henry said the crystals do not decompose at 104·4°, and they give off gas at 138°. These various statements are so much at variance that if the thermometers were right, the compounds tested were chemically different. C. A. Michaelis and O. Schumann considered that dinitrosylpyrosulphuric acid is formed at an intermediate stage in the thermal decomposition of nitroxylsulphonic acid: $NO_2.SO_2.\boxed{OH+H}O.SO_2.NO_2 \rightleftharpoons NO_2.SO_2.O.SO_2.NO_2+H_2O$. G. A. Elliott added that the reaction $NO.O.SO_2.OH+NO.O.SO_2.OH \rightleftharpoons NO.O.SO_2.O.SO_2.OH+HNO_2$ is also possible, but the change in the nitrous acid content of the system favours the former hypothesis. H. I. Schlesinger and A. Salathe studied the absorption spectrum of nitroxyl sulphuric acid. G. B. Taylor and co-workers represented the result of electrolyzing nitroxylsulphonic acid in a partitioned cell by: $NOHSO_4+2H_2O=HNO_3+H_2SO_4+H_2+2$ farads. In practice, the nitric acid or nitroxysulphonic acid diffuses through the diaphragm, and is reduced to nitric oxide and some free nitrogen.

W. Henry said that nitroxylsulphonic acid stains the skin yellow. G. Lunge and E. Berl discussed the possible *rôle* played by this compound as a carrier of oxygen in the manufacture of sulphuric acid by the chamber process. The crystals rapidly dissolve in **water** with the disengagement of heat, and the evolution of nitric oxide, and there remains sulphuric acid with much nitric oxide in soln.—the gas is expelled by boiling the liquid, but in air, some nitric oxide is converted into nitrogen peroxide which forms nitric acid—according to W. Henry; and both nitric and nitrous acids, according to H. G. de Claubry. If air be excluded, A. Rose, and T. Thomson showed that the sulphuric acid is free from nitric acid. C. F. Rammelsberg and J. Philipp represented the reactions by: $16NO_2HSO_3+9H_2O=16H_2SO_4+4NO+2HNO_3+5N_2O_3$, an equation which looks more like an algebraic exercise than a representation of a chemical process. According to G. Lunge, nitrous acid is first formed: $NO_2HSO_3+H_2O=H_2SO_4+HNO_2$; the nitrous acid then decomposes: $3HNO_2=HNO_3+2NO+H_2O$; and if a very small proportion of water is used, $2NO_2HSO_3+H_2O=2H_2SO_4+N_2O_3$. According to S. L. Dana, less red vapours are developed if the reaction occurs in an atm. of an inert gas—carbon dioxide, hydrogen or nitrogen—and the soln. appears at first blue, then green, and lastly yellow. When the crystals are laid on snow, they melt, and sinking in the snow, impart to it a dark blue colour, while the temp. may fall down to −26·7°, when no further action takes place. C. A. Girard and J. A. Pabst's observations on the action of **sodium chloride and bromide** have been discussed above. J. W. Döbereiner showed that when the soln. of nitroxylsulphonic acid in sulphuric acid is distilled with **sulphur,** it yields nitric oxide, sulphur dioxide, and a white sublimate; and when treated with **hydrogen sulphide,** sulphur with a red colour is first precipitated, the colour then turns yellow, and sulphur dioxide is rapidly evolved. E. Frémy said that **sulphur dioxide** decomposes the crystals of nitroxysulphonic acid, forming nitrous oxide; and, according to R. Weber, the soln. of nitroxylsulphonic acid in sulphuric acid is partly decomposed by that gas, and G. Lunge represents the reaction: $2NO_2HSO_3+SO_2+2H_2O \rightleftharpoons 2NO+3H_2SO_4$. E. Sorel found that at a high temp., with a deficiency of oxygen and an excess of water, nitroxylsulphonic acid is reduced, while at a low temp., with plenty of oxygen, and conc. acid, nitroxylsulphonic acid is formed. The solubility of nitroxylsulphonic acid in **sulphuric acid** was observed by J. W. Döbereiner, J. J. Berzelius, R. Weber, S. L. Dana, and R. Müller. The solubility is greater the more conc. the sulphuric acid, and increases with the temp., so that by cooling the hot sat. soln. crystals separate out, and R. Müller found that they are but slightly decomposed. G. A. Elliott and co-workers found that the solubility, *S* grms. of nitroxylsulphonic acid per 100 grms. of soln., in sulphuric acid containing *p* per cent. H_2SO_4, is:

	p . . .	56·7	62·1	73·1	74·9	84·1	90·4	99·8
S at	0·0° .	—	11·9	17·3	19·7	30·5	35·1	—
	20·0° .	19·3	22·6	27·0	31·4	42·4	49·2	62·0
	37·3° .	29·9	34·3	39·4	40·8	50·2	58·5	66·1
	49·6° .	35·6	39·3	46·0	46·2	56·5	61·6	67·8

G. Lunge and E. Weintraub showed that when nitrogen peroxide is mixed with sulphuric acid, nitroxylsulphonic acid and nitric acid are formed, but since the reverse change may also occur, the mixture contains all four compounds, and a state of equilibrium is attained. (1) When sulphuric acid of sp. gr. 1·84 is employed, the conversion of nitrogen peroxide into nitroxylsulphonic and nitric acids is the main reaction, the reverse reaction only coming into prominence when the quantity of sulphuric acid is small. (2) The affinity of sulphuric acid for nitric peroxide decreases rapidly as the amount of water is increased, hence with sulphuric acid of sp. gr. 1·65 a large proportion of the peroxide remains uncombined, although the quantity of nitric acid present is small. (3) In the manufacture of sulphuric acid, the nitrogen peroxide is almost completely converted into nitroxylsulphonic acid and nitric acid, owing to the presence of a large excess of sulphuric acid, and similarly, nitrous fumes are completely absorbed by a large excess of sulphuric acid. R. Weber showed that the soln. of nitroxylsulphonic acid in sulphuric acid can be distilled without losing nitrous acid. G. Lunge also made some observations on this subject. G. A. Elliott and co-workers did not succeed in dehydrating nitroxylsulphonic acid by cooling a sat. soln. in 98 per cent. sulphuric acid at 50°. Nitroxylsulphonic acid, indeed, can exist in sat. soln. in sulphuric acid at 300°. This is remarkable in view of the loss of water when sulphuric acid alone is heated. H. I. Schlesinger and A. Salathe measured the absorption spectrum of sulphuric acid soln. of nitroxylsulphonic acid. T. Thomson observed that no decomposition occurs when nitroxylsulphonic acid is triturated with **ammonium carbonate**; and J. Pelouze, that **ammonium sulphate** reacts with a soln. of nitroxylsulphonic acid in conc. sulphuric acid at 160°, giving off nitrogen gas. J. W. Döbereiner found that with the same acid menstruum at 62° **phosphorus** inflames with the emission of red sparks. G. A. Elliott and co-workers found that with **phosphorus pentoxide**, no anhydride is formed—nitroxylsulphonic acid is the main product, being probably formed by a recombination of the products of decomposition during the distillation. C. A. Michaelis and O. Schumann's observations on the action of **phosphorus pentachloride** have been already described.

H. G. de Claubry found that when nitroxylsulphonic acid is heated with **mercury,** there is formed mercuric sulphate, sulphur dioxide, nitric oxide, and nitrogen; and G. Lunge said that when a soln. in conc. sulphuric acid is shaken with mercury, nitric oxide and sulphuric acid are quantitatively formed; and F. Raschig observed that the reaction is completely inhibited by mercury, possibly with the formation of hydroxynitrosylsulphonic acid. A. Graire found that the acid is not reduced further than nitric oxide by agitation with mercury; but if sulphur dioxide is present, some nitrous oxide may be formed. J. W. Döbereiner found that a soln. of nitroxylsulphonic acid in conc. sulphuric acid oxidizes mercury; **copper, silver, zinc,** and **iron,** and the liquid is coloured red, violet-blue, or purple; and J. J. Berzelius added that nitric oxide is at the same time evolved. J. W. Döbereiner also found that **ferrous sulphide** is coloured a bright red. H. G. de Claubry showed that when nitroxylsulphonic acid is treated with **manganese oxide,** the solid becomes red-hot; and with **barium oxide,** the reaction is more vigorous, forming barium mono- and di-oxides, sulphate, and nitrate; while J. W. Döbereiner found that when **potassium hydroxide, calcium oxide,** or **magnesium oxide** is mixed with a soln. of nitroxylsulphonic acid in sulphuric acid, much heat is evolved, and nitric oxide is vigorously evolved; with **potassium nitrate,** there is much frothing, and nitrogen peroxide is given off. T. Thomson showed that when nitroxylsulphonic acid is triturated with **potassium hydrocarbonate,** nitric oxide is evolved which gives red fumes in air, and finally a mush is produced which contains the alkali carbonate, sulphate, and a trace of nitrate. J. W. Döbereiner observed that a soln. of nitroxylsulphonic acid in sulphuric acid is decomposed by **alcohol, ether, sugar, or starch.**

§ 65. Nitrosyl and Nitroxyl Compounds of Pyrosulphuric Acid

H. Rose,[1] G. Aimé, and F. Kuhlmann showed that sulphur trioxide absorbs nitric oxide, forming **dinitrosylpyrosulphuryl,** $N_2O_3.2SO_3$, or $NO.O.S_2O_5.O.NO$, according to A. Brüning, $3SO_3+2NO=SO_2+N_2O_3.2SO_3$. A. Morren claimed to have obtained the same product by passing a silent discharge through a dry mixture of oxygen, nitrogen, and sulphur dioxide; and M. Chevrier, and M. Berthelot obtained it by the action of the electric discharge on a mixture of sulphur vapour and nitrous oxide. According to F. H. de la Provostaye, when a mixture of liquid sulphur dioxide and nitrogen peroxide is sealed in a glass tube at ordinary temp., heat is evolved, and a greenish liquid is formed which deposits crystals of this compound. When the tube is opened, an explosion occurs unless the tube is surrounded by a freezing mixture. No reaction occurs between the liquids under atm. press. When sulphur trioxide is brought in contact with a liquid mixture of sulphur dioxide and nitrogen peroxide, this compound is immediately formed. G. Lunge and E. Berl consider that the product of the reaction between liquid sulphur dioxide and nitrogen peroxide is not this substance at all, but hydroxynitroxysulphonic acid—*vide supra*. R. Weber obtained dinitrosylpyrosulphuryl by heating nitrosylnitroxypyrosulphuryl—*vide infra*; and C. A. Michaelis and O. Schumann said that it is formed in an intermediate stage of the decomposition of nitroxylsulphonic acid.

F. H. de la Provostaye reported that the crystals consist of regular, rectangular prisms with the opposite lateral edges truncated; or a white mass of silky needles. The sp. gr. is 2·14. A. Brüning found the m.p. to be 217°, and F. H. de la Provostaye said that the compound begins to melt at 217°, and becomes quite fluid at 230°. The fused mixture near its b.p. is yellowish-red; on cooling to 230°, it is yellow; and it begins to solidify at 217°. The solid is transparent at 190°, and below this temp. it appears opaque and greenish-yellow, and is white when cold. The b.p. is 357·3°, the same as mercury, and it sublimes without decomposition. H. Rose added that the hard white solid does not fume in air. F. H. de la Provostaye said that it stains the skin at first dark red, then yellow, and then slightly blackish. A. Brüning, and H. Rose found that the compound attracts moisture from the air, and loses some nitrogen trioxide; H. Rose, and R. Weber said that the compound dissolves rapidly in water, forming sulphuric and nitric acids with the evolution of nitric oxide; aq. soln. of salts and alkalies act very much like water. H. Rose found it to dissolve freely in cold conc. sulphuric acid; but F. H. de la Provostaye said that it does not dissolve in the cold acid, and only slowly in the hot conc. acid, from which soln., crystals of nitroxylsulphonic acid are deposited. The compound fuses in a current of ammonia, there is a great rise of temp., and a yellowish mass is formed which becomes white ammonium sulphate; with the fused compound ammonia forms ammonium hydrosulphate with the evolution of nitrogen: $N_2O_3.2SO_3+4NH_3=2NH_4HSO_4+2N_2+H_2O$. Dry barium oxide does not act on the compound at ordinary temp., but when heated the mass becomes incandescent, forming barium sulphate with the evolution of red fumes; mercury, also, has no action at ordinary temp., but when heated, mercuric sulphate is formed with the evolution of nitric oxide and sulphur dioxide. H. Rose found it converts alcohol into ethyl nitrite without forming red fumes.

According to R. Weber,[2] if a slow current of the vapour of sulphur trioxide be passed into cold hydrated nitric acid, a solid mass of crystals of **mononitrosylpyrosulphuric acid,** $HO.S_2O_6(NO_2).H_2O$, is produced. The crystals can be drained and dried on a porous tile over conc. sulphuric acid. The colourless crystals are very deliquescent; they give off brown fumes when heated, and a sublimate of nitroxylsulphuric acid. They dissolve in water, forming sulphuric and nitric acids. No salts have been reported. A. Hantzsch and L. Wolf regard this product as *nitronium pyrosulphate*, $\{NO(OH)_2\}.HS_2O_7$, or $\{N(OH)_3\}.S_2O_7$. G. Oddo and A. Casalino obtained **nitrosylpyrosulphuryl,** $NO.O.SO_2{-}O{-}SO_2.O.NO$, by the action of sulphur trioxide on nitrogen peroxide (*q.v.*).

R. Weber[3] also reported what has been regarded as **nitrosylnitroxylpyrosulphuryl,** $N_2O_4.2SO_3$, or $NO.S_2O_7.NO_2$, to be formed by passing nitrogen peroxide into anhydrous sulphuric acid; if a rise of temp. is prevented, when the acid is sat., a white crystalline mass is formed which with a stronger heating gives off oxygen and produces dinitrosylpyrosulphuryl. R. Weber suggested that the product may be a mixture of $N_2O_3.2SO_3$ and $N_2O_5.2SO_3$.

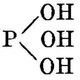
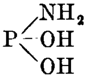
§ 66. Derivatives of Amidophosphorous and Amidophosphoric Acids

The ammonia derivatives of phosphorous acid can be conveniently regarded as substitution products obtained when the amido- or NH_2-group replaces the hydroxyl group of the parent phosphorous acid:



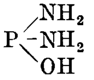
$$P{<}\begin{matrix}OH\\OH\\OH\end{matrix}$$

Phosphorous acid.



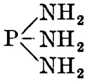
$$P{<}\begin{matrix}NH_2\\OH\\OH\end{matrix}$$

Monamidophosphorous acid.



$$P{<}\begin{matrix}NH_2\\NH_2\\OH\end{matrix}$$

Diamidophosphorous acid.

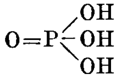


$$P{<}\begin{matrix}NH_2\\NH_2\\NH_2\end{matrix}$$

Phosphorous triamide.

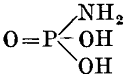
The *monamidophosphorous acid* has not been obtained; but **diamidophosphorous acid,** $(NH_2)_2POH$, was made in 1891, by T. E. Thorpe and A. E. H. Tutton,[1] by the action of ammonia on a soln. of phosphorous oxide in ether or benzene. The reaction is symbolized: $P_4O_6+8NH_3=4(NH_2)_2P(OH)+2H_2O$, followed by $2H_2O+(NH_2)_2P(OH)=(NH_4O)_2P(OH)$; or summating the two equations: $P_4O_6+8NH_3=(NH_4O)_2P(OH)+3(NH_2)_2P(OH)$. The product is a white solid which when heated in a test-tube gives off ammonia, and then fuses and sublimes. It dissolves in water with such great violence that the mass becomes incandescent. When treated with hydrochloric acid, ammonium chloride and phosphorous acid are formed; the reaction can be symbolized: $HO.P(NH_2)_2+2HCl+2H_2O=2NH_4Cl+P(OH)_3$, but the heat of the reaction is so great that the compound is partially resolved into phosphorus, phosphoric acid, and phosphine, which does not inflame spontaneously on exposure to the air. The substituted ammonias also react with the ethereal soln. of phosphorous oxide, forming the corresponding substituted diamides. *Phosphorous triamide*, or the normal *phosphorous amide*, has been previously discussed.

The following series of **amidophosphoric acids** has been reported:



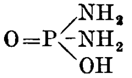
$$O{=}P{<}\begin{matrix}OH\\OH\\OH\end{matrix}$$

Phosphoric acid.



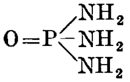
$$O{=}P{<}\begin{matrix}NH_2\\OH\\OH\end{matrix}$$

Monamidophosphoric acid.



$$O{=}P{<}\begin{matrix}NH_2\\NH_2\\OH\end{matrix}$$

Diamidophosphoric acid.



$$O{=}P{<}\begin{matrix}NH_2\\NH_2\\NH_2\end{matrix}$$

Phosphoric triamide.

Diamidophosphoric acid was found by H. N. Stokes[2] to unite with the elements of water, or rather with the bases, forming a series of salts of a pentabasic acid, **trihydroxydiamidophosphoric acid,** $(NH_2)_2P(OH)_3$, in which the amido-groups can play a similar *rôle* to that of hydroxyl, because their hydrogen atoms can be replaced by a metal. If silver diamidophosphate, $(NH_2)_2PO.OAg$, be treated with potassium hydroxide, a colourless, gelatinous mass, possibly **dipotassium silver trihydroxydiamidophosphate,** $(NH_2)P(OK)_2(OAg)$, is formed. This substance furnishes needle-like crystals of **potassium disilver trihydroxydiamidophosphate,** $(NH_2)_2P(OK)(OAg)_2$. When these crystals are washed with ice-cold water, they decompose, forming potassium diamidophosphate and **trisilver trihydroxydiamidophosphate,** $(NH_2)_2P(OAg)_3.2H_2O$. The yellow compound loses its water of crystallization at 100°, and it then appears orange-red. It is immediately decomposed by boiling water, forming a reddish-brown amorphous mass which, after boiling a few minutes, consists of **tetrasilver hydrotrihydroxydiamidophosphate,** $P(NHAg)_2(OAg)_2(OH)$. If gelatinous dipotassium silver trihydroxydiamidophosphate be mixed with water, and treated with carbon dioxide, in the cold, a yellowish-red flocculent substance, resembling ferric hydroxide, separates out. After washing by decantation with water, and drying over sulphuric acid in vacuo, for a few days, the red powder has a composition the same as that of the preceding salt, but is thought to be **tetrasilver trihydroxydiamidophosphate,** $P(NH_2)(NHAg)(OAg)_3$. When freshly made, it may be the same as the preceding salt. The freshly prepared salt does not change under cold water, but in boiling water it forms a compact powder which is almost black and which does not detonate by friction. The powder which has been drying for some days over sulphuric acid detonates when heated, exhibiting a reddish flame and giving off ammoniacal fumes. If treated with conc. sulphuric acid the mass inflames; and boiling water converts it into a red powder which contains more phosphorus and silver than the original salt. If gelatinous dipotassium silver trihydroxydiamidophosphate be diluted with water to which 2 or 3 per cent. of potassium hydroxide has been added, and boiled, the soln. becomes red, then turbid, and deposits a dark brown mass, which is washed by decantation with boiling water, and digestion with a 2–3 per cent. soln. of potassium hydroxide, then washed with boiling water, by suction, and dried over sulphuric acid. The product is **pentasilver trihydroxydiamidophosphate,** $P(NHAg)_2(OAg)_3$. It explodes very readily by friction, by heat, or by treatment with conc. sulphuric acid.

H. N. Stokes prepared **monamidophosphoric acid,** $(NH_2)PO(OH)_2$, by hydrolyzing diphenylamidophosphate, $(NH_2)PO(OC_6H_5)_2$, with a soln. of potassium or sodium hydroxide; by the action of ammonia on silver phosphate; by hydrolyzing the product of the action of ammonia on diethylmonochlorophosphate; and by the action of nitrous acid on diamidophosphoric acid. The acid is best obtained by converting the alkali salt into the lead salt, which is then suspended in water at 0°, and treated with hydrogen sulphide. The clear filtrate is mixed with five times its vol. of alcohol, and the acid is precipitated as a mass of tabular, or anisotropic, cubic crystals. The acid has also been called *phosphamic acid,* and *phosphamidic acid.* Monamidophosphoric acid is readily soluble in water, but insoluble in alcohol. The aq. soln. has a sweetish taste; and gradually changes into ammonium dihydrogen phosphate. The change is rapid in hot soln. The first sign of change is the white precipitate which is formed when silver nitrate is added to the soln. The aq. soln. does not give ammonia when heated with alkali-lye. The dibasic acid forms two series of salts, $MH(NH_2)PO_3$, and $M_2(NH_2)PO_3$. The salts are produced when soln. of the metal salts are added to the alkali salt soln. In aq. soln., the salt passes slowly into an ordinary phosphate. With phenolphthalein, methyl-orange, or litmus as indicator there is no sharp change during the passage from the free acid to the neutral salt.

H. N. Stokes, and A. Sabanéeff prepared **ammonium hydromonamidophosphate,** $(NH_2)PO(OH)(ONH_4)$, by the action of ammonium sulphide on the acid or neutral silver salt, followed by precipitating the clear soln. with alcohol; also by adding alcohol to a soln. of the normal ammonium salt. The acicular crystals are stable, but decompose at 120° without melting—the residue melts at about 305°. A. Sabanéeff found the f.p. of aq. soln. of the salt agree with the simple formula, and the salt is structurally isomeric with hydrazine phosphite, $N_2H_4.H_3PO_3$. The normal salt, **ammonium monamidophosphate,** $(NH_2)PO(OH)(ONH_4)$, may exist in ammoniacal soln., but it decomposes into the acid salt when the attempt at its isolation is made. H. N. Stokes, and A. Sabanéeff obtained **hydroxylamine hydromonamidophosphate,** $(NH_2)PO(OH)(ONH_2.OH)$, by the action of hydroxylamine monochloride on potassium hydromonamidophosphate. The rhombic plates and prisms are sparingly soluble in water. The salt decomposes at about 95° with the evolution of gas; and changes easily when kept. A. Sabanéeff found the salt to be a structural isomer of hydrazine orthophosphate, $N_2H_4.H_3PO_4$.

H. N. Stokes prepared **lithium monamidophosphate,** as a crystalline powder, by precipitation from a soln. of the potassium salt on the addition of a lithium salt. When boiled with water, it furnishes lithium phosphate. He also made **sodium monamidophosphate,** $(NH_2)PO(ONa)_2$, by the action of sodium hydroxide on the acid salt. The acicular or prismatic crystals are not hygroscopic; they are very soluble in water; and alcohol precipitates the salt as an oily liquid from its aq. soln. The salt is decomposed by carbon dioxide into sodium carbonate and the acid salt. The acid salt or **sodium hydromonamidophosphate,** $(NH_2)PO(OH)(ONa)$, is obtained by boiling diphenylamidophosphate for 10 minutes with a conc. soln. of sodium hydroxide, and acidifying the ice-cold soln. with acetic acid. The precipitate which gradually forms is washed with alcohol, dissolved in aq. ammonia, and again precipitated with acetic acid. The powder consists of hexagonal plates or prisms; it is sparingly soluble in cold water; and insoluble in alcohol. The salt is slowly hydrolyzed to the phosphate by cold water, and rapidly by hot water or dil. acids. When heated, the salt loses ammonia, leaving a glassy mass of hexametaphosphate. The salt is precipitated from an ammoniacal soln. by the passage of carbon dioxide, or by driving out the ammonia with a current of air. There is possibly a small proportion of water of crystallization which does not hydrolyze the salt at 100°, but does so at 150°. H. N. Stokes made **potassium monamidophosphate,** $(NH_2)PO(OK)_2$, from the free acid and the alkali-lye. It is very soluble in water, and is not perceptibly hydrolyzed by water. He also made **potassium hydromonamidophosphate,** $(NH_2)PO(OH)(OK)$, by a method similar to that used for the sodium salt. The rhombohedral crystals are very soluble in cold water. The aq. soln. has a neutral reaction, and is slowly decomposed into phosphate when cold; the change is rapid with hot soln. When the salt is heated, ammonia is evolved, and potassium metaphosphate remains. If the ammoniacal soln. in the acid salt is treated with alcohol, a syrupy precipitate is formed which decomposes into the potassium salt and ammonia when washed with alcohol. It is therefore thought to be **ammonium potassium monamidophosphate.**

H. N. Stokes prepared **silver hydromonamidophosphate,** $(NH_2)PO(OH)(OAg)$, by treating a soln. of the potassium salt, feebly acidified with nitric acid, with silver nitrate; or by adding alcohol to a cold soln. of the normal salt in dil. nitric acid. The crystalline powder consists of small needles, or short, thick, hexagonal prisms. The crystals are stable in light; sparingly soluble in water; readily soluble in dil. nitric or acetic acid, or in aq. ammonia. The boiling aq. soln. forms silver phosphate. When the salt is heated, ammonia is given off, and a fusible glass of silver hexametaphosphate is formed. Microscopic plates of **silver monamidophosphate,** $(NH_2)PO(OAg)_2$, are formed when silver nitrate and then ammonia are added to the filtrate from the preceding salt; or a soln. of that salt in dil. nitric acid is treated with silver nitrate and ammonia. The colourless salt is stable in air; it is almost insoluble in water; and soluble in nitric acid, and aq. ammonia. Alcohol precipitates the acid salt from the soln. in dil. nitric acid, and the spontaneous evaporation of the ammoniacal soln. furnishes the unchanged salt. The anhydrous salt is not changed at 150°, but at 180° it gives off half the nitrogen as ammonia, and forms an imidopyrophosphate, $NH\{PO(OAg)_2\}_2$; it is possible that H. Schiff obtained **lead monamidophosphate,** as a voluminous, white precipitate, insoluble in ammonia, by adding lead acetate to a soln. of the alkali salt. The precipitate is insoluble in ammonia. H. N. Stokes also obtained what was possibly **lead hydromonamidophosphate,** by adding lead acetate to a soln. of the potassium salt. The crystalline precipitate is somewhat soluble in water. He also obtained a **chromium amidophosphate.**

H. N. Stokes prepared **diamidophosphoric acid,** $(NH_2)_2PO(OH)$, by treating phenyl dichlorophosphate, $Cl_2.PO.OC_6H_5$, with ammonia to convert it into phenyldiamidophosphate, $(NH_2)_2PO.OC_6H_5$, and hydrolyzing the product with a soln. of potassium diamidophosphate. When a cold soln. of this salt is treated with acetic acid, crystals of diamidophosphoric acid are formed. If silver diamidophosphate is treated with hydrogen sulphide, the clear filtrate contains a soln. of the acid, which can be precipitated with alcohol. The salt can be purified by dissolving it in water, and again precipitating the aq. soln. with alcohol. This acid has been also called *phosphodiamic acid* or *phosphodiamidic acid.* The microscopic crystals consist of six-sided plates which are stable in air; freely soluble in water; almost insoluble in alcohol; easily decomposed by acids; and scarcely attacked by boiling alkali-lye. Cold nitric acid transforms diamidophosphoric acid into monamidophosphoric acid, and finally into ordinary phosphoric acid, but there are no signs of any differences in the nature of the two amido-groups. The diamidophosphates of the alkalies and alkaline earths are very soluble in water and have not been obtained in a crystalline state pure enough for analysis. A mol of the free acid unites with a mol of ammonia to form **ammonium diamidophosphate**; but with 2 mols of ammonia the soln. possesses the smell of that gas, and gives with silver nitrate a mixture of the primary and secondary silver salts. Soln. of the alkali hydroxide and the acid furnish non-crystallizable **potassium and sodium diamidophosphates,** which are readily soluble in water. By adding the calculated quantity of silver nitrate to a dil. soln. of the barium salt; washing the white, pulverulent precipitate; dissolving it in aq. ammonia; and re-precipitating with dil. nitric acid, white, pulverulent **silver diamidophosphate,** $(NH_2)_2PO(OAg)$, is formed. This salt can be obtained in short rhombohedral prisms by the slow evaporation of the ammoniacal soln. over sulphuric acid. The salt is almost insoluble in water, but freely soluble in ammonia. The ammoniacal soln. furnishes imidoamidophosphate when treated with silver nitrate. No ammonia is given off by the salt when confined over sulphuric acid, or when heated to 100°. The salt loses weight slowly when heated to 150°–160°; and when rapidly heated to a higher temp., the salt swells up, develops ammonia, and melts to a grey mass. For the action of potassium hydroxide, *vide supra,* trihydroxydiamidophosphoric acid.

H. Schiff claimed to have prepared $PO(NH_2)_3$, or **phosphoryl triamide,** by slowly leading a current of dry ammonia into cold phosphoryl chloride until the mass was quite sat. The ammonium chloride was washed from the product of the action with cold or warm water, and phosphoric triamide remained as a snow-white powder. H. Schiff claimed that the compound is scarcely attacked by boiling water, an aq. soln. of potassium hydroxide, or dil. acids; but that it is slowly attacked by conc. acids. When fused with potassium hydroxide, ammonium and potassium phosphates are formed; and when heated out of contact with air, ammonia, and phosphoryl nitrile are produced: $PO(NH_2)_3=PON+2NH_3$. J. H. Gladstone, A. Mente, and H. N. Stokes failed to confirm the preparation of H. Schiff's *triphosphoramide.* According to J. H. Gladstone, the third atom of chlorine cannot be replaced by an amido-group at any temp. below that at which further decomposition occurs (300°). The product of the action of ammonia on phosphoryl chloride is a mixture of ammonium salts of amido- and imido-tetraphosphoric acids.

C. Poulenc reported **phosphorus diamidotrifluoride,** $PF_3(NH_2)_2$, to be formed by the action of ammonia on phosphorus trifiuodichloride: $PF_3Cl_2+4NH_3=2NH_4Cl+PF_3(NH_2)_2$, as a white mass which cannot be separated from the ammonium chloride. When heated it furnishes phospham. T. E. Thorpe and J. W. Rodger obtained **thiophosphoryl diamidofluoride,** $PS(NH_2)_2F$, by the action of ammonia on thiophosphoryl fluoride: $PSF_3+4NH_3=2NH_4F+PS(NH_2)_2F$. The white mass deliquesces in air, and when treated with water furnishes diamidophosphoric acid: $PS(NH_2)_2F+H_2O=HF+PS(NH_2)_2OH$; and with a soln. of cupric sulphate it gives a yellowish precipitate which rapidly darkens, forming cupric sulphide; the filtrate, on standing, yields bluish-green crystals of $Cu_3(PO_4)_2.CuSiF_6$. J. H. Gladstone and J. D. Holmes had previously obtained **thiophosphoryl diamidochloride,** $PS(NH_2)_2ClS$, by the action of ammonia on thiophosphoryl chloride, and found that with water it yields diamidothiophosphoric acid. H. Schiff represented the reaction with ammonia in a different way: $PSCl_3+6NH_3=3NH_4Cl+PS(NH_2)_3$.

§ 67. Derivatives of Imidophosphoric Acid

By abstracting the elements of ammonia from the di- and tri-amidophosphoric acids, a series of **imido-compounds** has been prepared; these are represented by:

$O=P<^{NH}_{OH}$

Imidophosphoric acid.

$O=P<^{NH}_{NH_2}$

Phosphoryl imidoamide.

$O=P\equiv N$

Phosphoryl nitrile.

According to H. Schiff,[1] ammonia reacts with phosphorus pentoxide, forming what he called *Phosphaminsäure*, and his analyses agree with his empirical formula, PO.NH.OH—not $PO(NH_2)(OH)_2$. According to H. N. Stokes, the product of the reaction is a mixture consisting largely of this acid, which he called **imidophosphoric acid,** PO.NH.OH, or, perhaps, HO.PO : NH. The mixture is readily soluble in water and alcohol. It is not easily oxidized to phosphoric acid; ammonia is evolved when the mixture is boiled with water. The acid forms a series of salts which have not been obtained pure; the soluble salts give precipitates with the salts of the heavy metals—*e.g.* the precipitates with zinc, cadmium, lead, silver, and tin salts are white; with copper and nickel salts, blue; and with cobalt salts, violet. The precipitates are soluble in soln. of ammonia, and ammonium chloride and in acids. J. H. Gladstone and J. D. Holmes emphasized the general resemblance between the properties of H. Schiff's acid and what they called *pyrophosphodiamic acid*—*i.e. diamidodiphosphoric acid*—and they considered H. Schiff's acid to be a mixture of the latter with metaphosphoric acid. According to A. Mente, the product of the reaction between ammonia and phosphorus pentoxide below 0°, is imidodiphosphoric acid, and A. Mente considers that J. H. Gladstone and J. D. Holmes' diamidodiphosphoric acid and his imidodiphosphoric acid are the same.

Ammonia is absorbed by the phosphorus tri- and penta-chlorides with the evolution of much heat. According to A. Besson, ammonia unites directly with phosphorus pentachloride (dissolved in carbon tetrachloride) to form a white addition product, $PCl_5.8NH_3$; and, according to H. Rose, with phosphorus trichloride, to form the addition compound, $PCl_3.5NH_3$. At ordinary temp., some complicated reactions occur. Thus, (i) according to H. Rose, if the product of the action be extracted with ether, nitrogen phosphochloride, $N_3P_3Cl_6$, is obtained; (ii) according to C. Gerhardt, if the product be heated, hydrogen chloride and ammonium chloride are evolved, and a white powder called *phospham*, $(PN_2H)_n$, is obtained (*q.v.*); and (iii) according to C. Gerhardt, if the product be thoroughly washed, a white powder called **phosphamide,** or **phosphoryl imidoamide,** $[(NH_2)PO(NH)]_n$, remains. Phosphoryl imidoamide was obtained by C. Gerhardt by saturating phosphorus pentachloride with ammonia; extracting the white product with water to remove ammonium chloride; then boiling with a dil. soln. of alkali carbonate or hydroxide; then with dil. nitric or sulphuric acid; then with water; and finally heating so as to sublime any remaining ammonium chloride. F. Wöhler and J. von Liebig had previously noted how difficult it is to remove the soluble chloride from the product of the action of ammonia on phosphorus pentachloride. J. H. Gladstone extracted the mass with ether, or by a prolonged boiling in water. The mol. wt. of phosphoryl imidoamide is unknown, but it is generally thought to be higher than that represented by the regular formula, $NH_3.PO.NH$. The white powder is insoluble in the usual solvents, but is slowly transformed into phosphoric acid and ammonia when boiled with water. When heated out of contact with air, it forms ammonia and phosphoryl nitrile; when heated in moist air it gives metaphosphoric acid and ammonia; when fused with alkali hydroxide it gives ammonia and the alkali phosphate; and when heated with copper, it forms ammonia and silvery copper phosphide along with a reddish substance—possibly cuprous phosphate. Phosphamide resists the action of most oxidizing agents; it is not attacked by chlorine, boiling conc. hydrochloric acid, nitric acid, or aqua regia; nor is it attacked by cold sulphuric acid, but the hot acid forms phosphoric acid: $NH_2.PO.NH+2H_2SO_4+3H_2O=H_3PO_4+2(NH_4)HSO_4$.

When phosphoric imidoamide, phosphortriamide or a chloramide is heated, for preference in an oxygen-free gas, **phosphoryl nitrile,** PNO, is formed: $NH_2.PO:NH=NH_3+PNO$; or $PO(NH_2)_3=2NH_3+PNO$. This compound was described by C. Gerhardt in 1846 as *biphosphamide,* by J. H. Gladstone in 1850 as *phosphonitryle,* and by H. Schiff in 1857 as *monophosphamide.* It is a white powder which melts at a red-heat, and, on cooling, forms a black, glassy mass. It unites neither with alkalies nor acids, nor is it affected by boiling nitric acid. It is oxidized to phosphoric acid when fused with alkalies in air or with oxidizing agents. It forms ammonia when heated with hydrogen, and with steam, it forms an oxide of phosphorus and phosphine. The high m.p., and its inertness towards solvents, have led to the belief that the mol. is more complex than is represented by the simple formula PNO—G. Oddo thinks the mol. is $P_2N_2O_2$, or $NP{<}O_2{>}PN$.

According to A. Besson and G. Rosset, when phosphorus chloronitride is heated with nitrogen peroxide at 200°–250° in a sealed tube, nitrogen, nitrous and nitric oxides, chlorine, nitrosyl, and nitroxyl chlorides, and a substance of the composition $2P_2O_5,NO_2$, **phosphatonitroxyl,** are formed. This substance has been also obtained by heating phosphoric oxide with nitrogen peroxide at 200° in a sealed tube; it gives off nitrogen peroxide when heated, and deliquesces in the air with loss of nitrogen peroxide.

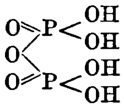
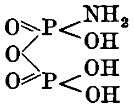
§ 68. The Amidodiphosphoric or Amidopyrophosphoric Acids

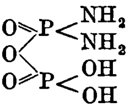
The chemistry of the amido- and imido-diphosphoric acids is not in a satisfactory state. The interpretation of the experimental work by different investigators is discordant, showing a lack of precise facts. The reports of the preparation and properties of the three amidophosphoric acids indicated above are largely based upon the work of J. H. Gladstone and J. D. Holmes.[1] A. Mente's and H. N. Stokes' re-survey of the field outlined by J. H. Gladstone and J. D. Holmes shows that the interpretation of the results was probably erroneous; in othe words, the amido-diphosphoric acids reported by J. H. Gladstone and J. D. Holmes may really be imido-diphosphoric acids, or mixtures of the same with meta- and pyro-phosphoric acids. A number of amidopyrophosphoric acids have been reported. For instance, starting from di- or pyro-phosphoric acid, $O[PO(OH)_2]_2$, and replacing the HO-groups by NH_2-groups, one by one,



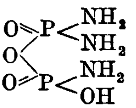
Diphosphoric acid.



Monamidodiphosphoric acid.



Diamidodiphosphoric acid.



Triamidodiphosphoric acid.

J. H. Gladstone and J. D. Holmes claimed to have made the tribasic **monamidodiphosphoric acid,** $(NH_2)P_2O_3(OH)_3$—which they called *diphosphamidic acid*—or its salts by the hydrolysis of an aq. soln. of nitrilodiphosphoric acid: $(NH_4O)P_2O_3{\vdots}N+2H_2O=NH_3+(NH_2)P_2O_3(OH)_3$; by the hydrolysis of an aq. soln. of diamidodiphosphoric acid, or of its salts: $(NH_2)_2P_2O_3(OH)_2+H_2O=NH_3+(NH_2)P_2O_3(OH)_3$; by heating the diamidodiphosphoric acid or its salts with an acidified soln. of a metal salt, $(NH_2)_2P_2O_3(OK)_2+KCl+H_2O=(NH_2)P_2O_3(OK)_3+NH_4Cl$; or by saturating an aq. soln. of pyrophosphoric acid with ammonia, and adding baryta-water—not in excess. As a result, ammonia is evolved, and barium monamidodiphosphate is precipitated. The salts in question are not very soluble in acids; they give a characteristic red coloration with ferric chloride. According to H. N. Stokes, monamidodiphosphoric acid is thought to be identical with A. Mente's imidodiphosphoric acid, $\{PO(OH)_2\}_2NH$, or $\{PO(OH).O.PO(OH)\}NH$. For **ammonium monamidodiphosphate,** *vide infra,* the diamidotetraphosphates. J. H. Gladstone treated the salt with potassium hydroxide, and obtained a gummy mass containing **potassium monamidodiphosphoric acid** when the neutral soln. was evaporated over sulphuric acid. The composition was variable owing to the decomposition of the unstable salt. If the neutral ammonium salt obtained by the action of alcoholic ammonia on phosphorus chloronitride be treated with an excess of silver nitrate, and the filtrate boiled, the **silver monamidodiphosphate,** $(NH_2)P_2O_3(OAg)_3$, is deposited as a white precipitate; again, if the ferric salt be treated with a cold soln. of potassium hydroxide, and the neutral liquid treated with silver nitrate, the same salt is formed. J. H. Gladstone made **barium monamidodiphosphate,** $(NH_2.P_2O_3.O_2)Ba$, by neutralizing an aq. soln. of pyrophosphoric acid with ammonia, and adding the calculated quantity of baryta-water. J. H. Gladstone and J. D. Holmes made it by dissolving phosphorus chloronitride in alcoholic ammonia and mixing the soln. with an excess of barium chloride. The filtrate when boiled deposits first barium diamidodiphosphate which when boiled still more passes into the monamido-salt. It is soluble in nitric and hydrochloric acids, and insoluble in acetic acid. J. H. Gladstone also made the **copper, silver, barium, lead, tin, chromium, manganese, ferric, cobalt, nickel, and platinum monamidodiphosphates.** The iron salt furnishes an ammino-salt. No **antimony or gold monamidodiphosphate** could be obtained.

The *tetramidodiphosphoric acid,* $(NH_2)_2PO.O.PO(NH_2)_2$, has not been reported. J. H. Gladstone and J. D. Holmes prepared dibasic **diamidodiphosphoric acid,** $(NH_2)_2P_2O_3(OH)_2$, or, as they called it, *diphosphodiamidic acid,* by the hydrolysis of nitrogen chlorophosphide, $N_3P_3Cl_6$, with alcoholic potash-lye, and afterwards with water: $2N_3P_3Cl_6+15H_2O=12HCl+3(NH_2)_2P_2O_3(OH)_2$; by the hydrolysis of aq. soln. of mono- or di-amidophosphorus oxychlorides, *i.e.* the product obtained by saturating phosphoryl chloride at a low temp. with ammonia, or by dropping phosphoryl chloride into conc. aq. ammonia: $2POCl_3+2NH_3+3H_2O=6HCl+(NH_2)_2P_2O_3(OH)_2$; or by the action of phosphorus pentachloride on conc., well-cooled, aq. ammonia. The hydrolysis of the higher amidophosphoric acids or imidoamidophosphoric acid can be symbolized: $2(NH_2)PONH+H_2SO_4+3H_2O=(NH_4)_2SO_4+(NH_2)_2P_2O_3(OH)_2$. According to H. Schiff, diamidodiphosphoric acid can be prepared by the action of ammonia gas on phosphoric pentoxide: $P_2O_5+2NH_3=(NH_2)_2P_2O_3(OH)_2$. While H. Schiff thought that the product of this last reaction was imidophosphoric acid, (NH)PO(OH), J. H. Gladstone and J. D. Holmes considered it to be diamidodiphosphoric acid; and A. Mente thought that the product of the reaction is a mixture of potassium meta- and pyrophosphates with the potassium salt of diimidophosphoric acid, $NH(PO)_2NH(OH)_2$. The acid is said to decompose into phosphorus pentoxide and ammonia when it is heated; the normal salts have been described. The insoluble metal salts dissolve in a soln. of ammonium chloride; and they are not so soluble in acids as the orthophosphates. Ammonia is formed when the salts are fused with potassium hydroxide, and they are but slowly oxidized to normal phosphates by treatment with a mixture of nitric acid and potassium chlorate. A. Mente thinks that this acid is identical with imidodiphosphoric acid. According to J. H. Gladstone and J D. Holmes, the acid is a colourless mass which readily dissolves in alcohol and in water. It decomposes into phosphorus pentoxide and ammonia when heated; and when its aq. soln. is boiled, or when its salts are treated with an excess of a metal salt soln., it forms ammonia and monamidodiphosphoric acid. If the soln. strongly acidified with sulphuric acid be treated with ferric chloride, until the soln. is red, and then boiled, the liquid becomes turbid, and a gelatinous precipitate of a ferric salt is formed which, when heated, gives off ammonia, without melting.

The acid is dibasic, and only the normal salts are known with certainty. The insoluble metal salts dissolve in soln. of ammonium chloride, and in dil. acids; they give off ammonia when fused with potassium hydroxide; and when evaporated many times with a mixture of nitric acid and potassium chlorate, the salts are transformed into orthophosphates. The modes of preparation of diamidophosphoric acid in ammoniacal soln., and the treatment of the acid with ammonia, furnishes a soln. of **ammonium diamidodiphosphate,** $(NH_2)_2P_2O_3(ONH_4)_2$, which yields radiating masses of crystals. H. Schiff said that during the evaporation there is always some ammonium phosphate formed which contaminates the final product. J. H. Gladstone and J. D. Holmes said that the ammonium salt is produced by burning phosphorus under a bell-jar standing over conc. aq. ammonia. They were not able to prepare **potassium diamidodiphosphate. Copper diamidodiphosphate** was also prepared. If the soln. obtained by treating phosphorus chloronitride with alcoholic ammonia be neutralized and mixed with silver nitrate, a mixture of silver chloride and **silver diamidodiphosphate,** $(NH_2)_2P_2O_3(OAg)_2$, is precipitated. Hot dil. nitric acid extracts the latter salt. J. H. Gladstone and J. D. Holmes made **barium diamidodiphosphate,** $(NH_2)_2P_2O_3(O_2Ba)$, as indicated in connection with the monamidodiphosphate. H. Schiff also prepared this salt. He also obtained strontium and calcium diamidodiphosphates; no **magnesium, mercuric, ferric, chromium, aluminium, or antimony diamidodiphosphate** was prepared, but **zinc, cadmium, manganese, cobalt, and nickel diamidodiphosphates** were obtained.

J. H. Gladstone and J. D. Holmes prepared monobasic **triamidodiphosphoric acid,** $(NH_2)_3P_2O_3(OH)$—also called *diphosphotriamidic acid*—by heating to 230° the product obtained by saturating phosphoryl chloride with ammonia, and then boiling it for a short time with water: $2POCl_3+3NH_3+2H_2O=(NH_2)_3P_2O_3(OH)+6HCl$. The acid is a white, tasteless powder; its aq. soln. reddens litmus, and expels carbon dioxide from carbonates. When heated, it decomposes into ammonia and ammonium nitrilopyrophosphate. When boiled with water, it forms diamidodiphosphoric acid and ammonia; with boiling hydrochloric acid it forms phosphoric acid and ammonium chloride; and with conc. sulphuric acid, ammonium diamidodiphosphate and sulphate. Triamidodiphosphoric acid forms a series of salts. The salts—even the alkali salts—are but sparingly soluble in water. J. H. Gladstone and J. D. Holmes report that it forms salts corresponding with the monobasicity of the acid; and also salts containing up to four atoms of the metal per mol of acid. Hence J. H. Gladstone and J. D. Holmes postulated a tetrabasic *triimidodiphosphoric acid*—possibly $(NH)_3P_2(OH)_4$. The alkali salts are insoluble in water and in acids. The acid reacts with metal salt soln. and metal oxides, forming insoluble salts. According to A. Mente, this acid is identical with diimidodiphosphamidic acid, $(NH)_2P_2O_2(NH_2)OH$. When the acid is treated with ammonium carbonate, **ammonium triamidodiphosphate,** $(NH_2)_3P_2O_3(ONH_4)$, is formed as an insoluble, white mass. A similar product, **potassium triamidodiphosphate,** is obtained by the action of potassium carbonate on the acid. According to J. H. Gladstone, he obtained mono- and di- **copper triamidodiphosphates** ; and he prepared **silver triamidodiphosphate,** $(NH_2)_3P_2O_3(OAg)$, as an amorphous, white, flocculent precipitate, by adding a soln. of silver nitrate to the acid suspended in cold water. The salt is insoluble in water. Dil. nitric acid, or aq. ammonia, extracts some silver from the salt, and hydrochloric acid decomposes it completely. J. H. Gladstone also obtained orange-yellow **trisilver triamidodiphosphate,** $(NH_2)(NHAg)_2P_2O_3(OAg)$, by adding a soln. of the acid to a feebly ammoniacal soln. of silver oxide ; or by treating the monosilver salt with an ammoniacal soln. of a silver salt. The precipitate is washed by decantation. Dil. aq. ammonia, or dil. nitric acid, transforms it into the monosilver salt ; boiling acetic acid acts similarly, but more feebly. J. H. Gladstone made **barium triamidodiphosphates,** $(NH_2)_2(NH.Ba:O)P_2O_3$, by adding barium chloride to the acid suspended in aq. ammonia, and also $\{(NH_2)_3P_2O_3\}_2Ba$, by suspending the acid in a soln. of barium chloride, and neutralizing the hydrochloric acid which is formed by means of ammonia. If the acid mixed with water is treated with an ammoniacal soln. of a magnesium salt, and the precipitate washed with water, J. H. Gladstone obtained a mixture of the **magnesium triamidodiphosphate,** $(NH_2)_2(NH.Mg.O)P_2O_3$, and $MgH_2(P_2O_4N_3)_2$. He also made the **mercury, lead, iron, cobalt, and platinum triamidodiphosphates.**

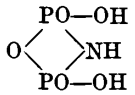
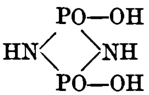
§ 69. Imidodiphosphoric or Imidopyrophosphoric Acid

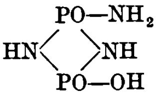
By the loss of the elements of water or ammonia from imidodiphosphoric acid there is formed diimidodiphosphoric acid, or mixed imido-amido-diphosphoric acids also called imido-diphosphamic or imido-diphosphamidic acid :



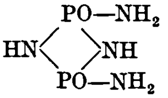
Imidodiphosphoric acid.



Diimidodiphosphoric acid.

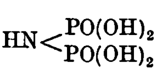


Diimidomonamidodiphosphoric acid.



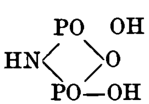
Diimidodiamidodiphosphoric acid.

According to H. N. Stokes, and A. Mente, there are two **monimidodiphosphoric acids,** differently constituted, but not isomeric—one is dibasic, and the other tetrabasic. H. N. Stokes[1] prepared the **tetrabasic monimidodiphosphoric acid**



$$HN{<}\begin{matrix}PO(OH)_2\\PO(OH)_2\end{matrix}$$

Tetrabasic monimidodiphosphoric acid, $NH[PO(OH)_2]_2$.



Dibasic monimidodiphosphoric acid, $PO(OH).O.PO(OH)NH$.

by heating trimetaphosphimic acid, $P_3N_3O_6H_6$ (*vide infra*), for about seven minutes ; on treating the ammoniacal soln. with a magnesium salt, magnesium ortho- and pyro-phosphates are precipitated, and the soluble magnesium imidodiphosphate remains in soln. By the addition of silver nitrate to this soln. a colourless, crystalline precipitate, sparingly soluble, trisilver hydroimidodiphosphate, $NHP_2O_2(OAg)_3OH$, is formed. The imidodiphosphate can be separated from the other phosphates by the treatment of their sodium salts with alcohol. The free acid has not been obtained. The acid is fairly stable in cold soln., but gradually decomposes into trimetaphosphimic acid. According to H. N. Stokes, the acid is probably identical with the so-called monamidodiphosphoric acid. The acid (or rather its salts) cannot be referred to the formula $(HO)_2PO.O.PO(NH_2)OH$, because the formation of pyrophosphate and not of orthophosphate would be expected, whereas if the constitution be $HN[PO(OH)_2]_2$, only orthophosphoric acid would be formed. Hence, it is possible that the constitution may be $(HO)_2PO.O.PO(NH_2)OH$.

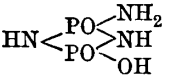
According to H. N. Stokes, **trisodium imidodiphosphate,** $NHP_2O_2(ONa)_3(OH)$, is produced when the trisilver salt is treated with sodium chloride. On evaporating the clear soln., a gummy mass is obtained; and the aq. soln. when treated with alcohol furnishes a non-crystallizable syrup. The salt is more soluble in dil. alcohol than sodium pyrophosphate. The **trisilver imidodiphosphate,** $NHP_2O_2(OAg)_3(OH)$, is formed by precipitation from the free acid or a tribasic salt soln. by silver nitrate. The white amorphous precipitate is insoluble in water, and stable in light. There are two modifications of **tetrasilver imidodiphosphate,** $NHP_2O_2(OAg)_4$—one is white, the other yellow. H. N. Stokes suggested that they are tautomeric modifications. The white form is obtained by adding sodium imidodiphosphate to a soln. of silver oxide in ammonium nitrate. The voluminous precipitate is stable only in the presence of its mother-liquor. It readily passes into the yellow form—*e.g.* by boiling the white form in its mother-liquor. The yellow form is amorphous. The amorphous precipitate is obtained by adding an excess of silver nitrate to an ammoniacal soln. of an imidodiphosphate. H. N. Stokes obtained **magnesium imidodiphosphate** as an amorphous, voluminous precipitate, almost insoluble in water, and freely soluble in soln. of ammonium salts.

According to A. Mente, a **dibasic imidodiphosphoric acid** is formed when a soln. of (4 grms.) ammonium carbonate, $(NH_2)CO(ONH_4)$, in (10 grms.) phosphoryl chloride is warmed to about 50° for a few hours. The reaction is supposed to occur in two stages: $4POCl_3+3(NH_4O)CO(NH_2)=2NH(POCl_2)_2+3CO_2+4NH_4Cl$; followed by $3H_2O+NH(POCl_2)_2=NH(PO.OH)_2O+4HCl$. The acid soln. is treated with ferric or barium chloride in order to precipitate the sparingly soluble ferric or barium salt. It is also formed by boiling diimidodiphosphoric acid with an acid soln. of ferric chloride so as to furnish the ferric imidodiphosphate which forms a good starting-point for the preparation of the other salts. The probable constitution is deduced from the mode of formation. This acid may be identical with the so-called amidodiphosphoric acid. The acid is dibasic, and the existence of a basic salt is in harmony with the assumption that an imido-group is present. A direct determination of the water in the imidophosphate is not possible; if the salt dried to constant weight over sulphuric acid be heated to 100°–110°, there is first a small decrease in weight followed by an increase which was not observed to attain a constant value. A. Mente prepared **barium imidodiphosphate,** $NHP_2O_5Ba.H_2O$, as a voluminous precipitate, by adding barium chloride to an ammoniacal soln. of the acid, or of the ammonium salt.

A. Mente prepared **diimidodiphosphoric acid,** $NH(PO)_2NH(OH)_2$, by heating a soln. containing an excess of ammonium carbamate in phosphoryl chloride, or better in a soln. of phosphoryl chloride in benzene. The reaction is supposed to occur in two stages: $2POCl_3+3(NH_4O)CO(NH_2)=4NH_4Cl+3CO_2+NH(PO)_2NH(Cl_2)$; followed by $NH(PO)_2NH(Cl_2)+2H_2O=2HCl+NH(PO)_2NH(OH)_2$. The dibasic acid has not been isolated. The aq. soln. reacts acid. A hydrogen atom of each of the imido-groups can also be displaced by an equivalent metal. See diamidodiphosphoric acid for other modes of preparation and properties, for the two acids are probably the same. A. Mente prepared **barium diimidodiphosphate,**

$NH(PO)_2NH(O_2Ba)$, by adding barium chloride to a soln. of the acid neutralized with ammonia. It is also formed when diimidomonamidophosphoric acid is boiled with baryta-water, or an ammoniacal soln. of barium chloride. It is sparingly soluble in dil. acids; and loses no water at 100°.

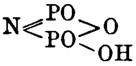
A. Mente prepared monobasic **diimidomonamidophosphoric acid,** or *diimidodiphosphorylmonoaminic acid,* $NH(PO)_2NH(OH)(NH_2)$,



$$\mathrm{HN}<\begin{matrix}\mathrm{PO}<\mathrm{NH_2}\\ >\mathrm{NH}\\ \mathrm{PO}<\mathrm{OH}\end{matrix}$$

by saturating phosphoryl chloride with ammonia, and washing the white mass with water. He supposed the reaction takes place in two stages: $2POCl_3 + 8NH_3 = 5NH_4Cl + NH(PO)_2NH(Cl)NH_2$, followed by the hydrolysis of the monochloride to hydrochloric acid and diimidomonamidophosphoric acid or *diimidodiphosphoamidic acid.* By boiling the acid with soda-lye, one-third of the total nitrogen is evolved as ammonia, and a salt of diimidodiphosphamidic acid is formed. The free acid reddens litmus. See triamidodiphosphoric acid for other modes of preparation and properties, for the two acids are probably the same.

According to J. H. Gladstone and J. D. Holmes, when potassium triamidodiphosphate is heated, it loses the equivalent of two mols of ammonia, and forms **potassium nitrilodiphosphate,** $(KO)P_2O_3N$, corresponding with **nitrilodiphosphoric acid,**



$$\mathrm{N}\lessdot\begin{matrix}\mathrm{PO}\\ \mathrm{PO}\end{matrix}\begin{matrix}>\mathrm{O}\\ <\mathrm{OH}\end{matrix}$$

The potassium salt is but sparingly soluble in water, and when suspended in dil. nitric acid, and treated with silver nitrate, it forms **silver nitrilodiphosphate,** $N:P_2O_3(OAg)$. The **ammonium nitrilodiphosphate,** $N:P_2O_3(ONH_4)$, is formed by heating triamidodiphosphoric acid. The ammonium salt is insoluble in water, but it is slowly hydrolyzed by water, forming ammonia and monamidodiphosphoric acid along with a trace of tetramidotetraphosphoric acid. The free acid has not been prepared.

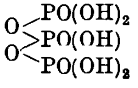
§ 70. Amides and Imides of the Higher Phosphoric Acids

Amido- or imido- derivatives of still higher phosphoric acids have been reported, principally by H. N. Stokes.[1]

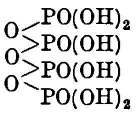
$$\mathrm{O}<\begin{matrix}\mathrm{PO(OH)_2}\\ \mathrm{PO(OH)_2}\end{matrix}$$

Diphosphoric acid.



$$\begin{matrix}\mathrm{O}<\mathrm{PO(OH)_2}\\ >\mathrm{PO(OH)}\\ \mathrm{O}<\mathrm{PO(OH)_2}\end{matrix}$$

Triphosphoric acid.

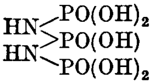


$$\begin{matrix}\mathrm{O}<\mathrm{PO(OH)_2}\\ >\mathrm{PO(OH)}\\ \mathrm{O}\\ >\mathrm{PO(OH)}\\ \mathrm{O}<\mathrm{PO(OH)_2}\end{matrix}$$

Tetraphosphoric acid.

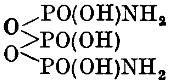
H. N. Stokes prepared **diimidotriphosphoric acid,** $PO(OH)_2.NH.PO(OH).NH.PO(OH)_2$, by heating trimetaphosphimic acid for about seven minutes with nitric acid. The soln. was then treated with an excess of ammonia, and a magnesium salt, and filtered. The acid in question appeared in the filtrate. The silver salt was precipitated by the addition of silver nitrate. Diimidotriphosphoric acid forms two series of salts—an acid salt with three, and a normal salt with five atoms of hydrogen replaced by the metal. For example, **trisodium diimidotriphosphate,**

$P_3N_2O_3H_4Na_3$, forms obtuse prismatic crystals, neutral to litmus, while **pentasodium diimidotriphosphate** has an alkaline reaction. The trisilver salt forms monoclinic crystals. Warming the pentasilver salt with ammonium nitrate destroys the yellow colour—yellow silver phosphate is not whitened by this treatment, while silver trimetaphosphimate becomes orange-yellow. The empirical composition of the acid corresponds with either:



$$\begin{array}{l}\mathrm{HN}{\diagup}\mathrm{PO(OH)_2}\\ \mathrm{HN}{>}\mathrm{PO(OH)}\\ \quad{\diagdown}\mathrm{PO(OH)_2}\end{array}$$

Diimidotriphosphoric acid.

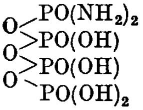


$$\begin{array}{l}\mathrm{O}{\diagup}\mathrm{PO(OH)NH_2}\\ \mathrm{O}{>}\mathrm{PO(OH)}\\ \quad{\diagdown}\mathrm{PO(OH)NH_2}\end{array}$$

Diamidotriphosphoric acid.

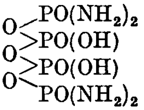
The latter does not agree so well with the existence and properties of the pentasilver salt as the former.

H. N. Stokes has obtained a number of derivatives of tetraphosphoric acid whose empirical compositions agree with the graphic formulæ:



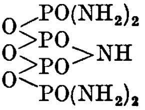
$$\begin{array}{l}\mathrm{O}{\diagup}\mathrm{PO(NH_2)_2}\\ \mathrm{O}{>}\mathrm{PO(OH)}\\ \mathrm{O}{>}\mathrm{PO(OH)}\\ \quad{\diagdown}\mathrm{PO(OH)_2}\end{array}$$

Diamidotetraphosphoric acid.



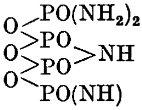
$$\begin{array}{l}\mathrm{O}{\diagup}\mathrm{PO(NH_2)_2}\\ \mathrm{O}{>}\mathrm{PO(OH)}\\ \mathrm{O}{>}\mathrm{PO(OH)}\\ \quad{\diagdown}\mathrm{PO(NH_2)_2}\end{array}$$

Tetramidotetraphosphoric acid.



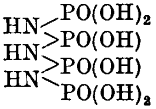
$$\begin{array}{l}\mathrm{O}{\diagup}\mathrm{PO(NH_2)_2}\\ \mathrm{O}{>}\mathrm{PO}{\diagdown}\\ \mathrm{O}{>}\mathrm{PO}{\diagup}{>}\mathrm{NH}\\ \quad{\diagdown}\mathrm{PO(NH_2)_2}\end{array}$$

Monimidotetramidotetraphosphoric acid.



$$\begin{array}{l}\mathrm{O}{\diagup}\mathrm{PO(NH_2)_2}\\ \mathrm{O}{>}\mathrm{PO}{\diagdown}\\ \mathrm{O}{>}\mathrm{PO}{\diagup}{>}\mathrm{NH}\\ \quad{\diagdown}\mathrm{PO(NH)}\end{array}$$

Diimidodiamidotetraphosphoric acid.



$$\begin{array}{l}\mathrm{HN}{\diagup}\mathrm{PO(OH)_2}\\ \mathrm{HN}{>}\mathrm{PO(OH)}\\ \mathrm{HN}{>}\mathrm{PO(OH)}\\ \quad{\diagdown}\mathrm{PO(OH)_2}\end{array}$$

Triimidotetraphosphoric acid.

These obviously represent but a small fraction of those theoretically possible; nor is there any particular evidence outside that furnished by the analysis and the rules of valency to show how the NH-, NH_2-, and the OH-groups are distributed in the mol. According to J. H. Gladstone, by saturating phosphoryl chloride with ammonia, and heating the product to about 200°, a white residue is obtained which furnishes **monimidotetramidotetraphosphoric acid,** $(NH)P_2O_7(NH_2)_4$, or $PO(NH_2)_2.O.(NH).O.PO.O.PO(NH_2)$, on treatment with water. The acid decomposes slowly when digested with water at ordinary temp., and rapidly when boiled. If the acid be treated with conc. aq. ammonia, a white-mass is obtained, which J. H. Gladstone said is not an ammonium salt. It is regarded as **amminomonoimidotetraphosphoric acid,** $NH_3.(NH)P_2O_7(NH_2)_4$. If monoimidotetramidotetraphosphoric acid be treated with a neutral or slightly acid soln. of silver nitrate, a yellowish-brown precipitate of the **silver diimidodiamidotetraphosphate** is obtained. The free acid, **diimidodiamidotetraphosphoric acid,** $(NH)_2P_2O_7(NH_2)_2$, has not been isolated.

H. N. Stokes prepared salts of **triimidotetraphosphoric acid,** $HN\{PO(OH).NH.PO(OH)_2\}_2$, by the hydrolysis of salts of pentametaphosphimic acid—*e.g.* a hot acetic acid soln. of sodium pentametaphosphate furnishes **sodium triimidotetraphosphate,** $NH\{PO(OH).NH.PO(ONa)_2\}_2$; and the addition of silver nitrate to the soln. furnishes the **silver triimidotetraphosphate,** $HN\{PO(OH).NH.PO(OAg)_2\}_2$. The acid is so unstable that it cannot be made by heating tetrametaphosphimate as might have been anticipated by the formation of diimidotriphosphoric acid by the action of heat on trimetaphosphimic acid.

The aq. soln. of the product of the action of gaseous ammonia on phosphoryl chloride contains a mixture of ammonium diamidodiphosphate and several amidotetraphosphates. The latter can be precipitated by treatment with alcohol. If the product is washed with alcohol, dissolved in water, again precipitated with alcohol, and dried in vacuo over sulphuric acid, **triammonium hydrodiamidotetraphosphate,** $(NH_4O)_3(HO)P_4O_7(NH_2)_2$, is formed. Free **diamidotetraphosphoric acid,** $(NH_2)_2P_4O_7(OH)_4$, is not known. The aq. soln. of the ammonium salt gives precipitates with the salts of many of the metals—silver nitrate, for instance, gives a white flocculent precipitate. The precipitates are probably mixtures of several amidotetraphosphates. The ammonium salt is decomposed into ammonium chloride and phosphoric acid when boiled with hydrochloric acid;

and when heated to 100°, it forms a white mass which smells of nicotine, and is possibly *triammonium amidodiphosphate*, $(NH_2)P_2O_3(ONH_4)_3$. Ammonium diamidotetraphosphate unites with ammonium to form a white mass; cold potash-lye decomposes it with the evolution of ammonia; and if covered with alcohol, and allowed to stand for a year, crystals of the ammonium salt of a new acid are formed. If the tertiary ammonium salt is heated to about 220°, it loses ammonia and forms a residue which is possibly **diammonium dihydrodiamidotetraphosphate,** $(NH_2)_2P_4O_7(OH)_2(ONH_4)_2$. This product is decomposed by water, forming diamidodiphosphoric acid, $(NH_2)_2P_2O_3(OH)_2$, and possibly also tetramidotetraphosphoric acid, $(NH_2)_4P_4O_7(OH)_2$.

J. H. Gladstone prepared **tetramidotetraphosphoric acid,** $(NH_2)_4P_4O_7(OH)_2$, by treating ammonium diamidotetraphosphate with mineral acids, potassium carbonate or hydroxide: $(NH_2)_2P_4O_7(OH)(ONH_4)_3+HCl=NH_4Cl+2H_2O+(NH_2)_4P_4O_7(OH)_2$. It is also produced along with diamido- and triamidodiphosphoric acids by the action of cold conc. nitric acid, or potassium carbonate or hydroxide on triammonium hydrodiamidotetraphosphate: $(NH_2)_2P_4O_7(OH)(ONH_4)_3+KOH=NH_3+3H_2O+(NH_2)_4P_4O_7(OH)(OK)$; and by boiling the same salt with water, $(NH_2)_2P_4O_7(OH)(ONH_4)_3=2H_2O+(NH_2)_4P_4O_7(OH)(ONH_4)$. The last reaction may proceed differently: $(NH_2)_2P_4O_7(OH)(ONH_4)_3+3H_2O=5NH_3+2H_4P_2O_7$. Tetramidotetraphosphoric acid does not appear to be affected by acids. The aq. soln. of tetramidotetraphosphoric acid gives no precipitate with hydrochloroplatinic acid. The acid unites with bases, forming salts; thus, **ammonium hydrotetramidotetraphosphate,** $(NH_2)_4P_4O_7(OH)(ONH_4)$, is obtained by neutralizing the acid with ammonia. The ammonium salt is soluble in water; the salt is precipitated from its aq. soln. by alcohol; and when dried in vacuo loses its ammonia. Similarly, **potassium hydrotetramidophosphate,** $(NH_2)_4P_4O_7(OH)(OK)$, can be prepared.

H. N. Stokes also made **sodium amidoheximidoheptaphosphate**—a salt of *amidoheximidoheptaphosphoric acid,* $PO(OH)(NH_2).NH.\{PO(OH)NH\}_5.PO(OH)_2$—by the hydrolysis of heptaphosphoric nitrilochloride with sodium hydroxide in an ethereal soln. He expected to obtain *heptametaphosphimic acid.* The sodium salt is decomposed by acids, forming tetrametaphosphimate.

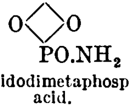
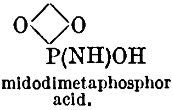
§ 71. The Metaphosphimic Acids and their Salts

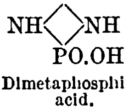
Just as the amidophosphoric acids can be called *phosphamic acids* or *phosphamidic acids,* so also can the imidophosphoric acids be called *phosphimic acid* or *phosphimidic acids.* The replacement of two hydroxyl groups or of phosphoryl oxygen in orthophosphoric acid by equivalent bivalent imido- or NH-groups, will furnish *orthophosphimic acids,* HO.PO.NH, or HN: $P(OH)_3$; so also will the substitution of HN-groups in place of the phosphoryl oxygen of metaphosphoric acids, $(HO.PO_2)_n$, furnish a series of polymerized *metaphosphimic acids,* $[HO(NH:P:O)]_n$ or $[PN(OH)_2]_n$. Several isomeric forms of each member of the series are theoretically possible, for example, with the second member, where $n=2$:



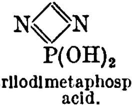
Diamidodimetaphosphoric acid.



Diimidodimetaphosphoric acid.



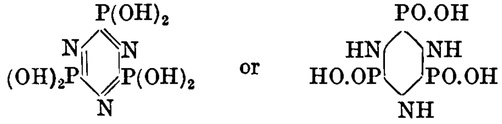
Dimetaphosphimic acid.



Nitrilodimetaphosphoric acid.

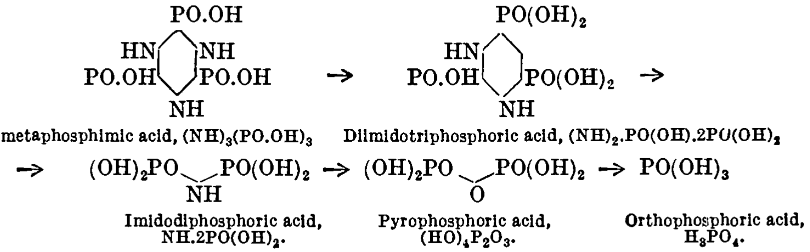
In 1888, A. Mente[1] described a product of the action of ammonium carbamate and water on phosphoryl chloride which he regarded as diimidodiphosphoric acid,

$HN<[PO(OH)]_2>NH$, with a possible constitution analogous with what had just been called *dimetaphosphimic acid*, and which he also considered to be identical with an acid prepared by J. H. Gladstone in 1850, and named *deutazophosphoric acid*, a cognomen subsequently altered to *pyrophosphodiamic acid*, $O[PO(OH)NH_2]_2$, because it was considered to be a diamide of pyrophosphoric acid. H. N. Stokes suggested that J. H. Gladstone's acid was impure **trimetaphosphimic acid,** because the analyses of the barium and silver salts agreed equally well with pyrophosphoric diamide, $(NH_2)_2(HO)_2P_2O_3$, or with $(NH_2)_3(HO)_3P_3O_3+1\frac{1}{2}H_2O$. Triphosphimic acid is obtained by the hydrolysis of an ethereal soln. of triphosphonitrilic chloride, $P_3N_3Cl_3$, by an aq. soln. of sodium acetate. The decomposition of a cold aq. soln. of silver trimetaphosphimate also furnishes a soln. of the acid. The acid is extremely soluble in water; the aq. soln. does not crystallize on evaporation, but it furnishes a gum-like mass. The constitutional formula assigned to trimetaphosphimic acid depends upon the formula assigned to triphosphonitrilic chloride from which it is formed by hydrolysis. Among other possibilities, H. N. Stokes suggests:



The latter type of formula is preferred, in agreement with the fact that no salt is known with six atoms of sodium per mol of the sodium salt. The ordinary sodium trimetaphosphimate has three sodium atoms per mol; although a most unstable salt with four sodium atoms per mol has been obtained by using a very large excess of sodium hydroxide, this readily passes into the trisodium salt. **Trisodium trimetaphosphimate,** $P_3N_3O_6H_3Na_3.4H_2O$, crystallizes in rhombic prisms from its aq. soln. at temp. below 80°; if the temp. exceeds 80°, needle-like crystals of the monohydrate, $P_3N_3O_6H_3Na_3.H_2O$, are deposited. The same salt is obtained by heating the tetrahydrate at 100°. It is not known if the difference between the two sodium salts is any more fundamental than a mere difference in the water of crystallization. Two anhydrous **silver trimetaphosphimates** are known: **trisilver trimetaphosphimate,** $P_3N_3O_6H_3Ag_3$, separates in monoclinic plates when an excess of silver nitrate is slowly added to a soln. of the sodium salt acidified with nitric acid, and **hexasilver trimetaphosphimate,** $P_3N_3O_6Ag_6$, is formed as a white, voluminous powder by adding sodium trimetaphosphimate to an excess of an ammoniacal soln. of silver nitrate. The existence of this salt is taken to show that the acid is probably a derivative of metaphosphimic acid. H. N. Stokes suggested that the hydrogen atoms are labile, and that the two graphic ring formula represent tautomeric compounds.

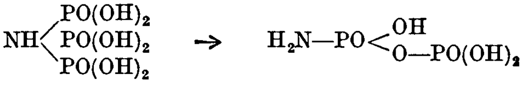
When an aq. soln. of trimetaphosphimic acid, or of one of its salts, acidified with one of the stronger mineral acids, is heated or kept for a long time, decomposition occurs—slowly if cold, rapidly if heated. Orthophosphoric acid and ammonia (ammonium phosphate) are the ultimate products of the decomposition. Several intermediate products have been detected; in addition to pyrophosphoric acid, what H. N. Stokes calls diimidotriphosphoric acid, and imidodiphosphoric acid have been found, and he represents the different stages of the decomposition:



Trimetaphosphimic acid, $(NH)_3(PO.OH)_3$ Diimidotriphosphoric acid, $(NH)_2.PO(OH).2PO(OH)_2$

Imidodiphosphoric acid, $NH.2PO(OH)_2$. Pyrophosphoric acid, $(HO)_4P_2O_3$. Orthophosphoric acid, H_3PO_4.

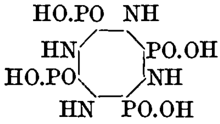
The hypothesis that imidodiphosphoric acid contains the group $\equiv P-NH-P\equiv$ explains very well its relationship with trimetaphosphimic acid, but it does not so readily explain its hydrolytic transformation into pyrophosphoric acid in view of the ease with which the latter passes into orthophosphoric acid, unless the fact be supplemented with the hypothesis that on account of the greater affinity of phosphorus for oxygen than for nitrogen, $PO(OH)_2$ can change places with a hydroxylic oxygen in the mol. $NH(PO(OH)_2)_2$ to form an unstable amidodiphosphoric acid:



$$NH{<}\begin{matrix}PO(OH)_2\\PO(OH)_2\\PO(OH)_2\end{matrix} \rightarrow H_2N-PO{<}\begin{matrix}OH\\O-PO(OH)_2\end{matrix}$$

which then breaks down into pyrophosphoric acid. The last-named formula is virtually that given by J. H. Gladstone for amidophosphoric acid, and is equivalent to that required for imidodiphosphoric acid. An amido-imidodiphosphoric acid, $(OH)_2PO-NH-PO(OH)NH_2$, intermediate between diimidotriphosphoric acid and imidodiphosphoric acid, has not been detected among the products of the decomposition of trimetaphosphimic acid.

While the hydrolysis of triphosphonitrilic chloride furnishes trimetaphosphimic acid, the hydrolysis of tetraphosphonitrilic chloride, $P_4N_4Cl_8$, furnishes **tetrametaphosphimic acid,** $P_4N_4H_8O_8$, which, by analogy with trimetaphosphic acid, has the ring formula:



Tetraphosphimic acid crystallizes in colourless needles, with the composition $P_4N_4H_8O_8.2H_2O$. The acid is sparingly soluble in water—100 parts of water at 20° dissolve 0·64 part of the crystalline acid; the solubility is diminished if other acids be present; thus 10 per cent. of acetic acid lowers the solubility nearly 30 per cent. The aq. soln. is far more stable than the corresponding trimetaphosphimic acid; indeed, tetraphosphimic acid is more stable than any other acid of the series. Nitric acid readily transforms trimetaphosphimic acid into metaphosphoric acid in a few minutes, but the tetrametaphosphimic acid is scarcely attacked even by evaporation to dryness with conc. nitric acid or aqua regia. The acid usually behaves as if it were di-, tetra-, or octo-basic. The salts readily crystallize, and are usually sparingly soluble in water. Thus, **dipotassium tetrametaphosphimate,** $K_2H_6P_4N_4O_8$, is formed by dissolving the acid in a dil. soln. of potassium hydroxide, when prismatic crystals of the salt separate on adding acetic acid: **tetrapotassium tetrametaphosphimate,** $K_4H_4P_4N_4O_8$, forms sparingly soluble tablets. The dibarium salt crystallizes with the eq. of two mols of water; the tetrasodium salt with 2½ mols of water; the diammonium salt is anhydrous; and the tetrammonium salt has the eq. of four mols of water. **Tetrasilver tetrametaphosphimate,** $Ag_4H_4P_4N_4O_8$, separates as a white precipitate on adding silver nitrate to a soln. of the acid; with ammoniacal silver nitrate and a soln. of the ammonium salt, yellow **octosilver tetrametaphosphimate,** $Ag_8P_4N_4O_8$, is formed.

While the hydrolysis of triphosphonitrilic chloride with sodium acetate furnishes trimetaphosphimic acid; and the hydrolysis of tetraphosphonitrilic chloride with water furnishes tetrametaphosphimic acid, the hydrolysis of pentaphosphonitrilic chloride, $P_5N_5Cl_{10}$, with sodium hydroxide in ethereal soln. furnishes **sodium pentametaphosphimic acid,** $P_5N_5H_{10}O_{10}$, or rather the alkali pentametaphosphimate—sufficient alkali must be present to maintain the alkalinity of the soln. The sodium salts are amorphous, and are precipitated in a gelatinous form by the addition of alcohol to the alkaline soln., or to the soln. neutralized with acetic or nitric acid. Penta- and tetra-sodium salts and salts with even less sodium each with the equivalent of two mols of water of crystallization have been obtained. The silver salts of the meta-phosphimic acids are all anhydrous. The composition of the silver salts depends upon the relative amounts of the reacting substances. The salt $P_5N_5O_{10}H_5Ag_5$ is precipitated by adding silver nitrate to an acidified soln. of the sodium salt; salts with a higher proportion of silver are precipitated from ammoniacal soln. Salts with up to five atoms of silver per mol are white, and those containing more silver are yellow, and this the more the greater the proportion of silver they contain. The free acid, contaminated with some impurities, is obtained by decomposing the silver salt by hydrogen sulphide under well-cooled water. A soln. of the acid has a somewhat astringent taste, and is imperfectly precipitated by alcohol in a gelatinous form. The aq. soln. is more stable than trimetaphosphimic acid; and has a lower rate of decomposition when acted upon by nitric acid. Tetrametaphosphimic, triimidotetraphosphoric, diimidotriphosphoric, and orthophosphoric acids have been detected among the products of decomposition. Pentametaphosphimic acid is conveniently regarded as the lactam (that is, the anhydride of an amido-acid):

$$\mathrm{POOH}<\begin{matrix}\mathrm{NH.POOH.NH.POOH}\\ \mathrm{NH.POOH.NH.POOH}\end{matrix}>\mathrm{NH}$$

of *amidotetrimidopentaphosphoric acid:*

$$\mathrm{POOH}<\begin{matrix}\mathrm{NH.POOH.NH.PO(NH_2)OH}\\ \mathrm{NH.POOH.NH.PO(OH)_2}\end{matrix}$$

formed by the loss of a mol of water. The acid is said to exist in the lactam form in the pentasilver salt and in soln. of the acid and normal salts; in alkaline soln. the acid is thought to be in the open form because the silver salt prepared in an alkaline soln. has a composition corresponding with this formula.

H. N. Stokes found that **hexametaphosphimic acid,** $P_6N_6H_{12}O_{12}$, is obtained from hexaphosphonitrilic chloride, $P_6N_6Cl_{12}$, in a manner analogous with the preparation of pentametaphosphimic acid from pentaphosphonitrilic chloride. The hexa- and penta-metaphosphimic acids and their salts closely resemble one another, but the former are rather less stable than the latter. A hexa-sodium salt is obtained by treating a soln. of the acid neutralized with sodium hydroxide by alcohol. The hexasilver salt is obtained in a manner analogous with that employed for the corresponding salt of pentametaphosphimic acid; and a yellow salt is obtained by precipitation from an alkaline soln. The acid is regarded as the lactam (anhydride) of *amidopentimidohexaphosphoric acid,* that is

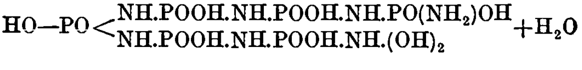
$$\mathrm{POOH}<\begin{matrix}\mathrm{POOH.NH.POOH.NH.POOH}\\ \mathrm{POOH.NH.POOH.NH.POOH}\end{matrix}>\mathrm{NH}$$

from

$$\mathrm{POOH}<\begin{matrix}\mathrm{POOH.NH.POOH.NH.PO(NH_2)OH}\\ \mathrm{POOH.NH.POOH.NH.PO(OH)_2}\end{matrix}$$

by the loss of a mol of water. When the sodium salt is heated with acetic acid it gives tetrametaphosphimic acid.

The hydrolysis of the higher homologues of the phosphonitrilic chlorides does not furnish corresponding metaphosphimic acids, for while hexaphosphonitrilic chloride furnishes hexametaphosphimic acid, heptaphosphonitrilic chloride, $P_7N_7Cl_{14}$, does not furnish heptametaphosphimic acid, but rather *amidohexaimidoheptaphosphoric acid—vide supra*—with the empirical formula $H_{16}P_7N_7O_{15}$, or $(PNO_2H_2)_7H_2O$, that is:



$$\mathrm{HO{-}PO}<\begin{matrix}\mathrm{NH.POOH.NH.POOH.NH.PO(NH_2)OH}\\ \mathrm{NH.POOH.NH.POOH.NH.(OH)_2}\end{matrix}+\mathrm{H_2O}$$

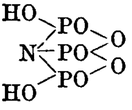
so that the homologous series of the phosphimic acids terminates with the acid

$(PNO_6H_2)_6$. The tri-, tetra-, penta-, and hexa-metaphosphamic acids may thus exist in two forms—the lactamic form, metaphosphimic acids, $(PNO_2H_2)_n$, where n is 3, 4, 5, or 6, which exists only in neutral or acidic soln.; and the open-chain form, $(PNO_2H_2)_n + H_2O$, which exists in alkaline soln. Acids derived from heptaphosphonitrilic chloride, and the higher members, do not appear to form lactams, and the open-chain form persists under all circumstances. The acid furnishes *sodium amidohexaimidoheptaphosphate*, $Na_7P_7N_7H_9O_{15}$, as a very soluble white powder, and *silver amidohexaimidoheptaphosphate*, $Ag_7P_7N_7H_9O_{15}$, as a sparingly soluble powder. The tri- and tetra-metaphosphimic acids give characteristic salts. The salts with five, six, and seven atoms of phosphorus have not been crystallized; alcohol precipitates the alkali salts from their aq. soln. as syrups which can be dehydrated to form amorphous powders. Trimetaphosphimic acid forms neutral sodium salts with three sodium atoms per mol; tetrametaphosphimic acid gives salts with two and four sodium atoms per mol; while the penta-acid gives a salt with five sodium atoms and which is strongly alkaline. The decreasing acidity of unneutralized hydroxyl-groups, well shown in orthophosphoric acid, is increasingly pronounced with the higher members of the metaphosphimic acids. The salts of the higher members of the series are readily hydrolyzed in aq. soln., and this, together with the feeble crystallizing powers, makes the preparation of even moderately pure salts very difficult.

H. N. Stokes mentioned *henametaphosphimic acid*, formed by hydrolysis from an oily liquid obtained in the preparation of the chloronitrides, with the composition $P_{11}N_{11}O_{22}$. The acid readily decomposes into diimidotriphosphoric, triimidotetraphosphoric, and tetrametaphosphimic acids.

Dry ammonia acts slowly on triphosphonitrilic chloride in ethereal soln., forming triphosphonitrilic chloramide, $P_3N_3(NH_2)_2Cl_4$, which remains in soln. The reaction slowly progresses yet further, but not to completion. The products of the further action are insoluble in ether. When the ethereal soln. of the chloramide is hydrolyzed with sodium hydroxide, **sodium diamidotrimetaphosphimate** is formed. Conc. aq. ammonia reacts vigorously with the tri-, tetra-, and the pentaphosphonitrilic chlorides in ethereal soln., and an indefinite proportion of the chlorine is replaced by amido-groups. Amido-compounds of constant composition have accordingly not been prepared.

According to A. Mente, if in the preparation of imidodiphosphoric acid, the products be heated to 290° or 300°, ammonia is evolved, and a white fiocculent powder is formed from which ammonium chloride can be removed by washing with water. The pale yellow residue dissolves in aq. ammonia; and when the soln. is acidified with nitric or hydrochloric acid, a white precipitate is formed, and the soln. contains what is thought to be **nitrilotrimetaphosphoric acid,**



.

The intermediate stages of the reaction are indicated by the scheme: $NH(POCl_2)_2 \rightarrow N(POCl_2)_3$, and this product, on hydrolysis, furnishes the acid in question. The free acid cannot be isolated, though lead, barium, and silver salts can be readily obtained. The alkali salts are crystalline and soluble in water. Oxidizing agents convert the soln. into orthophosphates.

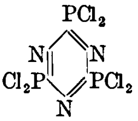
§ 72. Phosphorus Chloronitrides or Phosphonitrilic Chlorides

In the attempt to prepare the amides of phosphoric acid by the action of gaseous ammonia or ammonium chloride on phosphorus pentachloride, J. von Liebig,[1] in 1832, discovered a remarkable compound which he called *Chlorphosphorstickstoff* —remarkable because it was not expected that the compound would be so stable as to enable it to be distilled in steam, or boiled with acids or alkalies without appreciable decomposition. Analyses led J. von Liebig to the formula $P_3N_2Cl_5$, but A. Laurent, and C. Gerhardt showed that the empirical formula must be $PNCl_2$; and, in 1864, J. H. Gladstone and J. D. Holmes tripled Laurent and Gerhardt's formula so as to make it harmonize with the vap. density. H. Wichelhaus then suggested a constitutional cyclic formula :

to explain its stability; but H. N. Stokes argued that since (1) the compound decomposes into orthophosphoric acid and ammonia, (2) it is formed from ammonia and phosphorus pentachloride ; and (3) there are no signs of double or triple-linked phosphoric acids or of hydrazine in the decomposition products, the probability is that the phosphorus atoms are united by nitrogen atoms. He also believed that the absence of hydroxylamine in the decomposition products shows that the chlorine is probably united directly to the phosphorus and not to the nitrogen atoms. In agreement with these arguments, H. N. Stokes prefers the cyclic formula :



He has also shown that this compound—now called triphosphonitrilic chloride, $N_3P_3O_6H_6$—is the first member of a series of polymers with the general formula $(PNCl_2)_n$, where n ranges from 3 to 7 and upwards. The more important physical constants of these compounds, mainly investigated by H. N. Stokes, are indicated in Table XXXV. No member of the series lower than the triphosphonitrilic chloride has been obtained. Each member of the series can be converted by heat into a rubber-like polyphosphonitrilic chloride or mixture of these chlorides of high mol. wt. and which are highly elastic, and insoluble in neutral solvents, but swell up considerably in benzene. On distillation at a higher temp., the higher members break down into the lower members, which can then be separated by fractional distillation. The polymerization of any member of the series begins at about 250°, and is almost instantaneous at about 350° ; depolymerization begins just over 350°, and is rapid near incipient redness.

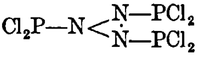
Table XXXV.—Physical Properties of the Phosphonitrilic Chlorides.

Phosphonitrilic chloride formula.	Melting point.	Boiling point at 13 mm.	Boiling point 760 mm.
Triphosphonitrilic chloride, $(PNCl_2)_3$.	114°	127°	256·5°
Tetraphosphonitrilic chloride, $(PNCl_2)_4$.	123·5°	188°	328·5°
Pentaphosphonitrilic chloride, $(PNCl_2)_5$.	40·5°–41°	223°–224·3°	polymerizes
Hexaphosphonitrilic chloride, $(PNCl_2)_6$.	90°	261°–263°	polymerizes
Heptaphosphonitrilic chloride, $(PNCl_2)_7$.	below −18°	289°–294°	polymerizes
Polyphosphonitrilic chloride, $(PNCl_2)_n$.	below 500°	depolymerizes	on distillation

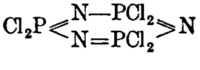
The preparation of the phosphonitrilic chlorides.—Equimolecular parts of ammonium chloride and phosphorus pentachloride are gradually heated in a sealed tube to 150°—frequently opening the tube to allow the escape of the hydrogen chloride, and prevent the development of too great a pressure. A reaction $n\mathrm{NH_4Cl}+n\mathrm{PCl_5}=(\mathrm{PNCl_2})_n+4n\mathrm{HCl}$ occurs. The contents of the tube are extracted with gasoline, and the insoluble residue is distilled by heating to incipient redness. The distillate is a crystalline mass permeated with a yellow oil. The mass is washed with hot water, and afterwards distilled at 200° (13–15 mm.) in a sublimate flask, since the distillate solidifies on cooling. This fraction contains the tri- and the tetra-phosphonitrilic chlorides ; the residue in the retort contains the higher members of the series. The distillate is re-fractionated, and crystallized from benzene three or four times ; the tetraphosphonitrilic chloride accumulates in the mother-liquid. The residue in the flask, boiling over 200° (13–15 mm.), is fractionally distilled at 13–15 mm. press. On redistilling the fractions, penta-, hexa-, and hepta-phosphonitrilic chlorides are obtained. The hexa-compound is contaminated with a compound $\mathrm{P_6N_7Cl_9}$, from which it is separated by fractional crystallization from benzene—the hexaphosphonitrilic chloride is the less soluble.

Instead of using the troublesome process of H. N. Stokes, R. Schenck and G. Römer added 120–130 grms. of ammonium chloride to a soln. of 400 grms. of phosphorus pentachloride in a litre of *s*-tetrachloroethane, and boiled the mixture in a reflux condenser at 135° until hydrogen chloride is no longer evolved from the calcium chloride tube at the top of the condenser. In about 20 hrs., the ammonium chloride is filtered off, and the solvent distilled off at about 11 mm. press. The residue is a buttery mass free from ammonium chloride. The yield, 220 grms., is nearly theoretical. The oil is removed by suctional filtration, and the last portions by benzene at 0°. About 100 grms. of mixed tri- and tetra-phosphonitrilic chlorides remain as a crystalline powder. This is recrystallized from benzene, fused at about 50°, and distilled under reduced press. At 10 mm. press., 75 grms. of the tri-polymer distil at 124°, and 25 grms. of the tetra-polymer at 185°. These are recrystallized from benzene or chloroform.

According to H. N. Stokes, the first member of the series, **triphosphonitrilic chloride,** $\mathrm{P_3N_3Cl_6}$, forms large thick rhombic crystals of sp. gr. 1·98. R. Schenck and G. Römer said that this compound boils at 124° and 10 mm., and melts at 114° ; and that it polymerizes to a colourless transparent mass resembling caoutchouc at temp. above 255°. H. N. Stokes found that it is soluble in ether, chloroform, benzene, carbon disulphide, etc. 100 grms. of ether at 20° dissolve 46·5 grms. of the solid, and 100 grms. of benzene at the same temp. 57·4 grms. The solid readily dissolves in glacial acetic acid, and in sulphuric acid ; when the latter soln. is boiled, a vapour with a pleasant aromatic odour is evolved, which soon attacks the respiratory passages, and makes breathing difficult. Although not readily attacked by water alone, it is hydrolyzed when a soln. in alcohol-free ether is shaken with water. The final product of the action is trimetaphosphimic acid, $\mathrm{P_3N_3(OH)_6}$, in which all the chlorine is replaced by hydroxyl ; an intermediate product of the hydrolysis, **triphosphonitrilic hydroxylchloride,** $\mathrm{P_3N_3Cl_4(OH)_2}$, has been isolated in well-defined, minute, prismatic crystals; other hydroxychlorides are probably formed at the same time. Orthophosphoric acid, ammonia, and hydrochloric acid are ultimate products of the hydrolysis. Aniline or piperidine transform the benzene soln. into the anilide $\mathrm{N{\equiv}P(NHC_6H_5)_2}$, melting at 261°, and the piperidide melting at 231°. R. Schenck found that cryoscopic and ebulliscopic methods show that the product of the action of aniline has the formula $\{\mathrm{NP(NHC_6H_5)_2}\}_3$. F. Wissemann studied its action on methyl and ethyl alcohols, benzyl and acetoacetic ethers, phenol, α-naphthol, and of hydrocyanic acid in pyrodine and quinoline soln. ; and H. Schäperkötter, the action on tertiary amines, amino-acid esters, and ammonia. Water in the presence of piperidine converts these compounds into pyridine hydrochloride and pyridinium metaphosphimate, $\mathrm{N{\equiv}P(OH)_2.C_5H_5N}$. All the pyridine is expelled at 200° and 11 mm. press., leaving a residue of metaphosphimic acid. It is thought that neither of the closed-ring formulæ



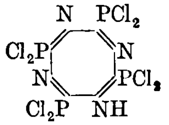
$$\mathrm{Cl_2P{-}N}<\genfrac{}{}{0pt}{}{\mathrm{N{-}PCl_2}}{\dot{\mathrm{N}}\mathrm{{-}PCl_2}}$$



$$\mathrm{Cl_2P}<\genfrac{}{}{0pt}{}{\mathrm{N{-}PCl_2}}{\mathrm{N{=}PCl_2}}>\mathrm{N}$$

adequately explained the reactions. According to A. Besson and G. Rosset, when triphosphonitrilic chloride is treated with liquid ammonia, one-third of the chlorine is replaced by an amido-group, forming white **triphosphonitrilic amide,** $P_3N_3(NH_2)_6$. This compound, when heated to about 220° for some days, loses ammonia, and furnishes phospham, PN_2H. If dry ammonia gas is passed into a soln. of triphosphonitrilic chloride in carbon tetrachloride, slender, prismatic, needle-like crystals of **triphosphonitrilic chloramide** are obtained, possibly $P_3N_3Cl_4(NH_2)_2$ are formed. The compound is insoluble in ether and carbon disulphide,and is probably an intermediate product in the action of ammonia on triphosphonitrilic chloride. Sulphur trioxide and nitrogen peroxide also form additional products with triphosphonitrilic chloride. When heated with nitrogen peroxide in a sealed tube to 20°–25°, triphosphonitrilic chloride forms a compound with the ultimate composition $P_4O_{12}N$, corresponding with $2P_2O_5.NO_2$—*vide supra.* The same compound is formed by heating phosphorus pentoxide with nitrogen peroxide in a sealed tube to 200°. It is sparingly soluble in water, and the aq. soln. quickly decomposes. According to A. Besson, also, when the compound of phosphorus pentachloride with ammonia is slowly heated, it loses ammonia, and, between 175° and 230° under a reduced press. (50 mm.), white crystals of what has been called **phosphorus dichloronitride,** $(PCl_2N)_n$, sublime. This compound is probably identical with H. N. Stokes' triphosphonitrilic chloride. The crystals, purified by resublimation in vacuo, melt at 106°, and are distinctly volatile under reduced press. at 100°, so that the compound does not preexist in the octammine from which it was prepared, for the latter does not form a sublimate below 175°.

The next member of the series, **tetraphosphonitrilic chloride,** $P_4N_4Cl_8$, forms colourless prisms with a sp. gr. 2·18. R. Schenck and G. Römer gave 185° for the b.p. at 10 mm. press., and 123·5° for the m.p., and added that above 255° it behaves like the tri-polymer. H. N. Stokes found that analyses, vapour density determinations in dry hydrogen, and the depression of the f.p. of benzene soln., agree with the formula $P_4N_4Cl_8$ and by analogy with triphosphonitrilic chloride, the constitution may be:



It dissolves in similar solvents to form the triphosphonitrilic chloride—thus, 100 grms. of ether at 20° dissolve 12·3 grms. of the compound; and 100 grms. of benzene, 20·9 grms. It is scarcely attacked by boiling water, acids, or alkali-lye, but water acts upon the ethereal soln. rather more slowly than is the case with the preceding compound, and forms tetrametaphosphamic acid, $P_4N_4(OH)_8.2H_2O$; an intermediate **tetraphosphonitrilic hydroxychloride** has been obtained. R. Schenck and G. Römer obtained similar reactions with aniline and piperidine to those obtained with the tripolymer. While the oily phosphonitrilic chlorides are thought to be open-chain products, the tri- and tetra-polymers are thought to be closed-chain compounds. According to R. Schenck, cryoscopic and ebulliscopic methods show that the product of the action of aniline has the composition $\{NP(NHC_6H_5)_2\}_4$. F. Wissemann studied the action of tetraphosphonitrilic chloride on methyl and ethyl alcohols, benzyl acetoacetic ethers, phenol, α-naphthol, and of hydrocyanic acid in pyridine and quinoline soln.; and H. Schäperkötter, the action on tertiary amines, amino-acid esters, and ammonia.

The next member of the series, **pentaphosphonitrilic chloride,** $P_5N_5Cl_{10}$, was found by H. N. Stokes to form a crystalline mass readily soluble in various organic solvents. It is readily attacked by water in ethereal soln. giving pentametaphosphimic acid. It is precipitated by water from its soln. in glacial acetic acid. Analyses and its effect on the b.p. of benzene soln. agree with the formula $P_5N_5Cl_{10}$. A. M. Vasilieff modifying the definition of a eutectic regarded the pentametaphosphonitrilic chloride as a eutectic: $(PNCl_2)_4+(PNCl_2)_6=2(PNCl_2)_5$. Finally,

H. N. Stokes found that **hexaphosphonitrilic chloride,** $P_6N_6Cl_{12}$, forms long, prismatic rhombic crystals. It gives hexametaphosphimic acid when its ethereal soln. is shaken with water, and is but slowly attacked by boiling water alone. Hydrogen chloride is slowly evolved when it is exposed to moist air. Analyses and the b.p. of benzene soln. correspond with the formula $P_6N_6Cl_{12}$. **Heptaphosphonitrilic chloride,** $P_7N_7Cl_{14}$, is a colourless, viscid liquid readily miscible with organic solvents, and it behaves similarly with the other phosphonitrilic chlorides towards water; its mol. wt. has been established by analyses, and its effect on the b.p. of benzene.

The oily residue remaining after the above compounds have been removed by distillation is doubtless a mixture of higher polymerides. **Hexaphosphoheptanitrilic chloride,** $P_6N_7Cl_9$, resembles the phosphonitrilic chlorides in its general properties; it fuses at 237·5°, and boils at 251°–261° (13 mm.) without change. It forms transparent rhombic prisms. Analyses and mol. wt. determinations in boiling benzene agree with the formula $P_6N_7Cl_9$. It may be hexaphosphonitrilic chloride in which three atoms of chlorine have been replaced by one of nitrogen.

A series of **phosphonitrilic bromides,** $(PNBr_2)_n$, analogous with the phosphonitrilic chlorides, have been made by the action of ammonia on phosphorus pentabromide. The phosphonitrilic bromide, $(PNBr_2)_3$, forms colourless rhombohedral crystals which melt at 188°–190°, and are insoluble in water. A. Besson obtained white crystals of the *phosphorus dibromonitride,* $(PBr_2N)_n$, or **triphosphonitrilic bromide,** in a somewhat similar manner to that employed for the corresponding chloride. The crystals melt at 188°–190°, and sublime in vacuo at 150°. This compound is insoluble in water, fairly soluble in ether, and less soluble in carbon disulphide and chloroform.

The antimony analogues of the phosphorus chloronitriles, produced by the action of ammonium chloride on phosphorus pentachloride, have not been prepared; instead of furnishing the analogous **antimony chloronitride,** $SbCl_5+NH_4Cl=SbNCl_2+4HCl$, the main reaction proceeds: $3SbCl_5+2NH_4Cl=3SbCl_3+8HCl+N_2$, showing that the antimonic chloride is reduced to the lower chloride—presumably the primary reaction is a decomposition of ammonium chloride by chlorine from dissociated antimony pentachloride. Ferric, cupric, and chromic chlorides under similar conditions are also reduced to the lower chlorides. This agrees with the general rule that only those metal chlorides which readily dissociate to a lower chloride when heated with ammonium chloride in a sealed tube, break up the ammonium salt liberating nitrogen. Mercuric chloride is exceptional in that it forms a double salt under similar conditions. With titanium and tin tetrachlorides there is no corresponding dissociation under the conditions of the experiment, and no reaction occurs other than the formation of a double salt. E. and P. Fireman tried also to prepare analogues of the polymeric phosphonitrilic chlorides with antimony or tin in place of phosphorus, and phosphorus in place of nitrogen by the action of phosphonium iodide, PH_4I, on antimony pentachloride, or tin tetrachloride. The action of phosphonium iodide is, however, radically different from that of ammonium chloride, since it acts as a reducing agent. When phosphonium iodide and antimony pentachloride are brought into contact, a reaction occurs with explosive violence, but when the two compounds are brought together in a sealed tube, and heated for say 5 hrs. between 95° and 105°, the pentachloride is reduced to the trichloride, and a third of the antimony is converted into the tri-iodide: $3SbCl_5+3PH_4I=SbI_3+2SbCl_3+9HCl+PH_3+2P$; and with phosphorus trichloride under similar conditions, the reaction is symbolized: $3PCl_5+3PH_4I=PI_3+PCl_3+12HCl+4P$. Stannic chloride, and phosphonium iodide under similar conditions furnish stannous chloride and iodide: $6SnCl_4+6PH_4I=3SnCl_2+3SnI_2+18HCl+2PH_3+4P$.

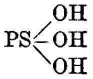
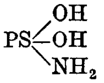
§ 73. Ammonia Derivatives of Thiophosphoric Acid

Ammonia derivatives of thiophosphoric acid, $PS(OH)_3$, have been reported in which the hydroxyl groups are replaced one by one by the amido-radicle; thus:



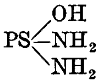
$$\mathrm{PS}\!\begin{array}{l}\diagup\mathrm{OH}\\ -\mathrm{OH}\\ \diagdown\mathrm{OH}\end{array}$$

Thiophosphoric acid.



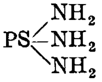
$$\mathrm{PS}\!\begin{array}{l}\diagup\mathrm{OH}\\ -\mathrm{OH}\\ \diagdown\mathrm{NH_2}\end{array}$$

Amidothiophosphoric acid.



$$\mathrm{PS}\!\begin{array}{l}\diagup\mathrm{OH}\\ -\mathrm{NH_2}\\ \diagdown\mathrm{NH_2}\end{array}$$

Diamidothiophosphoric acid.



$$\mathrm{PS}\!\begin{array}{l}\diagup\mathrm{NH_2}\\ -\mathrm{NH_2}\\ \diagdown\mathrm{NH_2}\end{array}$$

Thiophosphoryl amide.

J. H. Gladstone and J. D. Holmes[1] agitated dil. aq. ammonia with thiophosphoryl chloride, and obtained an acid liquor which contained ammonium chloride and **amidothiophosphoric acid,** $SP(NH_2)(OH_2)$, and from which the cadmium or lead salts could be precipitated, but not the salts of the alkaline earths, or of iron, nickel, or cobalt. Mercuric chloride gave a yellow thiochloride which became black when treated with acid.

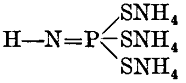
J. H. Gladstone and J. D. Holmes prepared **diamidothiophosphoric acid,** $SP(NH_2)_2(OH)$, by the action of ammonia gas on thiophosphoryl chloride, and digesting the product in water. T. E. Thorpe and J. W. Rodger obtained it by the action of ammonia on thiophosphoryl fluoride, and digesting the product in water: $SP(NH_2)_2F+H_2O=HF+SP(NH_2)_2OH$. The acid liquor gives the reactions neither of hydrogen sulphide nor of phosphoric acid. After neutralization, the soln. gives white, flocculent precipitates with zinc and cadmium salts; a greenish-white precipitate with a nickel salt; and a bluish-white one from a cobalt salt. The precipitates are soluble in aq. ammonia and in acids. Aq. soln. of lead chloride give a white precipitate soluble in dil. nitric acid, and when the precipitate is heated with water, it blackens. The neutralized aq. soln. gives a yellowish-white precipitate with a soln. of a copper salt; the precipitate becomes brown when dried, and it is soluble in an aq. soln. of potassium cyanide, but not in dil. acids or aq. ammonia. A soln. of stannous chloride gives a white precipitate; and one of mercuric chloride, a white precipitate which soon passes into yellow mercuric thiochloride. No precipitates are produced with soln. of calcium, barium, magnesium, aluminium, or ferric salts. The metal salts decompose when heated, forming ammonia, and ammonium sulphide. The soln. obtained by mixing silver or copper salts with an aq. soln. of the acid, decompose when evaporated over conc. sulphuric acid with the separation of sulphur.

H. Schiff,[2] and M. Chevrier reported **thiophosphoryl amide,** $SP(NH_2)_3$, to be formed along with ammonium chloride when ammonia is passed over thiophosphoryl chloride; the white solid first formed is pulverized and again exposed to the action of the gas. The product is rapidly extracted with water, and thiophosphoryl amide remains as a white (H. Schiff), or yellowish-white (M. Chevrier), amorphous mass of sp. gr. 1·7 at 13°. When heated over 200°, ammonium hydrosulphide is evolved, and at 240°, about 20 per cent. of sulphur is formed. H. Schiff said that if heated out of contact with air, the residue is free from sulphur and is probably phospham. According to H. Schiff, the compound is rapidly decomposed by water, particularly if warm, forming hydrogen sulphide, and also, according to M. Chevrier, ammonium thiophosphate. Fuming nitric acid oxidizes the triamide vigorously to phosphoric and sulphuric acids; and with potassium hydroxide, ammonia is evolved. The triamide is sparingly soluble in alcohol, ether, and carbon disulphide. The Zircon Glühlampenwerk tried the triamide in making filaments for incandescent electric lamps.

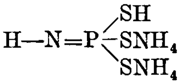
According to A. Stock and B. Hoffmann, phosphorus pentasulphide and ammonia at ordinary temp. form a yellow addition product, $P_2S_5.6NH_3$, and at $-20°$, a colourless addition product $P_2S_5.7NH_3$. The hexammine is considered to be ammonium diimidopentathiodiphosphate:

$$\begin{array}{l}\mathrm{NH_4S}\\ \mathrm{NH_4S}\end{array}\!>\mathrm{P}<\!\begin{array}{c}\mathrm{NH}\qquad\mathrm{NH}\\ \text{——}\mathrm{S}\text{——}\end{array}\!>\mathrm{P}<\!\begin{array}{l}\mathrm{SNH_4}\\ \mathrm{SNH_4}\end{array}$$

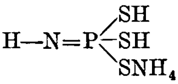
while the heptammine is regarded as a mixture of ammonium nitrilodithiophosphate and ammonium imidotrithiophosphate derived from the diimidopentathiodiphosphate: $NH_3+(NH_4S)_2P(NH).S.P(NH)(SNH_4)_2 \rightarrow NP(SNH_4)_2+HN.P(SNH_4)_3$. The ammonium imidotrithiophosphate can lose ammonia in successive stages to form a series of imidotrithiophosphoric acids, HN : P(SH)$_3$, thus:



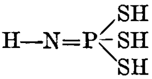
Triammonium imidotrithio-phosphate.



Diammonium imidotri-thiophosphate.



Ammonium imidotrithio-phosphate.



Imidotrithiophosphoric acid.

These three ammonium salts, and the free acid, when heated may pass into thiophosphoryl nitrile, and at a red-heat into phosphorus nitride. When diammonium nitrilodithiophosphate is heated, it loses ammonia, forming the monammonium salt —the free acid, nitrilodithiophosphoric acid, N ⋮ P(SH)$_2$, has not been made:

$N\equiv P=S$

Thiophosphoryl nitrile.

$N\equiv P<\begin{smallmatrix}SH\\SH\end{smallmatrix}$

Nitrilodithiophosphoric acid.

$N\equiv P<\begin{smallmatrix}SNH_4\\SH\end{smallmatrix}$

Ammonium nitrilo-dithiophosphate.

$N\equiv P<\begin{smallmatrix}SNH_4\\SNH_4\end{smallmatrix}$

Diammonium nitrilo-dithiophosphate.

E. Glatzel obtained **thiophosphoryl nitrile,** N ⋮ P : S, by heating a mixture of 3 mols of phosphorus pentasulphide, and one mol of ammonium chloride: $2NH_4Cl+P_2S_5=2NPS+2HCl+3H_2S$. A. Stock and co-workers obtained it by heating one of the ammonium imidotrithiophosphates in vacuo. The decomposition begins at 180°, but the temp. should be carried to 325° very slowly in order to complete the reaction. It is also formed by heating imidotrithiophosphoric acid to 250°–280°, in vacuo; or ammonium diamidopentathiodiphosphate to 270° in vacuo. The white product is stable; it is very slowly attacked by water; and quickly by hot dil. hydrochloric acid. When heated to 140° with water in a sealed tube it is completely decomposed: $NPS+4H_2O=H_3PO_4+H_2S+NH_3$. Red or fuming, warm nitric acid attacks the nitrile. Liquid ammonia has no action on the nitrile-group, but at high temp., phosphorus pentasulphide and nitride are formed.

A. Stock and co-workers were unable to isolate **nitrilodithiophosphoric acid,** N ⋮ P(SH)$_2$, because when its salts are treated with acids, the product decomposes instantly into phosphoric acid, hydrogen sulphide, and ammonia. No reaction occurs when the salts are boiled with alkali-lye. A. Stock and co-workers found that **ammonium hydronitrilodithiophosphate,** $NP(SH)SNH_4$, is obtained by heating the diammonium salt in vacuo at 100°; and by heating the product of the action of liquid ammonia on phosphorus pentasulphide to 125°. The product is a white crystalline mass, which has an odour of hydrogen sulphide when exposed to moist air; at 180°–200° in a current of an indifferent gas, or in vacuo, the ammonium salt yields ammonia and hydrogen sulphide; at 300°, thiophosphoryl nitrile; and at 800°, phosphorus nitride. A. Stock and co-workers found that **ammonium nitrilodithiophosphate,** $NP(SNH_4)_2$, is produced along with ammonium imidotrithiophosphate by the action of liquid ammonia on phosphorus pentasulphide or phosphorus hexamminopentasulphide; or by passing ammonia over phosphorus pentasulphide. The ammonium imidotrithiophosphate is very sparingly soluble in liquid ammonia and crystallizes out, while the ammonium nitrilodithiophosphate dissolves in that menstruum, and is obtained by evaporating off the solvent. The colourless product is soluble in liquid ammonia, and when this soln. is evaporated, the ammonium salt remains as a white resinous mass. When the salt is heated it furnishes a voluminous grey powder and finally phosphorus nitride. At 100°, in vacuo, it loses a mol of ammonia, forming the primary salt; at 180°–200° in vacuo or in a current of an indifferent gas, it behaves like the monammonium salt. It is easily soluble in water. When a mixed soln. of the diammonium salt and potassium hydroxide is treated with alcohol, an oily mass of

potassium nitrilodithiophosphate, $NP(SK)_2.nH_2O$, is produced, which does not crystallize when cooled in a freezing mixture. A similar product was obtained with the calculated quantity of sodium hydroxide, but, when cooled, the oil formed a mass of radiating needles of **sodium nitrilodithiophosphate**, $NP(SNa)_2.nH_2O$; a similar product was obtained by the action of sodium sulphate on the lead salt. When the soln. is treated with a lead salt, yellow **lead nitrilodithiophosphate**, NPS_2Pb, is formed ; with barium hydroxide, a voluminous, white mass of **barium nitrilodithiophosphate**, $NPS_2Ba.H_2O$, is produced.

A. Stock and co-workers found that when ammonium imidotrithiophosphate is heated in an atm. of hydrogen sulphide, **imidotrithiophosphoric acid**, $HN : P(SH)_3$, is formed: $NHP(SNH_4)_3+3H_2S=3NH_4SH+NHP(SH)_3$. The reaction begins at about 90°, and is continued for 12 hrs. at 140°–145°, and completed in several days at 175°–180°. The acid is pale yellow, and it becomes darker when heated and paler when cooled. It sp. gr. is 1·78 at 16·5°. No solvent is known which does not at the same time decompose the acid. It is insoluble in carbon disulphide even at 200° ; and it is hydrolyzed by water: $HNP(SH)_3+3H_2O=2H_2S+OP(OH)_2(SNH_4)$. The acid loses hydrogen sulphide at a high temp. ; and at 210°, it forms ammonium diimidopentathiodiphosphate. Liquid ammonia converts the acid into the triammonium salt ; gaseous hydrogen chloride has no action on the acid at ordinary temp., but with liquid hydrogen chloride, it forms **hydrochloroimidotrithiophosphoric acid**, $NP(SH)_3.HCl$, which gives off hydrogen chloride at 125° ; and with water forms sulphur and hydrogen sulphide. A. Stock and co-workers made **triammonium imidotrithiophosphate**, $HNP(SNH_4)_3$, along with diammonium nitrilotrithiophosphate by the action of liquid ammonia on phosphorus pentasulphide or hexamminopentasulphide : the imidotrithiophosphate is insoluble in liquid ammonia, the other product is soluble. The salt is obtained by the action of liquid ammonia on the free acid ; and by heating phosphorus with a soln. of sulphur in liquid ammonia at 100° when the brown soln. deposits this salt on standing. A similar result is obtained by dissolving phosphorus hexasulphide in liquid ammonia. The triammonium salt is a white, crystalline mass. The crystals are hygroscopic, and in dry air effloresce owing to the loss of ammonia ; but they can be preserved in sealed tubes. The salt is very sparingly soluble in liquid ammonia, and the solubility is but little affected even by raising the temp. to 100°. The salt is soluble in no other known organic or inorganic solvent without chemical change. The aq. soln. has an alkaline reaction, and the salt is hydrolyzed, for the imido-group is displaced by oxygen so that the liquid gives the reaction of the thiophosphates ; after some hours, the liquid smells of hydrogen sulphide, and it then reacts with a nitroprusside. If the aq. soln. be treated with alcohol, ammonium trithiophosphate is precipitated. The salt loses a mol of ammonia when heated in vacuo at 50°, and it is transformed into the diammonium salt ; and when heated to a high temp., phosphorus nitride is formed. When heated in an atm. of hydrogen sulphide, the ammonium salt is converted into the free acid. When the salt is treated with sodammonium in a sealed tube, **trisodium imidotrithiophosphate**, $NHP(SNa)_3$, is formed : $NHP(SNH_4)_3+3Na=HNP(SNa)_3+3NH_3+3H$. A. Stock and co-workers prepared diammonium imidotrithiophosphate, $NHP(SH)(SNH_4)_2$, by heating the triammonium salt in vacuo at 50° ; and by leaving the triammonium salt in vacuo over conc. sulphuric acid for 7 days. If the triammonium salt be treated with sodium ethoxide, **disodium imidotrithiophosphate**, $NHP(SH)(SNa)_2$, is formed. When the diammonium salt is heated in vacuo at 100°, it forms **ammonium imidotrithiophosphate**, $NHP(SH)_2(SNH_4)$.

A. Stock and co-workers obtained impure **diimidopentathiodiphosphoric acid**, $S\{P(SH)_2 : NH\}_2$, by heating imidotrithiophosphoric acid for a long time at 210°. It is suggested that *phosphoryl diimidosulphide*, $S\{PS(NH)_2\}_2$, is formed as an intermediate product of the decomposition at about 100°. They obtained **ammonium diimidopentathiodiphosphate**, $S\{P(SNH_4)_2 : (NH)\}_2$, by the action of ammonia at ordinary temp. on phosphorus pentasulphide ; and also by adding

3 grms. of the powdered sulphide to 12 c.c. of liquid ammonia near its b.p., and evaporating the ammonia from the yellow soln. The product is a yellow, hygroscopic solid which when heated to a high temp. furnishes phosphorus nitride; in vacuo, at 270°, it yields thiophosphoryl nitrile. The yellow soln. produced by cold water deposits sulphur, and has an odour of ammonium sulphide; the freshly prepared soln. does not give the reactions of phosphoric acid. The soln. in liquid ammonia forms ammonium imidotrithiophosphate and nitrilodithiophosphate as indicated above.

CHAPTER L

PHOSPHORUS

§ 1. The History of Phosphorus

Phosphorus is one of the most remarkable of the many remarkable substances known to the chemist. The curious method of its discovery, the universality of its distribution, its intimate connection with the phenomena of animal and vegetable life, its extraordinary physical properties and chemical activity, its abnormal molecular constitution, the protean ease of its allotropic transformation, all combine to make up a history which abundantly justifies its old appellation of the *phosphorus mirabilis.*—T. E. THORPE.

ACCORDING to F. Licetus,[1] somewhere near the beginning of the seventeenth century a boot-maker, V. Casciarolus or Casciorolus, found a stone on Mons Padernus, Bologna, which was so heavy that he thought it contained a heavy metal. He found that after the stone—barytes—had been calcined in a charcoal fire and cooled, it glowed in darkness with a reddish light. It was called *litheosphorus*, or *litheophorus*; and also *Bologna stone* or *lapis bononiensis*. Some years later, C. A. Baldewein discovered another variety which he called *phosphorus hermeticus*, or *magnes luminaris*; and which came to be known as *Baldwin's phosphorus* (*q.v.*). In the seventeenth century, the term phosphorus—from *φῶς*, light; *φέρω*, I bear—was applied to designate any substance which was capable of becoming luminous in the dark.

J. von Kunckel related in his *Laboratorium chymicum* (Hambourg, 1716) that he heard that Hennig Brand, whom he ironically called a *doctor teutonicus*, had prepared a kind of phosphorus which gave a continuous glow in darkness; without being illumined by any lucid substance. G. W. von Leibniz, in his *Historia inventionis phosphori* (Berlin, 1710), said that H. Brand was an impoverished merchant who sought to restore his wealth by converting base metals into gold; and during his alchemical experiments with urine discovered phosphorus, *zufällig*. A letter from H. Brand to G. W. von Leibniz, published by H. Peters,[2] makes it appear that H. Brand first prepared phosphorus in 1669. J. D. Kraft bought the secret from H. Brand for 200 thalers, on condition that it was not communicated to J. von Kunckel. J. von Kunckel, however, did learn that H. Brand's phosphorus was obtained from urine; and soon afterwards discovered the mode of preparation. The properties of the newly discovered phosphorus were first described in a dissertation: *Noctiluca constans et per vices fulgurans, diutissime quæsita, nunc reperta* (Wittenberg, 1676), by J. von Kunckel's friend, G. Kirchmaier, in 1676; in J. S. Elsholz's *De phosphorisquatuor observatio* (Berlin, 1676); and in G. Schulze's *De phosphoro liquido, observatio* (Berlin, 1677). Shortly afterwards, J. von Kunckel described this substance in his *Oeffentliche Zuschrift vom Phosphoro mirabili und dessen leuchtenden Wunderpilulen* (Leipzig, 1678). About 1677, J. D. Kraft exhibited this wonderful *das kalte Feuer*, or *das immerwährende Feuer*, to various crowned heads in Europe, including Charles II of England. Robert Boyle [3] heard of this substance without being informed of its mode of preparation, other than that it was obtained from an animal source. On October 14, 1680, he deposited a sealed packet with the Secretary of the Royal Society. This included a paper containing an account of the preparation of phosphorus from urine; it was published posthumously in 1693. Robert Boyle said:

> On September 30, 1680, there was taken a considerable quantity of man's urine (because the liquor yields but a small proportion of the desired quintessence), and of this a good part at least had been for a pretty while digested before it was used. Then this liquor was distilled with a moderate heat, till the spirituous and saline parts were drawn off, after which the superfluous moisture also was abstracted (or evaporated away), till the remaining substance was brought to the consistence of a somewhat thick syrup, or a thin extract. This done, it was well incorporated with thrice its weight of fine white sand, and the mixture being put into a strong stone retort, to which a large receiver (in good part filled with water) was so joyn'd that the nose of the retort did almost touch the water. Then, the two vessels being carefully luted together, a naked fire was gradually administered for five or six hours, that of that which was either phlegmatick or volatile might come over first. When this was done the fire was encreased, and at length for five or six hours was made as strong and intense as the furnace (which was not bad) was capable of giving (which violence of fire is a circumstance not to be omitted in the operation). By this means there came over good store of white fumes, almost like those that appear in the distillation of oyl of vitriol; and when those fumes are passed and the receiver grew clear, they were after a while succeeded by another sort, that seemed in the receiver to give a faint, blewish light, almost like that of little burning matches dipped in sulphur. And, last of all, the fire being very vehement, there passed over another substance that was judg'd more ponderous than the former, because it fell through the water to the bottom of the receiver, whence being taken out (and partly even whilst it stay'd there), it appeared by several effects and other phenomena to be such a kind of substance as we desired and expected.

According to G. W. Stahl, J. D. Kraft alleged that he communicated to R. Boyle the mode of preparing phosphorus during his visit to England, but this assertion is generally discredited. F. Hoefer summed up his opinion:

> Comme il est le premier qui ait fait connaitre publiquement la préparation de ce corps, à l'aide d'un procéde que personne ne lui avait appris, on pourrait, avec quelque justice, réclaimer pour lui l'honneur de la découverte du phosphore.

According to F. Hoefer, a manuscript entitled *Ordinatio Alchid Bechil Saraceni philosophi*—contained in the collection of alchemical manuscripts at the Bibliothèque Royal, Paris—shows that about the twelfth century Alchid Bechil obtained what he called *escarboucle* by distilling urine with clay, lime, and carbonaceous matters, and that it is highly probable that phosphorus was known as *un très-grand secret* to the Arabian alchemists. They seem to have been continually distilling all kinds of phosphatic materials—urine, bones, etc.—under conditions where phosphorus is sure to have been produced.

According to J. Bell, and G. Gore:

> In London, about the beginning of the eighteenth century, R. Boyle's assistant, A. G. Hanckewitz made phosphorus by R. Boyle's process and sold it in Europe The demand seemed in part due, as A. G. Hanckewitz expressed it, "to the alchemists who work on microcosmical substances, and out of it they promise themselves golden mountains." A. G. Hanckewitz had the monopoly of its sale for many years, so that it was sometimes called *English*, or *Boyle's phosphorus*; as well as *Kunckel's phosphorus*, *Brand's phosphorus*, and *Kraft's phosphorus*. To distinguish this new phosphorus from the phosphorescent minerals, J. von Kunckel called it *phosphorus mirabilis*, and *lumen constans*; R. Boyle designated it *noctiluca consistens*, *noctiluca gummosa*, *noctiluca constans*, *noctiluca aërea*, and *noctiluca glacialis*; while others also called it *phosphorus fulgurans*, *phosphorus igneus*, *phosphorus pyropus*, etc.

According to H. Peters,[4] there is a letter from J. G. Gmelin of Tübingen to J. W. Dieterich of Nürnberg, in the possession of H. Kämmerer, which shows that J. G. Gmelin described the preparation of phosphorus from urine and charcoal in Sweden in 1715. In 1737, the secret was learned in France, and a description of the process of manufacture, namely, by distilling urine with sand and carbon, was described by J. Hellot. A. S. Marggraf appears to have obtained better yields by using lead chloride in place of sand. In 1781, J. R. Spielmann described the preparation of phosphoric acid from urine. The history of phosphorus was discussed by L. Franck, H. Peters, and L. P. J. Palet. B. Albinus detected phosphorus in mustard and cress; and A. S. Marggraf, in the growths from mustard, cress, wheat, etc. In 1780, J. G. Gahn found a mineral in which the phosphorus was united with lead. T. Bergman, and J. L. Proust found phosphorus in apatite.

In 1771, C. W. Scheele mentioned the occurrence of phosphorus in bones, while T. Bergman said that the fact was discovered by J. G. Gahn, about 1770.

There is some doubt as to the discoverer of the phosphorus compounds in bones. Neither C. W. Scheele[5] nor J. G. Gahn published a special paper on the subject. In his paper: *Undersökning om fluss-spat och dess syra* (1771), C. W. Scheele said that "it has recently been discovered that the earth of bones or horns is calcarious earth combined with phosphoric acid." T. Bergman, in his edition of H. T. Scheffer's *Chemische Vorlesungen* (Greisswald, 1779), ascribed the discovery of phosphorus in bones to J. G. Gahn in 1769. A. E. Nordenskjöld, from one of C. W. Scheele's letters dated Frühjahr, 1770, inferred that J. G. Gahn and C. W. Scheele made the discovery together in the summer of 1770. H. Gahn, brother of J. G. Gahn, said that the discovery was made by J. G. Gahn and confirmed by C. W. Scheele.

G. Homberg[6] considered phosphorus to consist of phlogiston united with an acid so that during combustion the phlogiston escaped, and the acid remained as a residue. G. W. Stahl, and J. Hellot supposed the acidic constituent to be hydrochloric acid; F. Hoffmann, a compound of sulphuric and hydrochloric acids; H. Boerhaave, sulphuric acid; and A. G. Hanckewitz, sulphur. A. S. Marggraf showed that G. W. Stahl's hypothesis is very improbable, and that in the conversion of phosphorus to phosphoric acid (*q.v.*) there is an increase in weight. A. L. Lavoisier's investigations on combustion demonstrated the elementary nature of phosphorus; so that later suggestions of the complexity of phosphorus are mere speculations.

C. Girtanner's fanciful suggestion that phosphorus contains much hydrogen and a little oxygen, was disproved by H. Davy, who observed the formation of neither oxygen nor hydrogen chloride during the combustion of phosphorus in chlorine. H. Davy, however, did find so much hydrogen was given off from phosphorus during the passage of the electric current that he could say "the hydrogen cannot well be considered as an accidental ingredient of this body." J. N. Lockyer also assumed that phosphorus was a compound of hydrogen, but nothing new developed from the hypothesis. F. B. Fittica alleged that by heating phosphorus with ammonium nitrate it can be transformed into arsenic; that arsenic, in turn, is a compound of nitrogen, phosphorus, and oxygen, PN_2O; and that red phosphorus is a sulphide, N_2SH_2. C. Winkler, A. C. Christomanos, G. R. Gyzander, and M. C. Schuyten obtained no support for F. B. Fittica's sterile suggestion. Any arsenic in the final product of his experiment must have been present as impurity in the initial materials.

§ 2. The Occurrence of Phosphorus

> Phosphorus is nearly the most widely and evenly distributed element on the surface of the earth, and probably the most subdivided. This can be readily understood when the important part which phosphoric acid plays and has played in the vital cosmos is taken into consideration. Phosphorus was on the earth in gaseous, liquid, or solid form before the dawn of life, and since then, all animal and vegetable creations have combined with the physical forces always at work in inanimate nature to distribute and redistribute the phosphorus, to divide it up, and carry it from place to place. If the biography of atoms could be written, the chapters on phosphorus would be the most interesting and the most varied.—W. B. M. DAVIDSON (1893).

Phosphorus has not been found to occur in a free state on the earth. If it were formed by a natural process, the affinity of phosphorus for oxygen would result in the oxidization of the element where accessible to atm. air. Phosphorus is fairly abundantly distributed and, with a few minor exceptions, it occurs in the mineral kingdom as a phosphate. Thus, nearly all igneous rocks contain a little phosphate generally as apatite. According to F. W. Clarke and H. S. Washington's estimate,[1] it is more abundant than carbon, and less abundant than chlorine in the ten-mile crust of the earth, hydrosphere, and atmosphere. Phosphorus is 12th in the list of the elements which make up 99·6 per cent. of the crust of the earth. The numbers are: oxygen, 49·19 per cent.; iron, 4·68; chlorine, 0·228; phosphorus, 0·142; and carbon, 0·139. It is 10th in the list for igneous and sedimentary rocks, and also for igneous rocks. The average percentage of P_2O_5 in igneous rocks is 0·13; in shale, 0·17; in sedimentary rocks, 0·09; in sandstone, 0·08; and in limestone, 0·04. J. H. L. Vogt estimated that the igneous rocks contain 0·22 per cent. of phosphorus. This subject was discussed by H. S. Washington, V. M. Goldschmidt, W. D. Harkins, J. F. Kemp, W. Lindgren, W. Vernadsky, and G. Tammann. W. Vernadsky gave 0·056 for the percentage amount, and 0·1 for the atomic proportion. V. M. Goldschmidt estimated that the natural supplies of available phosphorus will last over a century, but M. Pietrkowsky pointed out that the estimate does not include the North African deposits. The subject was discussed by W. Packard.

H. A. Rowland,[2] and M. N. Saha could find no evidence in the solar spectrum of the existence of phosphorus in the sun; but phosphorus of extra-terrestrial origin has been found in meteorites. O. C. Farrington reported the occurrence of free phosphorus in the meteorite which fell in Saline Township. Iron phosphide, and iron nickel phosphide have been found in numerous meteorites [3]—*vide infra*, iron phosphide, and schreibersite, and rhabdite.

The salts of phosphoric acid are very widely distributed; and, as J. B. J. D. Boussingault [4] noticed, most of the naturally occurring phosphates are salts of orthophosphoric acid. This, however, does not necessarily mean that they were not formed at a high temp. W. B. Phillips has compiled a list of 141 minerals with the equivalent of over one per cent. of phosphoric acid. In the appended list, the formulæ are more or less variable and have not always the same significance as the formulæ of chemical compounds.

Amblygonite, $Al(Li,F,OH)PO_4$, a mixture of phosphate of aluminium and fluoride of lithium and sodium, with sometimes a little potassium (triclinic) ; *apatite* $(F,Cl)Ca_5(PO_4)_3$, normal calcium phosphate (hexagonal) ; *augelite*, $Al_2(OH)_3PO_4$, hydrated phosphate of aluminium, containing also a little calcium, iron, and manganese (monoclinic) ; *autunite*, $(UrO_2)_2Ca(PO_4)_2.8H_2O$, hydrated phosphate of uranium and calcium, containing also sometimes a little barium, manganese, magnesium, and possibly tin (rhombic) ; *barrandite* $(Al,Fe)PO_4.2H_2O$, hydrated phosphate of iron and aluminium (massive) ; *beraunite*, $Fe_5(OH)_6(PO_4)_3.3H_2O$, hydrated phosphate of iron (monoclinic) ; *beryllonite*, $BeNaPO_4$; *bobierrite*, $Mg_3(PO_4)_2.8H_2O$, normal phosphate of magnesium with water (monoclinic) ; *borickite*, $Fe_4(OH)_6Ca(PO_4)_2.3H_2O$, hydrated phosphate of iron and calcium, with sometimes a little magnesium (massive) ; *brushite*, $CaHPO_4.2H_2O$, hydrated monobasic calcium phosphate (monoclinic) ; *callaite*, $Al_2(OH)_3PO_4.6H_2O$ (rhombic) ; *calcioferrite*, $(Fe,Al)_3(OH)_3(Ca,Mg)_3(PO_4)_4.8H_2O$; hydrated phosphate of iron and calcium, containing also aluminium and magnesium (possibly monoclinic) ; *callainite*, $AlPO_4.2\frac{1}{2}H_2O$, hydrated phosphate of aluminium with a little silica, iron, and calcium (massive) ; *chalcosiderite*, $(AlFe)_2(FeO)_4Cu(PO_4)_4.8H_2O$, hydrated phosphate of iron with aluminium and copper (triclinic) ; *childrenite*, $Al(OH)_2(Fe_3Mn_3Ca)PO_4.H_2O$, hydrated phosphate of iron and aluminium, with manganese, and a little magnesium and calcium (rhombic) ; *cirrolite*, $Ca_3Al_2(OH)_3(PO_4)_3$, hydrated phosphate of calcium and aluminium with a little silica, manganese, iron, magnesium, and lead (massive) ; *collophane*, $Ca_3(PO_4)_2.H_2O$; *dahllite*, $Ca_7PO_4(CO_3).\frac{1}{2}H_2O$; *delvauxite*, $Fe_4(OH)_6(PO_4)_2.17H_2O$, variety arseniosiderite, hydrated phosphate of iron, and calcium (?) ; *diadochite*, $Fe_4O(OH)_2(HSO_4)_2(PO_4)_2$, hydrated sulphate and phosphate of iron (possibly monoclinic) ; *dihydrite*, $Cu(CuOH)_4(PO_4)_2$, hydrated phosphate of copper (triclinic) ; *chlite*, $Cu(CuOH)_4(PO_4)_2.H_2O$, hydrated phosphate of copper, with vanadium (rhombic) ; *eleonorite*, $(FeOH)_3(PO_4)_2.2\frac{1}{2}H_2O$, hydrated phosphate of iron (monoclinic) ; *eosphorite*, $Al(OH)_2(Mn,Fe)PO_4.H_2O$, hydrated phosphate of manganese, aluminium, and iron, with a little calcium and sodium (rhombic) ; *evansite*, $Al_3(OH)_6PO_4.6H_2O$, hydrated phosphate of aluminium (massive) ; *fairfieldite*, $(Ca,Mn,Fe)(PO_4)_2.2H_2O$, hydrated normal phosphate of calcium, with manganese and iron (triclinic) ; *fillowite*, $(Ca,Na_2,Fe,Mn)_3(PO_4)_2.\frac{1}{3}H_2O$, normal phosphate of manganese, iron, calcium, and sodium, with a little water (monoclinic) ; *fischerite*, $Al_2(OH)_3PO_4.6H_2O$, hydrated phosphate of aluminium, with a little iron, copper, and manganese (rhombic) ; *gibbsite*, $AlPO_4.4H_2O$; *hamlinite*, $3Al(OH)_2(SrOH)P_2O_7$; *hannayite*, $Mg_3(NH_4)_2H_4(PO_4)_4.8H_2O$, hydrated phosphate of ammonium and magnesium (triclinic) ; *henwoodite*, $CuAl_4,H_{10}(PO_4)_8 6H_2O$, hydrated phosphate of aluminium, containing copper (massive) ; *herderite*, $CaBe(OH,F)PO_4$, a mixture of phosphate and fluoride of calcium and beryllium, sometimes containing aluminium (rhombic) ; *hopeite*, $Zn_3(PO_4)_2.4H_2O$, hydrated phosphate of zinc, with a little cadmium (rhombic) ; *hureaulite* $(MnFe)_5H_2(PO_4)_4.4H_2O$, hydrated phosphate of manganese, and iron, with a little silica (monoclinic) ; *isoclase*, $Ca_2(OH)PO_4.2H_2O$, hydrated normal phosphate of calcium, with calcium hydrate ; contains, also, magnesium, sodium, and a little iron and aluminium (monoclinic) ; *kakoxene*, $Fe_2(OH)_3PO_4.4\frac{1}{2}H_2O$; *kraurite*, $Fe_2(OH)_3PO_4$ (rhombic) ; *laxmannite*, $(Pb,Cu)_3(PO_4)_2\text{-}Pb\{Pb_2O(CrO_4)_2\}$, a mixture of chromate and phosphate of lead and copper, with a little iron and water (monoclinic) ; *lazulite*, $(HOAl)_2.Mg(Fe,Ca)(PO_4)_2$, hydrated phosphate of aluminium, magnesium, and iron, sometimes containing a little calcium, manganese, silica, and copper (monoclinic) ; *libethenite*, $CuPO_4.CuOH$, hydrated phosphate of copper, with sometimes a little arsenic and iron (rhombic) ; *ludlamite*, $Fe_5(FeOH)_2(PO_4)_4.8H_2O$, hydrated phosphate of iron (monoclinic) ; *lüneburgite*, $Mg(BO_2)_2.2MgHPO_4.7H_2O$, a mixture of hydrated phosphate and borate of magnesium, with a little fluorine (hexagonal) ; *martinite*, $Ca_5H_2(PO_4)_4.\frac{1}{2}H_2O$; *messelite*, $(Ca,Fe,Mg)_3(PO_4)_2.2\frac{1}{2}H_2O$; *minervite*, $AlPO_4.3\frac{1}{2}H_2O$; *monazite*, $CePO_4$, with lanthanum and thorium (monoclinic) ; *monetite*, $CaHPO_4$, monobasic phosphate of calcium (triclinic) ; *natrophyllite*, $Na(Mn,Fe)PO_4$ (rhombic) ; *newberyite*, $MgHPO_4.3H_2O$, hydrated monobasic phosphate of magnesium (rhombic) ; *peganite*, $Al_2(OH)_3PO_4.1\frac{1}{2}H_2O$, hydrated phosphate of aluminium, with a little copper and iron (rhombic) ; *phosphorochalcite*, $Cu(OH)_3PO_4$; *phosphuranylite*, hydrous phosphate of uranium, with lead (massive) ; *polysphaerite* $(CaPbH)_5F(PO_4)_3$, variety of pyromorphite, containing 11 per cent. phosphate of calcium (massive) ; *pseudolibethenite*, $Cu(CuOH)PO_4.\frac{1}{2}H_2O$, variety of libethenite, but contains twice as much water (hexagonal or rhombic) ; *pyromorphite*, $CaPb_5(PO_4)_3$, a mixture of phosphate and chloride of lead, containing, also, sometimes aluminium, arsenic, calcium, iron, chromium, and silica (hexagonal) ; *reddingite* $(Mn,Fe)_3(PO_4)_2.3H_2O$, hydrated phosphate of manganese, sometimes containing iron (rhombic) ; *sphaerite*, $Al_5(OH)_9(PO_4)_2.12H_2O$, hydrated phosphate of aluminium, with a little magnesium, calcium, and silica (massive) ; *staffelite*, $Ca_0(PO_4)(CO_3)(CaF_2)_2.H_2O$, alteration product of apatite, contains calcium, iron, fluorine, carbonic acid, aluminium, water, and iodine (hexagonal) ; *stercorite*, $NaH(NH_4)PO_4.4H_2O$, hydrated phosphate of sodium and ammonium with sodium chloride, calcium carbonate, calcium phosphate, magnesium, etc. (monoclinic) ; *svanbergite*,

$Na_3(CaOH)(AlO)_6(SO_4)_2(PO_4)_2.3H_2O$, hydrated phosphate and sulphate of aluminium and sodium, with calcium and iron, and sometimes a little lead and magnesium (hexagonal); *tagilite*, $Cu(CuOH)PO_4.H_2O$, hydrated phosphate of copper, with sometimes a little iron (monoclinic); *tavistockite*, $Ca_3Al_2(OH)_6(PO_4)_2.8H_2O$, hydrated phosphate of calcium and aluminium (massive); *triphyline* $(Mn,Li,Fe)(PO_4)$, phosphate of iron, manganese, and lithium, with a little sodium, calcium, magnesium, potassium, silica, and water (rhombic); *triplite*, $F(Mn,Fe)_2PO_4$, phosphate of iron and manganese, sometimes with a little calcium, magnesium, sodium, fluorine, water, silica, and lithium (monoclinic ?); *triploidite*, $(Fe,Mn)(FeHO,Mn)PO_4$, phosphate of manganese and iron, with a little water and calcium (monoclinic); *trolleite*, $Al_4(OH)_3(PO_4)_3$, hydrated phosphate of aluminium, and a little iron and calcium (massive); *uranocircite* $(UO_2)_2Ba(PO_4)_2.8H_2O$, hydrated phosphate of uranium and barium (rhombic); *variscite*, $AlPO_4.2H_2O$, hydrated phosphate of aluminium, (rhombic); *vivianite*, $Fe_3(PO_4)_2.8H_2O$, hydrated phosphate of iron, sometimes with a little aluminium, manganese, silica, and organic matter; consists essentially of water and ferrous and ferric phosphate (monoclinic); *wagnerite*, FMg_2PO_4, normal phosphate of magnesium, with fluorine, iron and calcium, and sometimes a little manganese and aluminium (monoclinic); *wavellite* $(AlOH)_3(PO_4)_2.5H_2O$, hydrated phosphate of aluminium, sometimes a little iron, fluorine, silica, calcium, and manganese (rhombic); *xenotime*, YPO_4, phosphate of yttrium, sometimes, also, with cerium; lanthanum, didymium, uranium, titanium, zirconium, fluorine, iron, and silica (tetragonal); *zepharovichite*, $AlPO_4.3H_2O$, hydrated phosphate of aluminium, with silica and calcium (massive).

Deposits of phosphate rock occur in most countries; they are found in the marine beds ranging from the old Cambrian beds to the Tertiary beds, and in the oceans of to-day, dredgings show that such deposits are being formed. According to F. W. Clarke,[5] the phosphatic concretions found on the ocean floor consist mainly of calcium phosphate and carbonate mixed with sand and clay. They have been discussed by L. W. Collet, L. Cayeux, etc. According to J. Murray and A. F. Renard, they are derived from the decaying bones of dead animals upon which carbonic acid exerts a powerful solvent action. They form round various nuclei—principally shells. In many cases, the phosphatic matter was first deposited in the cavities of shells, around which the nodules continued to grow. The ammoniacal matters from the decomposing organic matter in bone probably played some part in the precipitation of the calcium phosphate. Lime is the predominant base in the natural phosphates which have an economic value, and such are often called *phosphorite* (*q.v.*). Analyses were reported by T. Steel, etc. The composition of a few samples is indicated in Table I. There is usually in addition some silica, organic matter, and chlorine. Iodine has been repeatedly detected in phosphorites, but the evidence with respect to bromine is not so clear. The first analysis is by G. Steiger[6]; the second by G. H. Eldridge; and the third by O. Tietze. Phosphate rock is often mined by steam shovels, and usually prepared for the market by a preliminary screening and washing to remove clay; it is then crushed, screened, and picked to a grade 65–80 per cent. normal calcium phosphate.

TABLE I.—COMPOSITION OF SOME NATURAL PHOSPHATES.

	Crawford Mts., Utah.	Land pebbles of Florida.	Gafsa, Tunis.	Acuba, West Indies.	Ain Dibha, Algiers.
Insoluble . . .	1·82	6·69	3·05	—	—

The guanos have undergone more or less decomposition by the action of rain, etc., and they are sold on the " per cent. of nitrogen " they contain. Some guanos are enriched by the addition of dried blood, ammonium phosphate, etc., and sold as special fertilizers. Nitrogenous matters and potash, all valuable manures, are also associated with guano. The animal skeleton is mainly composed of bone. Bones contain non-combustible mineral matters, and combustible organic matters. Fatty organic matter can be extracted by digesting the bones with solvents like benzene, carbon disulphide, ether, chloroform, etc., which dissolve the fat, and leave behind *degreased bones ;* the gelatinous matters—glue—can be extracted by digesting the bones with water heated under pressure—*degelatinized bones* remain behind. The degelatinized bones still contain combustible carbonaceous matters, and if they be heated in iron retorts, out of contact with air, gaseous and liquid products distil over, and a residue of *animal charcoal* remains in the retort. Dippel's bone oil occurs among the liquid products of the distillation. A similar result is obtained if degreased or raw bones be heated in the retorts. If animal charcoal, or degreased, degelatinized, or raw bones be heated in air, the organic matters burn, and *bone-ash* remains. The composition of bone-ash may be taken as

P_2O_5	CaO	MgO	Fe_2O_3 and Al_2O_3	SiO_2	CO_2	H_2O	Alkalies
39·5	52·5	1·0	0·2	0·5	0·9	1·8	1·4

with about 2 per cent. of organic matter. W. F. de Jong said that the X-radiograms of modern and fossilized bones show lines characteristic of the fluorapatite type of structure and nothing else. The fundamental mineral is probably $3Ca_3(PO_4)_2,CaCO_3$, in which the carbonate radical may be replaced, as in fossilization, by fluorine, chlorine, or sulphate, and perhaps by other radicals, whilst some of the calcium may be replaced by magnesium, and possibly also by iron and aluminium. The diffuse nature of the X-ray lines indicates that the crystals present contain only some tens or hundreds of mols, but on incineration the crystal size is increased. No evidence could be found of the existence in bones of the colloidal *collophanite*, $Ca_3P_2O_8.H_2O$, described by J. D. Dana. Bone-ash is used in the manufacture of manures, phosphorus, English porcelain, cupels, baking powder, etc.

The larger deposits of calcium phosphate or phosphorite are probably of marine origin. The traces of phosphates in sea-water are absorbed in the shell, bones, and tissue of marine organisms ; and the remains accumulate in the ooze at the bottom of the sea. The accompanying calcium carbonate is in part removed owing to its slight solubility ; some phosphate is at the same time dissolved and in part redeposited around fragments of shells or bones so as to form phosphatic nodules, common in phosphorite beds and on the ocean floor—*vide supra.* The deposits on the sea-bottom are further conc. when they are elevated into a land surface by the leaching away of calcium carbonate by subterranean water. The phosphorite deposits are not crystalline, but form compact or concretionary earthy masses. Some of the purer deposits approximate to apatite or fluorapatite, $Ca_5(PO_4)_3F$, in composition, but others approach normal calcium phosphate, $Ca_3(PO_4)_2$, in composition. A. Carnot says that the concretionary phosphates are deficient in fluorine, while in the sedimentary the fluorine approximates to the apatite ratio.

Large deposits of phosphorite are worked in the cretaceous beds of northern France ; while in south-western *France,* phosphates occur along with clay in irregular fissures in the Jurassic limestone. The French deposits are in Nord, Pas de Calais, Cambresis, Somme et Oise, Ardennes, Meuse, Marne, Yonne, Cote-d'or, Haute-Saône, Cher, Indre, Sarthe, Lot, Tarn-et-Garonne, Lot-et-Garonne, Gard, Ardêche, Drôme, Isère, Pyrenees, etc. The *German* deposits of phosphorite include those of Hessen-Nassau, Braunschweig, Leipzig, Vogtlandes, Amberg, Darmstadt, Ruhrrevier, etc. Deposits occur at Hesbaye, Hennegau, etc., in *Belgium ;* at Estremadura—Logrosan and Caceres—in *Spain ;* near Potalegre and Marvao in *Portugal.* The deposits in *Great Britain* are at Cwmgwnnen in the lower Silurian series of North Wales ; and in Bedfordshire, Cambridgeshire, Norfolk, Suffolk, Essex, etc. Phosphorite is found at Malta ; a zone extending from the Volga, near Simbirsk, into Desna (Smolensk) and into Grodno ; and in Podolia in *Russia ;* and in *Sweden.* There are also large deposits along the frontier of *Algeria* and *Tunis* in the lower Eocene beds over the Cretaceous strata. M. Pietrkowsky estimates that there are 1,000,000,000 tons of phosphates available in *Morocco,* and that there are also large deposits in *Egypt.* Deposits also occur in *Natal.* The deposits in the *United States* extend along the Atlantic coast belt of Tertiary rocks in North and South Carolina, Florida—Pennsylvania, and Alabama ; in Arkansas ; in the Silurian and Devonian strata of Tennessee ; and in the carboniferous beds of Utah, Wyoming, and Idaho. There is a phosphate bed in Montana. The deposits in Florida are the most productive. The phosphorites of Florida exist as *boulder or rock phosphate* found in ledges, and it contains as high as 80 per cent. normal calcium phosphate with 2·5 per cent. of iron oxide and alumina ; as *pebble rock*, found in mounds or beaches, and it contains about 62 per cent. of normal calcium phosphate, and 3 per cent. of iron oxide and alumina ; and *soft phosphate*, found in cavities or pockets, and it contains about 65 per cent. of normal calcium phosphate and 6 per cent. of iron oxide and alumina. Apatite occurs in the Laurentian limestone of North Elmsley and North Burgess, of Canada. Phosphorite deposits are found in the *West Indies*—Curaçao, Bonaire, Aruba, Leeward Isles, Redonda, Barbuda, St. Martin, Sombrero, Alta Vela, Navassa, Pedro Keys, and Avalo. In *Mexico* phosphorite occurs near Mazapil and Concepcion del Oro. They occur in Christmas Island in the Indian Ocean ; Noto, Bonin, Shimane, Hyuga, etc., in *Japan*; Ninh-Binh in *China ;* the islands of the coast of *Arabia ;* Palestine ; Bessarabia; etc. Phosphorite deposits occur near the coast in *Bolivia*, in *Chile*, and at Rata in *Brazil.* Phosphorite has also been found on the Ocean and Pleasant (Nauru) Islands, and the Islands of Huon, Baker, Howland, Jarvis, Malden, Starbuck, Enderbury, and Fanning; the *Polynesian* islands; Dandaraga in Western *Australia ;* in Otago, *New Zealand.* H. Laubmann and H. Steinmetz discussed the phosphatic rocks of Bavaria.

Thousands of analyses[7] reported in connection with agriculture show that fertile soils contain up to 0·5 per cent. of phosphoric acid—probably as aluminium or iron phosphates. All limestones, chalks, and dolomites contain small proportions, and this requires attention in the selection of limestone as a flux for smelting iron. The younger limestones were found by W. B. M. Davidson[8] to be usually the more phosphatic. G. Freda reported its presence in volcanic lava ; J. A. Barral, and A. Dupré, in rain-water ; and A. Voelcker, in boiler-scale. Analyses of the waters of the ocean show the presence of varying amounts of phosphoric acid—*e.g.* some parts of the Gulf-stream are said to be more phosphatic than the surrounding waters of the Atlantic. The presence of soluble phosphates has been reported in many springs, chiefly in limestone districts. D. J. Matthews found the amount of phosphoric acid in the sea-water off Plymouth reached a maximum—0·06 mgrm. P_2O_5 per litre—in December, 1915, and it decreased irregularly to a minimum—0·01 mgrm. per litre—in April-May, 1916 ; and again attained the same maximum as before about January, 1917. This seasonal variation is attributed to the removal of phosphates from soln. by algæ, diatoms, etc. The subject was studied by R. Gill, and W. R. G. Atkins.

As indicated in connection with the history of phosphorus, the presence of this element in the vegetable kingdom was recognized by B. Albinus,[9] and A. S. Marggraf near the middle of the seventcenth century ; and a few years afterwards by C. W. Scheele in bones. Numerous analysis of vegetable matters, plants, plant-ashes, and coal show that they probably contain phosphates. J. Davidson studied the changes in the phosphorus-content of wheat seedlings during germination and growth; and W. H. and C. B. Peterson, the phosphorus-content of cabbage. C. Palmer discussed the occurrence of phosphorus in petroleum. The presence of phosphorus in the animal kingdom has been established by numerous analyses of animal-tissue, bones,[10] blood,[11] brain, urine,[12] fæces,[13] etc., and in the eggs of fishes and birds, in oysters, in sponges, etc. Naturally therefore, phosphates occur in food-stuffs.[14]

The phosphorus cycle in nature.—Small quantities of phosphates are found in granite rocks. By the weathering and decay of these rocks, the combined phosphorus ultimately finds its way into the soil, spring-waters, and the sea. The geological *rôle* of phosphorus has been discussed by W. Lindgren,[15] and E. Blackwelder. The phosphates disseminated in rocks as apatite, or accumulated in iron ores, pegmatites, and veins, are to a large extent dissipated by weathering processes in the form of complex alkali calcium and iron phosphate soln., which eventually find their way to the sea. Part enters into the formation of new sediments as complex fluo-carbonato-phosphates. These sediments are folded and uplifted, and become dry-land. The surface waters concentrate part into deposits of economic importance, and dissipate part as soluble phosphates; or the sediments may become absorbed in rock magmas and re-form apatite. All fertile soils contain phosphorus, since phosphorus is needed to build up certain essential parts of the tissue of growing vegetation. Plants require phosphorus from their earliest life, and seeds contain a plentiful supply for the germination of the embryo. The equivalent of one pound of phosphorus is said to be present in about 100 lbs. of corn, and in about 1200 lbs. of fodder. Animals, too, like plants, must have phosphorus, and they are dependent for their supply upon the plants or upon the herbivorous animals upon which they feed. Animals concentrate the phosphorus in their bones and tissue. The bones of an adult man contain the equivalent of 1900 to 2400 grms. of normal calcium phosphate.

L. A. J. Quetelet's analysis of an average man weighing 154 lbs. is: Water, 116 lbs.; dry matter, 38 lbs. The 38 lbs. of dry matter consist of fat, 6 lbs.; flesh, skin, and blood, 18 lbs.; and bone, 14 lbs. The 14 lbs. of bone consist of gelatine, 4⅔ lbs., and 9⅓ mineral matter. The liquid blood contains water, 15⅔ lbs.; dry solid matter, 4⅓ lbs.; and this dry solid matter consists of fibrin, albumen, etc.; 4 lbs. fat, and a little sugar, ⅔ lb., and mineral matter, about ⅓ lb.

Dry bones, on the average, contain the equivalent of about 60 per cent. of tricalcium phosphate; teeth, 70 per cent.; crab and snail shells, 7 per cent. When the animals die, their remains help to build up phosphatic rocks. Thus, the story of the circulation of phosphorus is a cycle of processes involving the concentration and dissipation of that element. The waste of muscular and nervous tissue involves a decomposition of the phosphorus compounds. The products of decomposition are carried by the blood to the kidneys, and there excreted with the urine—chiefly as sodium ammonium phosphate. There seems to be a relation between the amount of phosphorus compounds discharged from the system, and the activity of the brain, and this led to the inference that phosphorus is a metabolic product of the activity of the brain, and that phosphate foods are needed for brain workers. The idea has crystallized in the well-worn phrase *ohne Phosphor kein Gedanke*—without phosphorus no thought. A similar statement might be made regarding several other elements. A normal adult excretes the equivalent of 3 to 4 grms. of phosphoric acid *per diem*. Part of this is derived from the food, and part from muscular waste. In this way, phosphorus finds its way back to the soil; or perhaps into the sewage, and finally into the sea. W. Lindgren thus describes the fate of the phosphorus which finds its way into the sea:

> In the sea-water the blue-green algæ concentrate phosphorus, certain molluscs, or crustaceans, feed on the algæ, and other meat-eating molluscs devour the vegetarians. Small fishes eat the molluscs, large fishes eat the small, finally seals and birds swallow the fishes, and so in about six transformations the phosphorus originally contained in the sea-water may come to rest in deposits of guano on desert islands or in accumulations of the bones of the vertebrate denizens of the sea.

Hence the origin of the phosphorus in the large deposits of guano—the excrement of sea-birds—on the islands off the Peruvian coast, and a number of islands in the South and the Caribbean Seas. Many islands have been stripped of the guano they once contained. The amount of phosphates returned from the sea as edible fish is insignificant in comparison with what is drained into the sea as sewage from towns. Processes for the recovery of the phosphates in sewage now attract attention, since that which escapes into the sea accumulates at the bottom, where it may be unproductive for countless ages before it is again able to take an active part in nature's great cycle of changes. The constant growth of crops by the farmer impoverishes the soil, and phosphatic manures are needed to make good the loss.

§ 3. The Preparation of Phosphorus

The early workers on phosphorus prepared that element from urine which normally contains ammonium and sodium phosphates. Thus, R. Boyle[1] evaporated the urine to a syrupy consistency, and distilled the product either alone or admixed with sand or charcoal. The carbon produced by the decomposition of the organic matter in the urine, or added to it in the form of charcoal, decomposes the ammonium phosphate, without affecting the sodium phosphate. A. S. Marggraf mixed the conc. urine with lead chloride and charcoal powder, and heated the mass until it became pulverulent. The ammonium and sodium phosphates were converted into lead phosphate, and on distillation, the carbon liberated the phosphorus from the lead phosphate. G. A. Giobert mixed the unevaporated urine with lead nitrate or acetate ; washed the precipitated mixture of lead phosphate and sulphate ; mixed the precipitate with charcoal ; and distilled the dried product.

After J. G. Gahn[2] had shown in 1770 that phosphorus is an essential constituent of bone, C. W. Scheele obtained that element by dissolving the bone-ash in nitric acid, precipitating the lime with sulphuric acid, concentrating the clear soln. by evaporation, and distilling the product admixed with charcoal. J. M. J. Funke, B. Pelletier, T. Graham, M. Donovan, and P. F. Nicolas simplified the process by digesting the bone-ash directly with an excess of sulphuric acid, evaporating the clear filtrate containing calcium hydrophosphate, and distilling the dried product admixed with charcoal. A. F. de Fourcroy and L. N. Vauquelin mixed the soln. of calcium hydrophosphate with lead acetate, and collected the precipitated lead phosphate ; while J. J. Berzelius obtained his lead phosphate from the nitric acid soln. of bone-ash. In both cases, the lead phosphate was mixed with charcoal and distilled for phosphorus.

A. Nicolle decomposed the phosphate with nitric acid, and treated the soln. with potassium sulphate. The filtrate from the calcium sulphate was treated with mercurous nitrate ; and the mercury phosphate mixed with carbon and distilled—mercury was first obtained, then phosphorus. J. G. Gentele proposed to combine the manufacture of phosphorus with that of ammonium chloride by adding crude ammonium carbonate to soln. obtained by digesting the bones with hydrochloric acid. Phosphorus was obtained from the precipitated calcium phosphate, and ammonium chloride from the soln. R. Lammy also proposed extracting first ammonia then phosphorus by heating an intimate mixture of ammonium phosphate and carbon. W. M. C. Folie-Desjardins tried to manufacture phosphorus and an alkali silicate simultaneously. The phosphate was heated with an alkali sulphate or carbonate, with or without silica or flux. The aqueous extract contained the alkali phosphate. He then heated the alkali phosphate with silica and carbon—phosphorus was evolved, and the alkali silicate escaped. H. Fleck proposed to manufacture phosphorus and glue or gelatine by decomposing the de-greased bones with dil. hydrochloric acid to dissolve out the calcium phosphate, and leave the cartilaginous matter undissolved. The acid phosphate liquor was mixed with carbon, dried, and distilled for phosphorus. E. C. Mantrand decomposed an intimate mixture of calcium phosphate, carbon, and silica at a high temp. in an atm. of hydrogen chloride, or chlorine, when phosphorus, hydrogen phosphide, carbon dioxide, etc., are given off. J. H. Player mixed the phosphoric acid liquor with spent tan or finely powdered coal or coke ; carbonized the mixture to remove volatile organic matter ; and then distilled the residue in the usual way. B. W. Gerland proposed decomposing the bone-ash with sulphurous acid. A. Rossel heated phosphoric acid, or an alkali phosphate with zinc or aluminium ; at a low red-heat, the metal was dissolved and phosphorus set free. In the presence of silica, all the phosphorus can be driven off ; $6NaPO_3+10Al+3SiO_2=3Na_2SiO_3+5Al_2O_3+6P$; or $3Ca(PO_3)_2+10Al+3SiO_2=3CaSiO_3+5Al_2O_3+6P$. E. Minary and R. Soudry prepared phosphorus from a mixture of iron phosphate and coke ; and R. A. Brooman heated a mixture of silica, iron, coal, and calcium phosphate so as to form a fusible slag and iron phosphide. The latter when heated with sulphur, hydrogen sulphide, carbon disulphide, etc., furnished phosphorus. J. Townsend heated a mixture of aluminium phosphate (native) either along with carbon and a flux of common salt and borax, or with a mixture of potassium and sodium sulphates, and so obtained phosphorus. A. Shearer and R. R. Clapp heated aluminium phosphate mixed with carbon and sodium chloride in an atm. of hydrogen chloride: $2AlPO_4+4NaCl+3C+6HCl=2(AlCl_3.2NaCl)+3H_2+3CO+P_2O_5$; and at a white-heat: $P_2O_5+5C=2P+5CO$.

The manufacture of phosphorus from bone-ash offers many advantages, but bone-ash is perhaps the most expensive source of phosphorus, per unit. Natural phosphates containing at least 70 per cent. of normal calcium phosphate can be worked economically by the distillation process.

The bone-ash is first treated with sulphuric acid, sp. gr. 1·5, with constant agitation in a large wooden tun. Enough sulphuric acid is used to convert the whole of the calcium phosphate into phosphoric acid: $Ca_3(PO_4)_2+3H_2SO_4=3CaSO_4+2H_3PO_4$. In some modifications, sufficient acid is added for the reaction: $Ca_3(PO_4)_2+2H_2SO_4=2CaSO_4+CaH_4(PO_4)_2$. When the reaction is completed, the calcium sulphate is filtered off, and washed until the filtrate has a sp. gr. of about 1·010. The first fraction of the filtrate is reserved for concentration, while that with a sp. gr. below 1·050 is employed partly as the first washing liquor and partly for the decomposition of a further lot of phosphate. The liquor is conc. by evaporation in shallow pans heated with high-press. steam, or by steam-coils. The liquor is agitated during the evaporation. Most of the calcium sulphate held in soln. is deposited during the evaporation. The conc. acid of sp. gr. 1·325 to 1·500 is cooled in lead-lined store-tanks.

The conc. phosphoric acid is mixed with coarsely ground wood-charcoal, coke, or sawdust, and dried and charred in a cast-iron pot or muffle-furnace. The charred mixture is then added to bottle-shaped retorts made from fireclay. The furnace employed is analogous to that employed in the distillation of zinc. A double tier of the phosphorus retorts is arranged back to back, with their necks slightly protruding from the furnace. The necks of the retorts are luted to the furnace so as to prevent the access of air to the interior of the furnace. The temp. of the furnace is then raised to bright redness, and the retorts charged with the mixture by means of long-handled scoops. There are several types of condenser: in one form cast-iron pipes are luted to the retorts and the free end dips an inch or two into water contained in a trough fitted with a lid through which pipes leading from the retorts pass by means of luted faucets. The bottoms of the trough is inclined, so that the water is deeper at one end than at the other. The water in the trough soon gets warm, and the melted phosphorus collects at the deeper end of the trough. The temp. of the retorts is gradually raised to whiteness; the distillation occupies about 16 hrs. The crude phosphorus is then ready for purification.

In the retort, the phosphoric acid is converted into metaphosphoric acid at a red-heat, and at a higher temp., this acid is reduced by the carbon $2HPO_3+5C=2P+H_2O+5CO$. According to M. Neumann,[3] the reduction commences between 650° and 850°; and W. Hempel said that between 300° and 600°, any sulphuric acid which is present is decomposed, forming sulphur dioxide; the gases which come off at about 700° are combustible; and traces of phosphorus appear in the escaping gases at about 740°; most of the phosphorus distils over above 1050°, and the distillation is ended at about 1170°. At first, a mixture of carbon dioxide and monoxide and hydrogen escapes, and later the escaping gas is almost wholly carbon monoxide. According to T. Graham, some hydrogen phosphide will be found in the escaping gases, and this the more, the greater the proportion of water present in the mixture in the retort. J. Javal said that phosphoric acid is not so well adapted for the reduction as calcium phosphate because part volatilizes undecomposed, and T. Graham because the phosphoric acid, owing to the water which is present, yields a greater quantity of hydrogen phosphide. These objections do not weigh so much now as formerly, since the different stages of the process are more under control. When the bone-ash is converted into the hydrophosphate, the preliminary heating converts it into the metaphosphate: $CaH_4(PO_4)_2=Ca(PO_3)_2+2H_2O$; and the metaphosphate reacts with carbon in the retort: $3Ca(PO_3)_2+10C=4P+Ca_3(PO_4)_2+10CO$. To avoid the loss of one-third the phosphorus by its reversion to the normal phosphate, sand is admixed with the charge in the retort, when $2Ca(PO_3)_2+2SiO_2+10C=4P+2CaSiO_3+10CO$. The manufacture of phosphorus by these methods is discussed by J. L. Smith, W. Jettel, G. W. Stose, E. Orloff, J. B. Readman, etc. Electrical heating has now virtually displaced the retort processes.

F. Wöhler proposed heating to whiteness a mixture of bone-black with fine quartz-sand to obtain phosphorus; the affinity of the silica for the lime was said to facilitate the reducing action of the charcoal. Modifications were devised by E. Aubertin and L. Boblique, E. C. Mantrand, J. P. Serve, C. Brisson, etc. B. Moore, and J. W. Mellor showed that silica begins to react with the calcium phosphate at about 1200°, and that the reaction is favoured by the presence of carbon.

J. B. Readman showed that silica, intimately mixed with carbon and normal calcium phosphate, can, at a high temp., expel all the phosphorus, and form a fusible calcareous slag. Similar results were obtained with other phosphates—*e.g.* aluminium phosphate. The phosphorus can thus be obtained directly from raw phosphates without the employment of sulphuric acid at an intermediate stage in the process. Retorts were found to be unsuitable as a refractory; and shaft furnaces were not successful in working. J. B. Readman then tried to heat the mixture by passing an electric current through the raw materials contained in a closed furnace. T. Parker and A. E. Robinson patented an analogous process for producing phosphorus direct from the raw materials by electrically heating the phosphorus-bearing mixture inside the furnace, and not as in retort-distillation, outside the furnace. The idea is illustrated diagrammatically by Fig. 1.

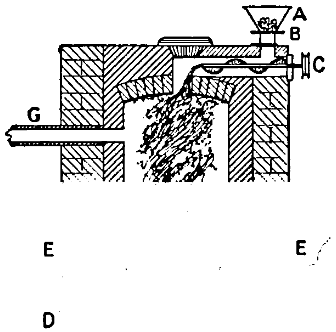

FIG. 1.—Electrical Furnace for the Manufacture of Phosphorus.

The mixture is heated in an electrical furnace fitted with carbon rods for conducting the electric current as illustrated in Fig. 1. Liquid slag is periodically tapped, and run from the bottom of the furnace *D*; and a new charge introduced so that the process is continuous. The charge is fed into the hopper *A*, and then passed into the chamber *B*, and to the conveyor *C*, which works something like an Archimedean screw, and carries the charge to the furnace. At the beginning of the operation an alternating current is sent through a pair of thin carbon "electrodes," not shown in the diagram, until the furnace is hot. When heated, the resistance of the furnace is reduced, and a current is sent through the electrodes *E*, and the thin electrodes are withdrawn. The phosphorus vapours and gases escape through a tube *G*. The electric current does its work by raising the temp. of the mass, not by electrolysis.

According to W. Hempel, and R. Müller, the reaction commences at about 1150°, when phosphorus vapour and carbon monoxide are evolved; the reaction is completed at about 1450°. The chemistry of the process is somewhat as follows: When calcium phosphate is heated with finely divided silica, SiO_2, calcium silicate, $CaSiO_3$, and phosphoric oxide are produced: $Ca_3(PO_4)_2+3SiO_2=3CaSiO_3+P_2O_5$. The latter is reduced by the carbon: $P_2O_5+5C=5CO+2P$. The carbon probably accelerates the rate of decomposition of the phosphate by the silica because the reaction progresses more quickly at a lower temp. in the presence of carbon than when carbon is absent. The composition of the slag is of importance, for the slag must be fluid enough to enable it to be run periodically from the furnace. This is determined by the mixture employed for charging the furnace. Most if not all the world's supply of phosphorus is obtained by the electrical process. Several modifications in the furnaces have been devised—by C. K. Harding, W. T. Gibbs, H. A. Irvine, T. Parker, R. K. Duncan, G. C. Landis, etc. H. Hilbert and A. Frank patented a process for phosphorus by heating a mixture of calcium phosphate and carbon in an electric furnace. Calcium carbide, CaC_2, is then the by-product: $Ca_3(PO_4)_2+14C=3CaC_2+8CO+2P$. The carbide is not pure enough for making acetylene, but is used for the preparation of calcium cyanamide. F. Tharaldsen used ferrosilicon or silicon carbide as the reducing agent; and A. E. V. Zealley discussed triplite as a source of phosphorus. C. S. Bradley and C. B. Jacobs used phosphates and phosphides of other metals than calcium in a similar manner.

The subject has been discussed by G. W. Stose, C. Herrmann, J. C. Chorley, etc. According to J. W. Richards, the furnaces at Niagara consume 11·6 kilowatts per hour per kilogram of phosphorus.

L. Dill electrolyzed a mixture of phosphoric acid of sp. gr. 1·7 to 1·9 and carbon in a closed vessel provided with a suitable opening, for the escape of phosphorus, etc. Carbon electrodes were used. The Electric Reduction Co., and F. J. Machalske proposed an analogous process.

If phosphorus vapour be condensed in cold water, the product resembles the raspings of cork and floats on water. The phosphorus from the condensers varies from a pale buff to brick-red, chocolate, or black colour. The variation in colour is mainly due to impurities, as well as the presence of the lower oxides, and of red phosphorus. The contamination of phosphorus by arsenic through the use of sulphuric acid contaminated with arsenic was observed by C. F. Bärwald,[4] C. Wittstock, F. P. Dulk, H. W. F. Wackenroder, E. Noelting and W. Feuerstein, G. Denigès, E. Merck, and J. von Liebig. According to P. I. Bonz, some samples of phosphorus which are yellow when fused, turn black when suddenly cooled—he said that boiling in alcohol destroys, while fusion with phosphoric acid develops, this property. Crude phosphorus mixed with fragments of sand, clay, and flue-dust can be cleaned by melting it under hot water, and agitating it with a wooden rake to allow the impurities to rise to the surface. When the phosphorus has solidified, the impurities can be collected, and redistilled, if necessary, to recover the phosphorus. The phosphorus can also be pressed through chamois-leather under hot water. The phosphorus can also be redistilled from an iron retort; or it can be agitated for a couple of hours with a warm mixture of sulphuric acid and potassium or sodium dichromate, as recommended by F. Wöhler, and A. Michaelis and M. Pitsch. The phosphorus has been purified by warming it with agitation in dil. nitric acid, or chlorine-water; by warming it in potash-lye or aq. ammonia, and then in water; by warming it in a soln. of potassium hydroxide in 75 per cent. alcohol as recommended by R. Böttger; and by dissolving it in carbon disulphide, and precipitating by potash-lye as recommended by R. Böttger. E. Noelting and W. Feuerstein freed phosphorus from arsenic, by distillation in steam. The purification of phosphorus for special purposes by distillation in a stream of hydrogen or other inert gas has been recommended by I. Remsen and E. H. Keiser, J. Böeseken, and A. Stock. A. Smits and H. L. de Leeuw purified the element by distillation and fractional crystallization in a highly exhausted atm., and obtained a colourless crystalline product. The phosphorus melted under hot water can be readily moulded into any desired shape, and it is commonly moulded into sticks. K. Seubert has devised a mould for this purpose. It is preserved in darkness under water, or under a non-freezing liquid like alcohol and water, or glycerol.

If the fused element be shaken up with a warm liquid until cold, it furnishes the so-called **granulated phosphorus**. J. L. Casaseca recommended alcohol of sp. gr. 0·85 in preference to water; R. Böttger, human urine, or an aq. soln. of urea; N. Blondlot, soln. of various salts, or sugar; and H. Schiff, methyl alcohol, actone, aq. ammonia, soln. of gum, dextrine, glue, starch, ammonium carbonate, etc.

§ 4. The Allotropic Forms of Phosphorus

L. Wolf and K. Ristau [1] observed that *colourless phosphorus* can be obtained pure only in a darkened room in the absence of oxygen and moisture. It is best obtained in an atm. of nitrogen either by fractional distillation, or by fractional crystallization. It is either a colourless, transparent, glassy mass, or it is white and finely crystalline. It melts to a clear, colourless liquid. It is stable under the abovenamed conditions, but rapidly becomes yellow in light.

The early workers—H. A. von Vogel, C. W. Böckmann, M. Bengieser, R. Böttger, R. F. Marchand, J. Pelouze, and U. J. J. Leverrier—frequently observed that a reddish-coloured substance was formed along with ordinary phosphorus, and they usually attributed this to the formation of a lower oxide. E. Kopp observed, in 1844, during the preparation of ethyl iodide from phosphorus, iodine, and alcohol, that a red pulverulent residue was obtained which during the distillation passed into ordinary phosphorus. He referred to it as *Phosphor in der roten Modifikation.* J. J. Berzelius, in 1843, alleged that the red phosphorus insoluble in carbon disulphide which has been obtained by previous workers—*e.g.* by H. A. von Vogel by the action of sunlight on phosphorus—is an allotropic modification of phosphorus. Hence, R. Winderlich maintained that H. A. von Vogel, and J. J. Berzelius are the discoverers of allotropic phosphorus. The proof, however, was wanting. J. Nicklès

discussed the history of the so-called amorphous phosphorus. In 1848, A. Schrötter demonstrated that in most cases the red substance is nothing but pure phosphorus in a peculiar state of aggregation—*ein neuer allotropischer Zustand des Phosphors.*

A. Schötter showed that ordinary phosphorus can be converted into the red form in a variety of ways. Thus, it is formed when phosphorus is exposed to *light* either under water or alcohol, in vacuo, in hydrogen, nitrogen, carbon dioxide, or in a hydrocarbon. The depth of penetration of the red film increases with the intensity of the light. F. Scriba exposed to sunlight a rod of phosphorus, half of which was wrapped round with tin-foil, and found the exposed part was alone transformed into red phosphorus. Observations on the reddening of phosphorus in light were made by H. A. von Vogel, C. W. Böckmann, A. Pedler, H. Reinsch, E. Riegel, and J. W. Retgers. The formation of red phosphorus by exposing to light a soln. of phosphorus in carbon disulphide, benzene, or chloroform was observed by A. Lallemand, A. Pedler, and A. Michaelis and K. von Arend. The last-named also observed that if the solvent be carbon tetrachloride, the red phosphorus produced contains some carbon ; and that if the insolated phosphorus be under water, some phosphorus tetritoxide is formed. W. A. Wahl found that a drop of yellow phosphorus under water immediately receives a coating of red phosphorus when illuminated by a quartz mercury lamp. When yellow phosphorus is placed in the ultramicroscope, either as a solid, or dissolved in carbon disulphide, the dark field becomes illuminated with submicroscopic points which increase in size and brightness, finally becoming red in colour. H. Siedentopf inferred from this that an intermediate, colloidal phase is formed during the passage from yellow to red phosphorus. W. R. Grove found that red phosphorus is produced when an *electric discharge* is sent through the vapour of ordinary phosphorus; and H. Geissler, V. Kohlschütter and A. Frumkin, and W. Hittorf made a similar observation—*vide infra*, colloidal phosphorus.

A. Schrötter showed that *heat* may convert ordinary phosphorus into the red form. He said that when heated in an atm. free from oxygen, sublimation begins at 150° without change of colour, but at about 226° ordinary phosphorus slowly passes into the red variety. After being heated to 240°–250°, for 50 hrs., the product is treated with carbon disulphide so as to wash out the ordinary phosphorus. The product is purified by boiling it with potash-lye of sp. gr. 1·3, and subsequently washing with water acidulated with nitric acid, and then with water alone. To remove the ordinary phosphorus, T. Weyl recommended boiling for 2 hrs. with 10 per cent. soda-lye. A. Stock and M. Rudolph also purified red phosphorus by treatment with alkali-lye. J. Nicklès recommended levigation of the mixture with carbon disulphide with a soln. of calcium chloride of sp. gr. 1·349–1·384—the soln. of ordinary phosphorus in the carbon disulphide floats, while the red phosphorus sinks in the calcium chloride soln. Several modifications of the process have been devised. V. Meyer heated a tube of the yellow phosphorus in the vapour of diphenylamine, at 310° ; L. Troost and P. Hautefeuille heated the sealed tube for 650 hrs. at 265° ; W. Muthmann, 24 hrs. at 230° ; J. W. Retgers, 24 hrs. at 240° ; and R. Schenck heated ordinary phosphorus in an atm. of hydrogen at 310°. A. Stock, H. Schräder, and E. Stamm found that the sudden quenching of phosphorus vapour at 900°–1175° furnishes red phosphorus. B. C. Brodie found that the reaction is accelerated by a trace of iodine. The reaction then progresses slowly at 100°, and with almost explosive violence at 200°. It is assumed that the iodine acts catalytically. There is a cyclic series of reactions in which the yellow phosphorus forms a subiodide which decomposes into red phosphorus and iodine. A. Besson held that phosphorus tetritatriiodide (*q.v.*) is the intermediate product ; R. Boulouch agreed with B. C. Brodie that the catalytic conversion of yellow to red phosphorus is due to the formation of the diiodide which in contact with an excess of phosphorus is converted into a subiodide which, at temp. above 160°, undergoes a series of decompositions resulting in the formation of the diiodide which immediately dissociates, forming red phosphorus. W. Hittorf did not accept this view of the conversion.

R. Schenck said that the initial change is a polymerization of P_4-mols. to P_8-mols.; and that the P_8-mols. are extremely labile, changing quickly into a more highly polymerized form. J. Böeseken does not believe that the catalytic action is due to the formation of a series of intermediate products, but considers that the transformation of yellow to red phosphorus is preceded by a decomposition of the P_4-mols. into P- or P_2-mols., which at once condense to the red form. The reactions are symbolized $P_4 \rightarrow 2P_2$; and $nP_2 \rightarrow P_{2n}$, in which the velocity of the second reaction is much greater than that of the first. The catalyst is supposed to hasten the dissociation of the P_4-mols. The reaction was discussed by W. Hittorf, R. Schenck, A. Besson, A. Pedler, and R. Boulouch; J. Böeseken found that aluminium chloride also stimulates the reaction. Red phosphorus is also produced when a soln. of phosphorus in carbon disulphide, benzene, toluene, or xylene, containing a little iodine, is boiled in a flash with a reflux-condenser. This reaction was discussed by B. Corenwinder, W. Hittorf, F. Rüdorff, and F. Todenhaupt. W. Hittorf said that selenium acts like iodine in accelerating the change; and F. Isambert found that red phosphorus mixed with some phosphorus sulphide, is formed when ordinary phosphorus is heated with a little sulphur or phosphorus sulphide.

N. Blondlot said that red phosphorus is formed by the action of soln. of potassium, sodium, or ammonium hydroxide on ordinary phosphorus; A. Commaille said that with aq. ammonia, some phosphorus hydride is formed—*vide infra*—and A. Stock and co-workers found that red phosphorus is produced by the aq. ammonia treatment. E. J. Houston considered the phosphorus produced by a protracted heating under potash-lye to be a special modification. B. Lepsius found that red phosphorus is formed when phosphine is decomposed by an electric arc; and A. Stock and co-workers, when the solid hydride is heated in vacuo for 24 hrs. at 340°–360°.

The manufacture of red phosphorus.—Red phosphorus is made commercially by heating yellow phosphorus in a glass or porcelain vessel embedded in sand placed in a large iron pan. The vessel containing the phosphorus is covered with an air-tight lid, and provided with a safety-valve dipping in water in case the press. inside the closed vessel becomes too great. When most of the air has been expelled, the safety-valve is closed, and the phosphorus is heated between 240° and 250° until it is converted into the red variety. If the temp. rises above 300°, there is a risk of explosion. When the conversion is effected in open iron vessels with a limited access of air, the process, though tedious, is said to be free from danger. The hard compact lumps of red phosphorus so obtained are ground with water, and boiled with sodium hydroxide soln. so as to remove the unaltered yellow phosphorus. The residual red phosphorus is then washed with boiling water, and dried, or preserved moist.

According to R. Schenck, when a soln. of yellow phosphorus in rectified phosphorus tribromide is maintained at 170°–190°, red phosphorus is slowly deposited. The transformation does not occur in very conc. soln., and a conc. of about 1 per cent. is favourable. A trace of phosphorus tetraiodide trebles the velocity of the reaction, without otherwise affecting the character of the change. R. Schenck thought the reaction is bimolecular, but when the disturbance due to the mechanical removal of the catalyst from the system by the precipitated red phosphorus was eliminated, the reaction was unimolecular. The precipitated phosphorus has a bright scarlet colour—**scarlet phosphorus**—and is an extremely finely divided form of red phosphorus. It resembles the form obtained by J. W. Retgers from liquid yellow phosphorus at temp. below 250°, and also with the red phosphorus precipitated by light from carbon disulphide soln. J. Böeseken found that the scarlet variety is also produced if a soln. of phosphorus in benzene (or better, phosphorus trichloride) containing a little aluminium chloride is kept at the b.p. of the solvent for a few hours (or minutes respectively). R. Schenck regards scarlet phosphorus as an amorphous or colloidal variety of red phosphorus, related to ordinary red phosphorus much as precipitated silica is related to quartz.

W. Hittorf prepared **metallic or violet phosphorus** by heating phosphorus in contact with lead for 10 hrs. at a temp. near 500°. The phosphorus dissolves in the lead at the high temp., and on cooling separates from the lead in the form of small, dark, reddish-violet, rhombohedral crystals. The crystals can be separated from the lead by treatment with dil. nitric acid, which dissolves only the lead. The crystals are further purified by boiling them with hydrochloric acid. A. Stock and F. Gomolka recommended the following procedure:

W. Hittorf's phosphorus is best prepared by heating 3 grms. of pure phosphorus with 200 grms. of lead in a sealed hard glass tube, packed in sand, to 800° for 48 hrs. The glass is broken and removed in a freezing mixture, and the lead cleaned by brushing and by washing with hydrofluoric acid. As nitric acid attacks the phosphorus, the lead is best removed by electrolysis in acetic acid containing lead. The cathode is placed at the bottom of the vessel, a clock-glass being fixed below the rod. The residue thus obtained contains some lead, mechanically dislodged from the anode, and is purified by boiling with hydrochloric acid in an atm. of carbon dioxide, followed by treatment with hydrofluoric acid. The purest product still contains 1·5 per cent. of lead.

Bismuth may be used in place of lead, but it dissolves only one-fifth as much phosphorus, and the crystals obtained are less pure. The metals appear to be held in solid soln. Only very minute quantities of Hittorf's phosphorus are obtained by sublimation. According to L. Troost and P. Hautefeuille, the same variety is formed when red phosphorus is heated under press. to 580°. The work of A. Pedler, J. W. Retgers, and D. L. Chapman shows that this variety differs from ordinary red phosphorus only in the size and development of the crystals. *Fine-grained red phosphorus is scarlet phosphorus, while coarse-grained red phosphorus is metallic or violet phosphorus.* A number of other allotropes have been reported, but many of them are the result of a misinterpretation of facts, or of an incomplete knowledge of facts.

The so-called *liquid phosphorus* reported by T. de Grotthus,[3] H. Rose, J. Kallhofert, and E. J. Houston were shown by D. Gernez, and F. P. Venable and A. W. Belden to be under-cooled or surfused phosphorus.

Sometimes ordinary or yellow phosphorus is called *white phosphorus.* The term "white phosphorus" was formerly applied to the white skin or crust which appears on the surface of phosphorus which is confined under water in diffuse daylight. It was mentioned by C. Cagniard de la Tour. H. Rose supposed it to be pure white phosphorus, but J. Pelouze, J. W. Retgers, and R. F. Marchand supposed it to be a hydrated form of phosphorus; G. J. Mulder, a compound of phosphorus hydride and oxide; B. Franke, $P_4(OH)H$; A. Dupasquier, a compound of calcium oxide and phosphorus derived from lime in the water; and E. Baudrimont, to an irregular corrosion of the surface of the phosphorus by the oxygen dissolved in the water. R. Böttger obtained it by cooling phosphorus which had been melted under an alcoholic soln. of potassium hydroxide; and R. Napoli obtained an opaque form by melting phosphorus under water at 50°.

In 1788, P. I. Bonz mentioned a black variety—*vide supra*—which came to be called *black phosphorus.* L. J. Thénard prepared what he called *phosphore noir* by suddenly cooling phosphorus at 70°. N. Blondlot supposed the coloration to be due to the presence of impurities, and he was able to imitate the effect by melting phosphorus in the presence of mercury or mercurial compounds; and this was confirmed by C. H. Hall, and D. Gernez. E. J. Maumené observed the production of black phosphorus among the first drops collected when phosphorus is distilled in a current of hydrogen prepared from zinc and sulphuric acid, but not in a current of carbon dioxide. F. A. Flückiger attributed E. J. Maumené's result to the presence of arsine in the hydrogen employed. E. Ritter supposed the coloration is produced by arsenic—*vide supra*, F. B. Fittica—but E. Reichardt said that arsenic is not necessary for the blackening of phosphorus. R. Wild said the blackening occurs with phosphorus which has been kept under water in a lead vessel; and W. N. Rae observed a case due to traces of copper salts in the water under which the yellow phosphorus was preserved. P. Thénard attributed the black colour to the presence of red phosphorus. The work of A. Schrötter, J. W. Retgers, R. Schenck, and A. Stock lends no support to the view that a distinct allotropic form of phosphorus is involved in these observations.

I. Remsen and E. H. Keiser considered that they had obtained a special allotropic form of phosphorus by suddenly cooling the vapour of phosphorus by iced-water. The product is here red phosphorus, for, as shown by A. Stock and co-workers, red phosphorus can be produced by suddenly quenching phosphorus vapour at 900°–1175°. H. M. Vernon reported that *rhombic phosphorus, i.e.* rhombic crystals of phosphorus, can be obtained by slowly cooling liquid phosphorus. This observation, however, remains unverified;

S. U. Pickering and A. E. H. Tutton could not produce the rhombic form. P. Jolibois obtained what he called a polymorphous form of red phosphorus stable below 450°, but there is nothing to show that this is essentially different from ordinary red phosphorus.

E. Cohen and K. Inouye[3] observed no sign of the formation of an allotropic form of yellow phosphorus at low temp.; but P. W. Bridgman observed the formation of an allotropic modification of ordinary yellow phosphorus during some experiments on the effect of high press. on ordinary phosphorus. This variety is formed when yellow phosphorus at 60° is compressed under 11,000 kgrms. per sq. cm., and there is a transition point at —76·9° which is readily shown by the terrace in the heating curve of phosphorus as it rises in temp. from —90°, Fig. 2. There is also a vol. contraction of about 2 per cent. during the change. The crystalline form of the **β-yellow phosphorus** is probably hexagonal, whereas ordinary, or **α-yellow phosphorus** is cubic. D. Vorländer and co-workers gave —68° for the transition temp., and they were unable to obtain well-defined crystals, but thought that they are either monoclinic or rhombic.

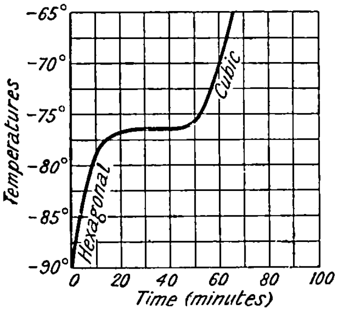

FIG. 2.—Heating Curve during Passage from α- to β-yellow Phosphorus.

Again, in attempting to change yellow into red phosphorus by the application of press., P. W. Bridgman found that a denser crystalline variety is formed at 200°, with press. ranging from 12,000 to 13,000 kgrms. per sq. cm. This variety is called **black phosphorus**; and it is not to be confused with older black or dirty phosphorus. The change is irreversible, since black phosphorus is more stable than red. Ordinary yellow phosphorus has a sp. gr. of 1·83 to 1·85; red phosphorus, 2·05 to 2·39; and black phosphorus approximates 2·69, that is, 15 per cent. higher than the densest red phosphorus. He did not succeed in converting yellow into black phosphorus at 175°, and a press. of 13,000 kgrms. per sq. cm., although at higher press. the change would probably occur, because at 200° the conversion was successful. At 200°, yellow phosphorus is converted into the red modification, using a little sodium as catalyst and a press. of 4000 kgrms. per sq. cm. The chemical properties of black phosphorus are very much like those of red phosphorus—both varieties are insoluble in carbon disulphide; they are attacked by cold nitric acid, and they resist the action of cold sulphuric acid. Black phosphorus ignites at nearly 400° in air, and, unlike red phosphorus, it is not ignited when struck on an anvil with a hammer. When heated in a closed glass tube, it vaporizes, and the vapours condense to a mixture of white and red phosphorus, hence it is probable that the vapours from both black and red phosphorus are nearly alike. The black variety, unlike yellow or red phosphorus, is a fairly good conductor of electricity, and the conductivity increases rapidly with rise of temp. It is also a better conductor of heat, and is less diamagnetic than either red or yellow phosphorus. Black phosphorus under press. can be melted at a rather higher temp. than red phosphorus similarly treated, and on cooling, both varieties solidify to a chocolate-brown mass of sp. gr. 2·18. C. H. Hall, and A. Smits and co-workers support the view that P. W. Bridgman's black phosphorus is a true allotrope. The former held that L. J. Thénard's black phosphorus was a colloidal suspension of mercury in phosphorus. W. Ipatieff and W. Nikolaieff observed that a purple, crystalline phosphorus is produced when yellow phosphorus is heated with water at 248° and at a press. of 48 atm. It is soluble in carbon disulphide; over 216° and 89 atm. press., black crystalline phosphorus, insoluble in carbon disulphide, is formed. When red phosphorus is heated in hydrogen at 200° and 90 atm. press., W. Ipatieff found that black phosphorus is formed. W. Marckwald and K. Helmholtz found black phosphorus changes into the scarlet form at 575°.

A. Müller[4] prepared **colloidal red phosphorus** by boiling the commercial product for some time, with water, and after allowing the mixture to stand some time, pouring off that remaining in suspension. This was repeated a number of times. Colloidal soln. with high viscosity—produced by additions of the colloid gelatin, gum, starch, casein, albumin, glue, dextrin, or sugar—are flocculated with difficulty on adding sodium chloride. Thus, with 50 c.c. of the phosphorus suspension, and 5 c.c. of a 10 per cent. soln. of sodium chloride :

	After 24 hrs.	After 48 hrs.
No colloid	clear	clear
Gelatin : 10 c.c. of 5 per cent. soln. . .	very turbid	very turbid
Gelatin : 5 c.c. of 5 per cent. soln. . .	turbid	turbid
Dextrin : 10 c.c. of 5 per cent. soln. . .	turbid	nearly clear
Sucrose : 10 c.c. of 5 per cent. soln. . .	slightly turbid	clear
Sucrose : 10 c.c. of 25 per cent. soln. .	very turbid	turbid

The viscosity of the medium protects the suspension against gravitational and electrical forces. T. Svedberg prepared colloidal soln. of red phosphorus in isobutyl alcohol by sending a series of small arc discharges about the red phosphorus immersed in the medium. P. P. von Weimarn obtained **colloidal yellow phosphorus** by pouring an alcoholic soln. into a great excess of water. A. Lottermoser found the ethereal soln. was clear and colourless, but in diffuse daylight it had an orange-yellow opalescence, and in transmitted light it appeared clear and yellowish-red—*vide supra*, scarlet phosphorus. V. Kohlschütter and A. Frumkin found that when an electric discharge is passed through yellow phosphorus vapour, red phosphorus is deposited in a highly dispersed condition on the walls of the containing vessel. The deposit is loosened in the presence of indifferent gases—hydrogen, argon, helium, and nitrogen—and more so in the case of argon than of helium. Hydrogen and nitrogen react chemically with the gas ; argon and helium are absorbed. When the deposit is heated, it forms ordinary red phosphorus. The deposit formed at first is considered to be identical with the product obtained by suddenly cooling the superheated phosphorus vapour, and when heated, this sinters and passes with ordinary red phosphorus, and has the appearance of a homogeneous, dried gel of stannic oxide.

A review of the alleged allotropes of phosphorus reduces their number to four, namely, the α- and β-forms of yellow phosphorus, red or violet phosphorus, and black phosphorus. Most of the work of various investigators has been directed towards elucidating the nature of red phosphorus, and of the transformation of yellow to red phosphorus and conversely. Red phosphorus was formerly considered to be amorphous, and it was often called amorphous phosphorus. The term "amorphous," however, here referred more to the general appearance of the powder rather than to its minute structure. J. W. Retgers[5] showed that the particles of ordinary red phosphorus are rhombohedral crystals, which are well developed in those of W. Hittorf's violet phosphorus. All four varieties are therefore crystalline. J. W. Terwen has reviewed this subject in a general way ; and M. Copisarow discussed the theory of allotropy.

P. Jolibois found that the velocity of transformation of yellow to red phosphorus increases with the temp. It is very slow at 360°, but it can be observed at 250° if a trace of iodine as catalyst be present. G. Lemoine investigated the transformation of yellow to red and red to yellow under the influence of heat, and he concluded that the transformations are reciprocal ; and that a balanced reaction is involved. If yellow phosphorus be heated in a sealed glass tube to 440°, a state of equilibrium is attained between the yellow and red phosphorus : $P_{yellow} \rightleftharpoons P_{red}$. The slopes of the curves in Fig. 3 illustrate the speeds

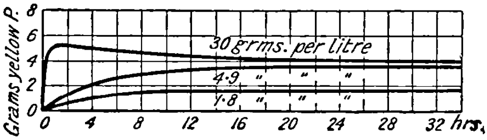

FIG. 3.—Speed of Transformation of Red to Yellow Phosphorus (Diagrammatic).

of transformation of red to yellow phosphorus in closed vessels containing initially 1·8, 4·9, and 30 grms. per litre of space. The experiments were made by heating the vessels to the specified temp. and time, and then suddenly quenching the vessel. Similar results were obtained in the conversion of yellow to red phosphorus. The actual values depended upon the amount of phosphorus in unit vol., and on the capacity of the containing vessel. This shows that the surface of the containing vessel plays some part in the reaction. The results follow the mass-law, $dx/dt=k(a-x)$, where k, the velocity constant=0·31 for one set of experiments with red to yellow phosphorus, for the converse change the velocity constant is 0·041 nearly. There is an anomaly when a large proportion of phosphorus is present in the vessels, for the yellow phosphorus condensed from the vapour attains a maximum and then decreases instead of remaining constant with time. L. Troost and P. Hautefeuille showed that the properties of red phosphorus depend on the temp. at which it is produced; and the variety peculiar to the particular temp. at which it is produced is acquired only slowly. The vap. press., for example, is higher the lower the temp. at which the red phosphorus has been prepared. Thus red phosphorus prepared at 265° behaves with respect to that prepared at 440°, as white phosphorus acts with respect to red. This, said P. Duhem, means that varieties of red phosphorus prepared at a low temp. should be regarded as existing in a state of *faux equilibre*, and when they are brought to a higher temp., they change into the variety corresponding with this temp.

A. Colson showed that there is no common solvent for red and yellow phosphorus. He studied the rate of conversion of yellow into red phosphorus when the former is dissolved in turpentine or in carbon disulphide. The rate of conversion follows the same laws as when phosphorus alone is heated, and is dependent on the temp. and conc. of the soln. For example, a soln. of phosphorus in oil of turpentine, containing 23 grms. per litre, remained clear after heating for 52 hrs. at 230°–235°, but gave a thick deposit of red phosphorus after heating for 8 to 10 hrs. at 285°–290°. A soln. containing 20 grms. of phosphorus in a litre of oil of turpentine, deposited red phosphorus after heating for 55 hrs. at 260°–265°, whilst a soln. of phosphorus in carbon disulphide, containing 90 grms. per litre, deposited red phosphorus after heating for 15 hrs. at the same temp. Three tubes containing respectively 150, 125, and 10 grms. of phosphorus in 100 grms. of carbon disulphide were heated at 225°–230°; at the end of 4 hrs. the first tube contained a large quantity of red phosphorus, the second tube contained traces of the red phosphorus, whilst the contents of the third tube were unaltered. He said that the slow irreversible change of yellow to red phosphorus in turpentine soln. at 250°, is due to the formation of small quantities of hydrogen phosphide and its subsequent decomposition into red phosphorus to form a further quantity of hydrogen phosphide. A 2 per cent. soln. of phosphorus in oil of turpentine was sealed in a tube with hydrogen phosphide and enclosed in a tube containing a further quantity of the soln. After heating at 240° for 4 hrs., the inner tube contained a copious deposit of red phosphorus, whilst the contents of the outer tube remained clear even after 12 hrs. at 250°. Phosphorus dissolved in an oxygenated solvent, such as ethyl benzoate, does not undergo any allotropic transformation even when the soln. is heated at 305°–310° for 25 hrs.

The density of the vapour from red or yellow phosphorus is the same, and it corresponds with the mol. P_4; hence, from the analogy between a vapour and a solute —1. 10, 8—it might be inferred that the two varieties of phosphorus would become identical in a common solvent. If a soln. of yellow phosphorus in phosphorus tribromide—with a trace of iodine as catalytic agent—is kept between 170° and 190°, red phosphorus is gradually deposited. R. Schenck measured the conc. of the yellow phosphorus in soln. after the lapse of different intervals of time, and found the reaction to be bimolecular, but when allowance is made for the mechanical removal of the catalytic agent from the soln. by the precipitated red phosphorus, the reaction is unimolecular.

Violet phosphorus is the stable form at ordinary temp. and yellow phosphorus the unstable modification. The reason the yellow phosphorus does not pass into the violet form at ordinary temp. is due to the extremely slow velocity of the change. By the distillation of violet phosphorus at 290°, yellow phosphorus is obtained, and at ordinary press. the transition-point of the stable violet into the unstable yellow is masked by the vaporization of the phosphorus. According to A. Stock and F. Gomolka, when violet phosphorus is heated under press. in capillary tubes so as to prevent distillation, it forms a yellow fluid at 610°, and red particles begin to separate from the cooling soln. at 580°. At 570°, the mass turns red. Violet phosphorus begins to melt at 589·9°. The vap. press. of yellow phosphorus is greater than the red; under ordinary conditions the curves cannot be carried above 400° because the yellow phosphorus passes into the violet variety so very quickly. A. Smits and S. C. Bokhorst's two vap. press. curves are illustrated in Figs. 4 and 5. Both vap. press. curves converge towards the transition point as is the case with allotropic modifications of other elements. It is inferred that both varieties would be in equilibrium with the vapour phase at the transition point—589·9°—were it possible to make the experiment. The vaporization of phosphorus is therefore a complex phenomenon. If violet phosphorus be heated in a closed space to a given temp. until its vap. press. is constant, and then heated to a higher temp. until a greater vap. press. is reached, on cooling, the vap. press. does not return to its original value, but lags behind, thus making it probable that the vaporization is not to be explained by a simple dynamic equilibrium between the streams of mols. approaching and departing from the surface of separation between the two phases. In explanation, it is supposed that the vaporization of phosphorus involves the reversible process of true vaporization together with a rapid irreversible polymerization of the mols. of the vapour.

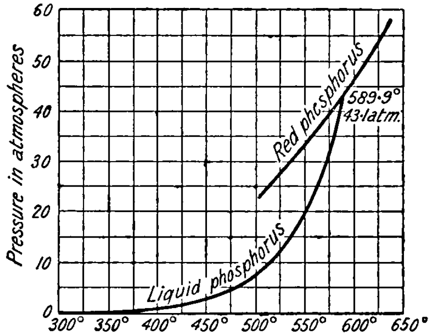

Fig. 4.—Vapour Pressure Curve of Liquid Phosphorus and Sublimation Curve of Red Phosphorus.

The term "red phosphorus" includes a large number of products with properties which differ more or less from one another, and depend upon the temp. at which the substance was formed. W. Hittorf's violet phosphorus, crystallized from molten lead, stands at one end of the series, and scarlet phosphorus stands at the other end. E. Cohen and J. Olie consider ordinary red phosphorus to be an isomorphous mixture or solid soln. of yellow and violet phosphorus in dynamic equilibrium: $P_{yellow}=P_{violet}$, where the equilibrium constant depends upon the temp. One objection has been made to this hypothesis: the denser varieties prepared at high temperatures do not assume an appropriate lower density when kept for a long time at lower temp. The answer may be that the equilibrium condition is very slowly attained at the lower temp. or that the reverse change is arrested by what P. W. Bridgman calls *frictional passive resistance.* Increase of temperature lessens the frictional resistance and the change can proceed further. This hypothesis explains: (i) Why the reverse change does not occur on cooling; (ii) Why the nuclei formed during the change from yellow to red phosphorus do not increase in size, but rather increase in number; (iii) Why the sp. gr. of red phosphorus prepared at different temp. vary—thus the sp. gr. of R. Schenck's variety formed at 30° is 2·05, and W. Hittorf's variety has a sp. gr. of 2·39; (iv) Why red phosphorus does not melt sharply like a pure chemical individual, but rather melts over an interval of temp. like a solid soln.—thus, according to A. Stock and O. Johannsen, red phosphorus melts between 600° and 615°, and violet phosphorus between 620°

and 625° ; (v) Why the vap. press. of yellow phosphorus remains constant, when it is heated, until all the yellow phosphorus has disappeared ; instead of changing abruptly to that of the red, the change diminishes quite rapidly ; and (vi) Why the amount of heat developed by the combustion of red phosphorus is not constant, but varies with the different varieties. Hence, it is inferred that **red phosphorus is not a single homogeneous species, but rather a transitional product formed during the passage of yellow to violet phosphorus.** In agreement with L. Troost and P. Hautefeuille, A. Stock made the counter-suggestion that red phosphorus is a solid soln. of several varieties of red phosphorus in each other. J. Böeseken said that red phosphorus is a mixture of much violet phosphorus with a little colloidal phosphorus. A. Smits and S. C. Bokhorst also developed the hypothesis that red phosphorus is a mixture of two or more kinds of mols. in equilibrium. As pointed out by A. Stock and F. Gomolka, the heterogeneous character of red phosphorus really means that many of the measurements of the physical constants of this substance have *nicht geringste Wert.* W. Puttfarcken found some lower oxide in commercial red phosphorus.

H. W. B. Roozeboom suggested that the relations between white and red phosphorus may be like those of cyanogen, and that the vap. press. curve of liquid yellow phosphorus may terminate below the m.p. of the violet form ; he also said that it may be that liquid yellow phosphorus is super-cooled violet phosphorus. A. Smits and co-workers showed that liquid yellow phosphorus is to be taken as super-cooled liquid violet phosphorus. It is usual to consider under-cooled liquids as being still in the liquid state, and since yellow phosphorus crystallizes in the cubic system, it is necessary to modify the ordinary meanings of some of these terms. A. Smits and co-workers represent the press.-temp. diagram of the phosphorus system schematically by Fig. 5. Here the curve *RC′* represents the vap. press. of violet phosphorus at different temp. ; *C′E*, the vap. press. curve of liquid phosphorus ; *C′C″*, the effect of press. on the m.p. of violet phosphorus; *C″C‴*, the effect of press. on the m.p. of black phosphorus ; *C″D*, the effect of press. on the transition point of violet to black phosphorus. If molten phosphorus be cooled below the temp. at which it is converted into violet phosphorus, the curve *B′C′E* represents the vap. press. curve of liquid yellow phosphorus ; *B′*, the m.p. of α-yellow phosphorus ; *B′B″*, the effect of press. on the m.p. of α-yellow phosphorus ; *A′B′*, the vap. press of ordinary yellow phosphorus ; *WA′*, the vap. press. of β-yellow phosphorus ; *A′A″*, the effect of press. on the transition temp. of α- into β-yellow phosphorus. When molten phosphorus cooling from the state represented by *E* reaches the state represented by *C′*, it may remain liquid, passing through the states *C′B′*, or it may pass into violet phosphorus assuming the states represented by *C′R.*

§ 5. The Physical Properties of Phosphorus

As ordinarily prepared, phosphorus is a yellow solid with a waxy lustre. When well purified the so-called yellow or white phosphorus is colourless, and transparent if slowly cooled, and more or less opaque if rapidly cooled. J. B. Trautwein,[1] and J. A. Buchner said that when cooled after fusion, yellow phosphorus may furnish large dodecahedral or octahedral **crystals**. According to J. W. Retgers, if a rod of yellow phosphorus is broken, the crystalline structure of the fractured surfaces recalls that of a broken zinc rod. N. Blondlot, W. D. Herman, G. Whewell, and C. A. Burghardt described the preparation of crystals of phosphorus from molten phosphorus. E. Mitscherlich obtained crystals by sublimation in a sealed tube containing an inert gas, and kept warm for a few days. B. Pelletier said that soln. of phosphorus in volatile oils yield octahedral crystals; and E. Mitscherlich, that soln. in phosphorus sulphide furnish dodecahedral crystals. J. W. Retgers found that soln. of phosphorus in turpentine, oil of aniseed, oil of lemons, or oil of almonds give combinations of the dodecahedron and cube; while the crystals obtained by cooling warm conc. soln. in carbon disulphide, benzene, xylene, alcohol, ether, methylene iodide, and petroleum give dodecahedral crystals which are almost always columnar. Very good crystals were obtained from methylene iodide, and carbon disulphide; T. Bokorny obtained good crystals by adding alcohol or ether to a carbon disulphide soln. of phosphorus, and pouring the soln. into cold water; and A. C. Christomanos obtained octahedral or doubled tetrahedral crystals by evaporating ethereal soln., and thick prisms, or needles from a benzene soln. O. Lehmann described skeletal crystals. The different forms of the cubic crystals were measured by N. S. Maskelyne, and E. Mitscherlich; P. W. Bridgman's β-yellow phosphorus is hexagonal, while the ordinary or α-yellow phosphorus is cubic.

According to L. Troost and P. Hautefeuille, the colour of red phosphorus varies with the temp. of preparation for that prepared at low temp. is scarlet, and that at a high temp. has a violet or purple tinge; while that at a still higher temp. is almost black. Red phosphorus was considered by A. Schrötter to be amorphous, but W. Muthmann, and J. W. Retgers showed that while a little amorphous phosphorus may be present the bulk of the material consists of doubly refracting crystals. The crystalline nature of red phosphorus was confirmed by A. Pedler, L. Troost and P. Hautefeuille, J. Böeseken, D. L. Chapman, A. Stock, and H. Arctowsky. As indicated above, red phosphorus ranges from the possible colloidal, scarlet phosphorus of R. Schenck to the so-called metallic or violet phosphorus of W. Hittorf. R. Engel, and W. Hittorf suggested that the crystals are possibly isomorphous with those of arsenic, antimony, and bismuth; but, according to

G. Linck, the crystals are trigonal with the axial ratio $a:c=1:1·1308$, and are not eutropic nor isomorphous with those of arsenic, antimony, and bismuth; but G. Linck and P. Möller, A. Stock and co-workers, F. von Wolff, and O. Johannsen regarded the crystals as monoclinic. This makes yellow phosphorus analogous with the cubic forms of antimony and arsenic; and red phosphorus with monoclinic antimony and arsenic. H. C. Burger, and S. von Olshausen obtained an **X-radiogram** of red phosphorus, but no detailed study has been made of the result; although S. von Olshausen inferred that it has a simple cubic lattice of side $a=7·331$ A. P. W. Bridgman's black phosphorus is crystalline. G. Linck and H. Jung found the X-radiogram of black phosphorus, like that of arsenic, antimony, and bismuth, corresponds with the trigonal or rhombohedral space lattice with $a=5·96$ A., and $\alpha=60°\ 47'$. There are 8 atoms per unit cell. D. Gernez found the **velocity of crystallization** of the under-cooled liquid is 1·2 units at 43·8°, 56·9 units at 41·4°, 243·1 units at 38°, and 1030·9 units at 24·9°.

C. W. Böckmann[2] gave 1·896 for the **specific gravity** of yellow phosphorus; A. F. de Fourcroy and L. N. Vauquelin, 2·0332; A. Wigand, 1·828; while A. Schrötter gave 1·826–1·840. For the value at 0°, G. Quincke gave 1·986; G. Pisati and G. de Franchis, 1·83676, and G. Vincentini and D. Omodei, 1·83676, and at 4·44°, 1·80654; at 10°, H. Kopp gave 1·826; at 13°, B. C. Damien, 1·8177, and H. M. Vernon, 1·814; at 17°, R. Böttger, 2·0332; at 18°, J. Böeseken, 1·831; at 20°, G. Pisati and G. de Franchis, 1·82321; at 24·2°/4°, B. C. Damien gave 1·828; at 35°, J. H. Gladstone and T. P. Dale gave 1·823; at 44°, G. Pisati and G. de Franchis gave 1·8068; and at 44·2°/4°, B. C. Damien gave 1·814. J. Böeseken gave for phosphorus purified by distillation in vacuo, 1·831 at 18°. For liquid phosphorus, J. H. Gladstone and T. P. Dale gave 1·763 at 35°; H. Kopp, 1·743 at 44°; G. Quincke, 1·833 at 43°; G. Vincentini and D. Omodei, 1·74529 at 44·4°; B. C. Damien, 1·7555 at 44·2/4°; G. Pisati and G. de Franchis, 1·74924 at 40°; 1·69490 at 100°; 1·60270 at 200°; and 1·52867 at 280°; and W. Ramsay and O. Masson, 1·4850 at the b.p. Observations were also made by A. Schrötter, and F. C. O. von Feilitzsch. G. A. Erman found the sp. gr. of yellow phosphorus just before melting to be 1·8121, and just after, 1·7560. According to P. W. Bridgman, the sp. gr. of β-yellow phosphorus corresponds with a contraction of 2 per cent. during its formation from ordinary or α-yellow phosphorus with a sp. gr. of 1·83–1·85.

For the sp. gr. of red phosphorus, A. Schrötter gave 1·964 at 10°, and 2·089–2·106 at 17°; J. Böeseken, 2·31–2·34; A. Wigand, 2·296; B. C. Brodie, 2·14–2·23; G. Linck and P. Möller, 2·18–2·29 at 16°–19°; A. Colson, 2·094; A. Stock and co-workers, 2·14 at 17°, and 2·17 at 22°, when for scarlet phosphorus under similar conditions the sp. gr. was 2·02–2·05, and for violet or metallic phosphorus, 2·35–2·37 at 22°. E. Cohen and J. Olie gave 2·18–2·23 for red phosphorus at 18°/4°, and 2·23–2·24 at 18°/4° for violet phosphorus. P. Jolibois found the sp. gr. of slowly cooled red phosphorus to be 2·27. L. Troost and P. Hautefeuille showed that the sp. gr. of red phosphorus is dependent on the temp. at which it has been prepared. Thus, for that prepared at 265° he obtained 2·148 at 0°; at 360°, 2·19 at 0°; at 500°, 2·293 at 0°; and at 580°, 2·34 at 0°. W. Hittorf, and G. Linck gave 2·34 at 15·5° for the sp. gr. of violet or metallic phosphorus; A. Smits and co-workers, 2·21–2·34; and A. Stock and F. Gomolka, 2·39 for crystals with 3·5 per cent. of lead; 2·36 for crystals with 1·5 per cent. of lead; and 2·36–2·37 for crystals prepared with bismuth in place of lead. P. W. Bridgman gave 2·699 for the sp. gr. of black phosphorus. This constant is thus 15 per cent. higher than that of any of the other allotropic forms of phosphorus. The best representative values of the sp. gr. of the four allotropic forms of phosphorus are:

	β-yellow.	α-yellow.	Violet.	Black.
Sp. gr. . .	1·88	1·84	2·34	2·699

H. Buff gave 25 for the calculated **atomic volume** of tervalent phosphorus, and

22 for quinquevalent phosphorus; and T. E. Thorpe gave 25·3. E. Petersen gave 17·0 for the at. vol. of yellow phosphorus, and 14·7 for red phosphorus. T. E. Thorpe, H. Buff, and J. I. Pierre calculated the at. vol. of phosphorus in combination as PCl_3, PBr_3, $POCl_3$, $PSCl_3$, $POBrCl_2$, and $PCl_2.C_2H_5OH$ to range from 24·0 to 26·1; that of free phosphorus, by G. Pisati and G. de Franchis, is 20·2. I. I. Saslowsky gave 2·34 for the sp. gr. at room temp., and 13·3 for the at. vol. W. Ramsay and O. Masson gave 20·91 for the at. vol. of the free element, and 25·3 for the combined element. H. Buff suggested that the sp. vol. of phosphorus in combination varies with the valency. Accepting H. Kopp's value of 7·8 for singly linked oxygen atoms, and 12·2 for the doubly linked atoms, T. E. Thorpe and A. E. H. Tutton calculated that at. vol. of phosphorus in phosphorous oxide to be 20·9—about the same value as that of free phosphorus. S. Sugden studied this subject. E. B. R. Prideaux gave 20·04 for the at. vol. of the liquid at 290°, and he calculated 15·1 for the at. vol. of quinquevalent phosphorus, and 25·06 for the tervalent element. He calculated the at. vol. of phosphorus in some different combinations to be:

	PCl_3	PBr_3	PCl_5	PBr_5	$POCl_3$	$POCl_2Br$
At. vol. . .	25·1	28·4	15·1	23·3	18·9	21·0

W. A. Kowalewsky gave 18·09–23·31 for the at. vol. of phosphorus in the alkyl phosphates. T. W. Richards found the at. vol. under 493·5 atm. press. is 14·4. For the observed **specific volume** of the solid, A. Hess gave 0·55399, and 0·57305 for the liquid—this corresponds with an expansion of 3·44 per cent. W. Ramsay and O. Masson found the sp. vol. at the b.p. to be 0·6734. E. Donath and J. Mayrhofer made some observations on this subject. G. Tammann gave for the change of volume, δv c.c., on melting at 50·03°, 69·98°, 90·21°, and 100·18°, and respectively 220, 959, 1720, and 2155 atm. press., the respective values of δv $=0·01862$, 0·01756, 0·01579, and 0·01478 c.c.; or $\delta v=0·01908-0·000077(\theta-43·9)$. A. Hess gave 0·0190 c.c. per gram; H. Kopp, 0·01894 c.c.; B. C. Damien, 0·0179; G. Pisati and G. de Franchis, 0·01939; and A. Leduc, 0·0191. P. W. Bridgman's values of δv are indicated below. G. le Bas showed the approximate convergence of the temp.-vol. curves of the liquid and solid states towards absolute zero. A. Smits and S. C. Bokhorst calculated the value of the constant b of **J. D. van der Waals' equation.** This when taken to represent the size of the molecule becomes 0·00539, at the critical temp.; the corresponding value calculated for the phosphorus atom in phosphine is 0·00124; so that there are $0·00539/0·00124=4·33$ atoms in the molecule. This is taken to indicate a slight association of the P_4-mols. J. J. van Laar calculated for b of J. D. van der Waals' equation, $b=0·00140$; for a, $\sqrt{a}=0·066$; and for the valency attraction A, $\sqrt{A}=33$. M. Trautz calculated 20×10^{-8} cm. for the **molecular diameter** of phosphorus. B. Cabrera calculated 1·11 A. to 1·37 A. for the at. radius of P'''. W. P. Davey, and C. del Fresno studied the at. vol. of phosphorus; and S. Mokruschin, the mol. diameter at the b.p.

A. W. Williamson[3] gave 2·805 grms. for the weight of a litre of phosphorus vapour calculated for normal conditions. J. B. A. Dumas obtained 4·42 for the **vapour density** of phosphorus vapour when the value calculated for P_4 is 4·3; E. Mitscherlich gave 4·58; and H. St. C. Deville and L. Troost found 4·35 at 500°, and 4·50 at 1040°; while J. Mensching and V. Meyer gave 4·16 for the vapour density at a red-heat; and 3·03 at a white-heat, while H. Biltz and V. Meyer obtained 3·632 at 1484°; 3·226 at 1677°; and 3·147 at 1708°. The vap. density, said V. Meyer, is considerably less than corresponds with the P_4-mol at elevated temp., and at a white-heat approximates to the value required for P_2. G. Preuner and J. Brockmöller made observations on this subject; they found the total press., P, at temp. between 500° and 1200°, at constant vol., with the amounts of red phosphorus calculated in grams per c.c., shown in Fig. 6. The corresponding partial press. for p_4 of P_4; p_2 of P_2; and p of P are indicated in Table II.

TABLE II.—PARTIAL PRESSURES DUE TO P_4-, P_2-, AND P-MOLECULES.

Total press. P mm.	800°			1000°			1200°

750	692·0	50·0	8·0	576·0	142·0	35·0	361·0	283·0	106·0

The average number of atoms, i, per molecule is as follows :

800°	P . .	37	84	158	349	470	482 mm.
	i . .	2·90	3·51	3·72	3·75	3·84	3·87
1000°	P . .	58	123	225	290	458	64·4 mm.
	i . .	2·20	2·77	3·07	3·18	3·27	3·42
1200°	P . .	88	187	346	440	617	890 mm.
	i . .	1·65	2·05	2·29	2·35	2·73	2·83

The calculated thermal values of the dissociation $P_4=2P_2$ are 30,200 cals. at 800° ; 30,000 cals. at 900° ; 28,500 cals. at 1000° ; and 28,000 cals. at 1100° ; and for the $P_2=2P$ transformation, 23,200 cals. between 800° and 1200°. The effect of temp. on the equilibrium constant K_4 for $P_4=2P_2$ is $\log (K_4/760)=-(29000+2T)/4{\cdot}75T+1{\cdot}75 \log T-1{\cdot}4$; and K_2 for $P_2=2P$ is $\log (K_2/760=-(23000+2T)/4{\cdot}75T+1{\cdot}75 \log T-3{\cdot}0$, where the chemical constant for the P_4-mol is —1·4, and for the P_2-mol, —3·0. The dissociation constants are :

	800°	900°	1000°	1100°	1200°
K_4	350	13·7	40·0	98·0	211
K_2	7·4	3·8	9·0	18·9	36·0

According to A. Stock and co-workers, the vap. density between 500° and 700° corresponds exactly with P_4-mols ; at higher temp. dissociation occurs, but at 1200° and 175 mm. press., only 61 per cent. is dissociated. Calculations agree with $P_4=2P_2$. Under atm. press., the dissociation is 0·01 at 800°, 0·1 at 1000°, and 0·33 at 1200° ; and under a press. of 0·25 atm., there is almost 66 per cent. dissociation at 1200°. S. Dushman studied the reactions : $P_2 \rightleftharpoons 2P$; and $P_4 \rightleftharpoons 2P_2$. R. Wegscheider and F. Kaufler argued that yellow and red phosphorus are not merely polymorphous, but that they are chemically different, because, if polymorphous, the liquid forms should be identical, and if violet phosphorus is the stable form, molten yellow phosphorus, or a sat. soln. of yellow phosphorus in carbon disulphide,

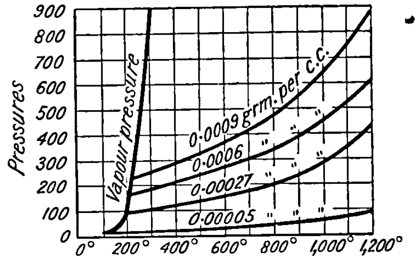

FIG. 6.—Dissociation Pressures of Phosphorus Vapour at Different Temperatures.

when sown with red phosphorus, should furnish red phosphorus, whereas no perceptible change occurs. According to D. L. Chapman, the vapours of ordinary and of red phosphorus are identical; and W. Ostwald suggested that phosphorus vapour is neither that of ordinary nor of violet phosphorus. K. Schaum said that this hypothesis applies only to phosphorus vapour at a high temp. At lower temp., in consequence of different rates of transformation, the vapours appear to be different. Again, when energy—actinic, thermal, or electrical—is added to the system, the vapour from ordinary phosphorus furnishes red phosphorus in agreement with the assumption that polymerization occurs during the formation of violet phosphorus. This, however, neither proves nor disproves the assumption that the vapours of violet and yellow phosphorus are different. W. R. Fielding discussed the polymerization of phosphorus.

G. Lemoine's work, previously cited, is in agreement with the assumption that in the vaporous state a balanced reaction is involved: $P_{yellow}=P_{violet}$. Contrary to the statement of H. Arctowsky, A. Stock and E. Stamm maintained that red phosphorus is not appreciably volatile at 100°, or even at 200°; and that the vapour of red phosphorus condenses partly as red phosphorus when heated at 280°–400°; and that the so-called metallic phosphorus of W. Hittorf, at 300°–350°, gives a vapour which condenses as yellow phosphorus even if it has been subjected to an intermediate heating at 500°. Colourless phosphorus also gives a colourless distillate. Hence, the vapour of red phosphorus must contain mols. peculiar to red phosphorus; in agreement with the observation of A. Stock and co-workers, that red phosphorus can be sublimed in the crystalline form. They also found in agreement with W. Hittorf that when phosphorus vapour is rapidly cooled, a portion is condensed as red phosphorus, and the proportion of red phosphorus deposited is greater the higher the temp. of the vapour before the chilling occurs. The duration of the heating has no appreciable effect, but the cooling of the vapour must be effected rapidly. The surface of the containing vessel has a catalytic influence on the quantity of red phosphorus formed by chilling the vapour, but comparative experiments by A. Stock and E. Stamm showed that the quantity of red phosphorus formed diminishes as the press. decreases; A. Stock and co-workers added that these facts are in agreement with the assumptions that (i) the two forms of phosphorus are chemically different; (ii) that red phosphorus is formed by the union of the dissociated mols of phosphorus either among themselves, or with the undissociated mols; and (iii) that the formation of the P_4-mols of yellow phosphorus, $P_4=2P_2$, is relatively slower than the formation of the mols of red phosphorus. The condensation of red phosphorus from the vaporous state is independent of the presence of liquid yellow phosphorus. A. Stock and E. Stamm found that more red phosphorus is produced by chilling the vapour than corresponds with the dissociation into P_2-mols. The red phosphorus produced by chilling the vapour at 1200°, and 5 mm. press., does not contain more than one per cent. of yellow phosphorus. Hence, it is inferred (iv) that both P_2- and P_4-mols take part in the formation of red phosphorus, possibly in accord with the equation: $mP_2+nP_4=P_{2m+4n}$, which is a relatively faster reaction than $2P_2=P_4$. These results are in agreement with the observations of W. Marckwald and K. Helmholtz, who explain the phenomena observed by cooling liquid red phosphorus by assuming that the liquid contains both P_4-mols of yellow and P_n-mols of red phosphorus in equilibrium: $aP_4\rightleftharpoons bP_n$. Above the m.p. of red phosphorus, 592·5°, most of the mols are P_4, so that on rapid cooling the yellow variety is formed, but slow cooling allows a change of equilibrium in favour of the system on the right, and red phosphorus is deposited on solidification.

From observations on the effect of dissolved phosphorus on the vap. press. of carbon disulphide at 0°, G. Guglielmo concluded that the element is present in the form of P_4-mols; E. Beckmann, and A. Helff came to the same conclusion from ebulliscopic observations with the same solvent; and E. Paterno and R. Nasini, with benzene. J. Hertz obtained values in agreement with the presence of P_4-mols from observations on the effect of phosphorus on the f.p. of benzene. C. A. Seyler considered that the P_4-mol agrees best with the observed latent heat of fusion; E. Aston and W. Ramsay with the observed surface-tension of the molten liquid; and A. Smits and S. C. Bokhorst, with the critical constants. G. le Bas said that the mol. vol. of phosphorus does not agree with a 4-membered ring:

$$\begin{array}{c} P=P \\ P=P \end{array}$$

but is an agreement with a tetrahedron having a phosphorus atom at each corner—*i.e.* four 3-membered rings.

According to J. R. Rydberg,[4] the **hardness** of phosphorus is 0·5, when that of potassium is also 0·5; lead, 1·5: and copper, 3. C. A. Edwards gave 0·63 for the Brinell's hardness. J. Davy said that yellow phosphorus is brittle when cold, but of waxy consistency at ordinary temp. He added that it again becomes brittle at 34·33°, and it is then easy to pulverize. N. Slatowratsky and G. Tammann measured the **plasticity** of yellow phosphorus at various temp. up to the m.p., and found that a load of 55 kgrms. per sq. cm., sank into the material 2·5 units at 20°; 5·8 at 30°; 8·7 at 35°; 22·2 at 40°; and 79·0 at 43°—rather smaller values were obtained with a falling temp. G. Quincke, and R. Schiff measured the **capillary constants** of phosphorus. E. Aston and W. Ramsay found that molten phosphorus does not readily wet glass; they gave 43·09 dynes per cm. for the **surface tension** at 78·3° and 35·56 dynes per cm. at 132·1°; with the respective sp. gr. 1·714 and 1·664. These data give for the **molecular surface energy,** 748·2 and 629·6. T. W. Richards and co-workers [5] found the **compressibility** of yellow phosphorus to be $(\delta v/\delta p)/v=0{\cdot}0000199$ kgrm. per sq. cm., between 100 and 500 atm. 0·0000203 megabar, or 0·0000206 atm. at 20°; while the mean compressibility of red phosphorus between 100 and 500 atm. is 0·0000092 kgrm. per sq. cm., 0·0000290 megabar, or 0·0000091 atm. at 20°. The sparking which occurs when phosphorus is struck by a hammer is attributed by O. Ohmann to the evaporation of the element, and oxidation of the vapour.

According to H. Kopp,[6] the coeff. of **thermal expansion** of ordinary phosphorus from 0° up to its m.p. is quite regular, and its vol. at 44° is 1·017 times its vol. at 0°; when the solid melts, there is an abrupt expansion of 3·4 per cent., so that the vol. changes from 1·017 to 1·052. The vol. of the solid at $\theta°$ is $v=1{\cdot}05173+0{\cdot}000383\theta$; of the liquid, $v=1{\cdot}05173+0{\cdot}000532\theta$, or $v=1+0{\cdot}000506\theta$. G. Pisati and G. de Franchis gave for the solid at $\theta°$, when the vol. at 0° is v_0, $v=v_0(1+0{\cdot}0_3200\theta+0{\cdot}0_6115\theta^2)$; for the vol. of the liquid between 50° and 60°, $v=v_{50}\{1+0{\cdot}0_32969(\theta-50)+0{\cdot}0_62115(\theta-50)^2\}$. E. B. R. Prideaux gave $v=v_0(1+0{\cdot}000505\theta+0{\cdot}0_6118\theta^2)$ between 50° and 235°. Solid phosphorus has the mean coeff. of cubical expansion $0{\cdot}0_33674$; and the liquid, between 50° and 60°, $0{\cdot}0_3520$. A. Leduc gave for the coeff. of cubical expansion of the solid between 0° and the m.p., 0·000372; and for the liquid between 26° and 50°, 0·000560. G. Vincentini and M. Omodei gave 0·000520 for the solid, and 0·0005670 for the liquid; while A. Hess gave the respective numbers 0·000426 and 0·000595. The percentage expansion in passing from the solid to the liquid state was found by G. Vincentini and D. Omodei to be 3·5; G. Pisati and G. de Franchis gave 1·03446 for the vol. ratio of liquid and solid at 40°, and 1·0504 at 44°; and A. Leduc, 1·0345 at the m.p., 44·1°. H. F. Weibe studied the relation between the thermal expansion and the at. wt., b.p., m.p., and sp. ht.

H. Kopp [7] gave 0·202 for the **specific heat** of solid yellow phosphorus between 13° and 36°; C. C. Person, 0·212; and H. V. Regnault, 0·1895 between 7° and 13°; 0·1788 between −21° and 70°; and 0·1740 between −78° and 10°; and T. W. Richards and F. G. Jackson, 0·169 between −188° and 20°. For liquid phosphorus, C. C. Person gave 0·2045; P. Desains, 0·2; and A. Wigand, 0·202 between 13° and 36°. P. Nordmeyer gave 0·178 for the sp. ht. of yellow phosphorus between the temp. of liquid air and room temp. G. Schmidt gave 5·08 for the **atomic**

heat of solid yellow phosphorus, and 6·086 for gaseous phosphorus. D. H. Drummond gave for solid phosphorus $C_p=5{\cdot}30+0{\cdot}000341T$; and for liquid phosphorus $C_p=6{\cdot}10+0{\cdot}000341T$. W. A. Kurbatoff said that the at. ht. of phosphorus is lower than that of the metals, and the mols in the crystalline state are more complex than those of the metals. G. de Lucchi gave 1·175 for the mean ratio of the two sp. hts. of phosphorus vapour at 300°. The extreme values were 1·15 and 1·22. For solid red phosphorus, H. V. Regnault gave 0·16981–0·1705 between 15° and 98°; and A. Wigand, 0·1829 between 0° and 51°; 0·2121 between 0° and 134°; and 0·2162 between 0° and 199°. J. C. G. de Marignac found the sp. ht. of soln. of phosphorus in carbon disulphide $P+nCS_2$ to be 0·219 for $n=0{\cdot}25$; 0·222 for $n=0{\cdot}5$; 0·225 for $n=1$; 0·229 for $n=2$; and 0·2295 for $n=4$.

The **melting point** of ordinary phosphorus given by J. Davy[8] is 44·5°; P. Heinrich gave 46·25°; G. Quincke, 43°; H. M. Vernon, 45·3°; A. Smits and H. L. de Leeuw, and H. Kopp, 44°; A. Stock and E. Stamm, and A. Leduc, 44·1°; P. Desains, G. A. Hulett, C. C. Person, and A. Helff gave 44·2°; S. Lussana, 44·27°; A. Schrötter, 44·3°; and G. Pisati and G. de Franchis, G. Vicentini and D. Omodei, and A. Hess, 44·4°–44·5°. J. Böeseken obtained 44·77°, and claimed that the lower values have been obtained with imperfectly dried samples. Phosphorus which has been kept many days in vacuo still retains some adsorbed water. F. Scriba described an experiment in which a layer of water was cautiously poured over some conc. sulphuric acid, and a piece of ordinary phosphorus dropped on the water. The phosphorus sinks in the water and floats on the acid, where it is melted by the heat of the reaction between the water and the acid. G. A. Hulett, and G. Tammann measured the effect of press. on the m.p. G. Tammann gave for the m.p., θ°, at a press. of p kgrms. per sq. cm., $\theta=43{\cdot}93+0{\cdot}0275p-0{\cdot}0_650p_2$, or

p . . .	1	232	578	956	1431	1872
Melting point .	43·90°	50·01°	59·85°	70·18°	81·79°	92·01°

A. Stock found that the m.p. of phosphorus depends on the rate of heating; and in contradistinction to A. Smits and H. L. de Leeuw, A. Stock and E. Stamm did not find the m.p. of yellow phosphorus to be altered by heating it to 100° followed by rapid cooling. Molten phosphorus is easily obtained as an under-cooled liquid, even at temp. 40° below its m.p. A. Bellani, and H. Rose noted that contact with solid phosphorus causes an immediate solidification of the under-cooled liquid. The phenomenon is particularly marked with phosphorus which has been boiled under an aq. or alcoholic soln. of potassium hydroxide. Observations on this subject were made by T. de Grotthus, J. B. Kallhofert, A. Schrötter, F. P. Venable and A. W. Belden, P. Heinrich, J. W. Retgers, and D. Gernez. The last-named also measured the velocity of crystallization of the under-cooled liquid—*vide supra.*

When red phosphorus is warmed, said A. Schrötter, it becomes dark violet, but it does not melt, although W. Hittorf observed that the particles sinter together when it is heated in an evacuated sealed glass tube. H. Arctowsky said that when kept for 48 hrs. under a press. of 14–16 mm., red phosphorus forms microscopic crystals. Red phosphorus passes into ordinary phosphorus when heated. W. Hittorf said that the change does not occur at 324°, but the yellow phosphorus appears at 358°. A. Pedler observed no reaction when red phosphorus is heated in mercury vapour, but at a high temp., an inflammable vapour is given off without any signs of the residue changing. D. L. Chapman melted red phosphorus at 630° in a sealed tube and ordinary phosphorus was produced. A. Stock and co-workers found that in a sealed tube red phosphorus begins to sinter between 600° and 605°, and at 610° melts to a yellow liquid, while W. Hittorf's phosphorus melts at 620°. P. Jolibois gave 725° for the m.p. of red phosphorus in a sealed tube, and said that red phosphorus is stable between 450° and 610°. W. Marckwald and K. Helmholtz gave 592·5°±0·5° for the m.p. of red phosphorus, and A. Stock said that the m.p. depends on the rate of heating. W. A. Wahl observed that red phosphorus becomes black at 500°, and when confined in a capillary tube, it forms a yellow mobile liquid at 600°; on cooling, the colour deepens to a reddish-brown until solidification occurs. M. Volmer and I. Estermann observed that the fraction a of vaporized phosphorus which is condensed on a cold surface, while $1-a$ is reflected, varies between 0·2 and 0·5.

A. Smits and S. C. Bokhorst gave 589·5° at 43·1 atm. for the **triple point** of violet phosphorus. D. L. Chapman, and P. Jolibois estimated the triple point to be *c.* 600°. W. Marckwald and K. Helmholtz found the **transition point** of red to black phosphorus to be 575°. P. W. Bridgman found that the transition point of cubic or α-yellow phosphorus to hexagonal or β-yellow phosphorus to be:

p	1	6000	8000	10,000	12,000 kgrms. per sq. mm.
Transition point .	−76·9°	−2·4°	21·4°	43·7°	64·4°

R. Lorenz and W. Herz studied some relations of the transition temp. A. Smits and S. C. Bokhorst gave 690·9° for the **sublimation point** of violet phosphorus. C. Zengelis observed signs of the volatilization of red phosphorus at ordinary temp. According to B. Pelletier, the **boiling point** is 290°; J. Dalton gave 288°; E. Mitscherlich, 260°; P. Heinrich, 250°; G. Preuner and I. Brockmöller, 290° at 770 mm.; and G. Pisati and G. de Franchis, 278·3° at 762 mm. A. Smits and S. C. Bokhorst gave 265·5° at 562 mm.; 280·5° at 760 mm.; and 298·46° at 1048 mm.; while P. Jolibois gave 262° at 536 mm.; 281° at 786 mm.; and 295° at 1010 mm. According to A. Schrötter, the b.p. at different press., *p* mm., are:

p	120	173	204	266	339	393	514	760
Boiling point .	165°	170°	180°	200°	209°	226°	230°	287·3°

N. Blondlot found that ordinary phosphorus slowly sublimes at 40°; according to B. Pelletier, the vapour is colourless. The vapour of phosphorus is given off when phosphorus is boiled under water, and the luminosity produced in the condenser furnished E. Mitscherlich with a means of detecting phosphorus. The element also vaporizes slowly at ordinary temp. J. Joubert found the **vapour pressure** of solid yellow phosphorus at 5° to be 0·03 mm., and at 40°, 0·50 mm. M. Centnerszwer gave 0·0253 mm. for the vap. press of solid at 20°; 0·0724 mm. at 30°; 0·0893 mm. at 35°; and 0·1221 mm. at 40°. D. MacRae and C. C. van Voorhis represent these results by $\log_{10} p = 9·6511 - 3297·1T^{-1}$ mm. These investigators found the vap. press., *p* mm., of liquid yellow phosphorus from 44° to 150°; G. Preunier and I. Brockmöller, from 200° to 290°; and A. Smits and S. C. Bokhorst, from 210° to 581°:

	44·1°	69·92°	100·11°	150°	250°	280·5°	331·8°	504°	581°
p . . .	0·173	0·823	3·66	27·20	426	760	1877·2	17532	31236

D. MacCrae and C. C. van Voorhis represented their measurements between 44·1° and 150° by $\log_{10} p = 7·9542 - 2757·5T^{-1}$ mm. L. Troost and P. Hautefeuille measured the vap. press. of liquid yellow phosphorus between 360° and 510°, and found that above 510°, the liquid was transformed so rapidly into red phosphorus that its vap. press. could not be measured. They also measured the vap. press. of red phosphorus between 360° and 577°. E. Riecke represented their values for solid red phosphorus by $\log_{10} p = -45·01 + 16·28 \log_{10} T - 832T^{-1}$ atm.; and for liquid phosphorus, $\log_{10} p = -2·450 + 2·064 \log_{10} T - 1530\ T^{-1}$ atm. P. Jolibois also measured the vap. press. of red and yellow phosphorus. A. Smits and S. C. Bokhorst gave for solid and liquid violet phosphorus from 308·5° to the critical temp., 695°:

	308·5°	379·5°	486·5°	589·5°	593°	634°	695°
p . . .	0·07	0·35	5·46	43·1	44·2	58·6	82·2 atm.
		Solid.		M.p.	Liquid.		

They represented their results by $\log_{10} p = 19·2189 - 3585·96T^{-1} - 3·59 \log_{10} T$ mm.; and on the assumption, rendered probable by the work of L. Troost and P. Hautefeuille, and A. Smits and co-workers, that under-cooled liquid violet phosphorus and liquid yellow phosphorus are identical, D. MacRae and C. C. van Voorhis represented the vap. press. of liquid violet and yellow phosphorus from 145° to 634° by $\log_{10} p=11\cdot5694-2898\cdot1T^{-1}-1\cdot2566 \log_{10} T$ mm. In the vap. press. formula $-\log(p/p_c)=f(T_c/T^{-1})$, A. Smits and S. C. Bokhorst found that $f=3\cdot11$, between 200°–300°; 2·84, between 300°–400°; 2·60, between 400°–500°; and 2·40, between 500°–600°. A. Smits and co-workers found the vap. press. of black phosphorus to be rather less than that of violet phosphorus below *c.* 560°; about the same at 560°; and above that temp., the vap. press. is rather higher than that of violet phosphorus. Thus:

		515°	553°	567°	568°
Vap. press.	Black . .	8·5+	19·3+	28·6	39·5 atm.
	Violet . .	10·5	21·5	28·5	35·0 ,,

It is assumed that violet phosphorus is the stable form; but the metastable state of the element should have a higher vap. press. than the stable state, hence, it is further assumed that the mols. of the black and violet forms of phosphorus are not built up of the same kind of molecules. M. Centnerszwer found the partial press. of phosphorus vapour at 20° in an atm. of hydrogen is 0·0253 mm.; oxygen, 0·0251 mm.; carbon dioxide, 0·0312 mm.; coal-gas, 0·0242 mm.; air and iodobenzene, 0·0253 mm. W. Herz found that the constant c in the equation $\theta_1/\theta_2 = T_1/T_2+c(T_2-T_1)$ varies from 0·001374 to 0·001990. θ_1 and θ_2 denote the b.p. of two liquids at any press., and T_1 and T_2, the b.p. of the same liquids at another press.

W. Marckwald and K. Helmholtz found the **critical temperature** of yellow phosphorus to be 720·6°; J. J. van Laar gave 675° for the critical temp., and 80 atm. for the **critical pressure.** W. A. Wahl gave 695° for the critical temp. of violet phosphorus; and A. Smits and S. C. Bokhorst gave 82·2 atm. for the critical press. C. C. Person[9] found the **heat of fusion** of yellow phosphorus to be 4·71 to 5·2 cals. per gram at 44·2°; P. Desains gave 5·06 to 5·4 cals. per gram; and O. Pettersson, 4·74 cals. per gram, or, 0·15 cal. per gram-atom, at 29·73°; and 4·97 cals. per gram, or 0·15 cal. per gram-atom at 40·05°. G. Tammann gave for the heat of fusion, L Cals. per gram, at the following temp. and press. in kgrms. per sq. cm., 50·03° and 220, $L=4\cdot94$; at 69·98° and 959, $L=5\cdot28$ Cals.; at 90·21° and 1720, $L=5\cdot26$ Cals.; and at 100·18°, and 2155, $L=5\cdot19$ Cals. P. W. Bridgman found for the latent heat of fusion of phosphorus, L kilogrammetres per gram; the change of energy, δE; the change in vol., δv c.c. per gram; and the temp. θ, at a press. p kgrms. per sq. cm.:

	Yellow phosphorus.				Black phosphorus.			
p .	1	2000	4000	6000	6000	8000	10,000	12,000
θ .	44·2°	99·3°	148·2°	191·9°	−2·4°	21·4°	43·7°	64·4°
δv .	0·01927	0·91667	0·01436	0·01218	0·00851	0·00799	0·00746	0·00694
L .	2·09	2·41	2·63	2·78	18·61	20·24	21·82	23·29
δE .	2·09	2·07	2·06	2·4	18·10	19·61	21·06	22·44

A. Smits and co-workers calculated 10·2 Cals. for the molar heat of fusion of violet phosphorus. C. A. Seyler employed the heat of fusion and the sp. gr. of solid and liquid at the m.p. to calculate the number of atoms in the mol. R. de Forcrand, for the **heat of vaporization** of yellow phosphorus, gave 130·4 cals. per gram, or 4 Cals. per gram-atom, at 287°; and H. Giran obtained 3·89 Cal. per gram-atom for yellow phosphorus, and 7·60 Cals. per gram-atom for red phosphorus. A. Smits and co-workers calculated 12·5 Cals. for the heat of vaporization of liquid phosphorus at its b.p., 280°. A. Henglein gave 1·956 Cals. for the mol. heat of evaporation of phosphorus. The subject was studied by K. Bennewitz. This gives the normal value 22 for **Trouton's constant;** but the **heat of sublimation** of violet phosphorus is 25·8 Cals., and this gives the abnormally high value 37·5 for Trouton's constant. R. de Forcrand calculated values for the heats of fusion and vaporization of phosphorus. G. N. Lewis and co-workers calculate the **entropy** of gaseous phosphorus at 25° and 760 mm. press. to be 35·95 units per gram. D. H. Drummond gave $-70-0\cdot8T\log T+4\cdot87T$ cals. for the free energy of fusion, *i.e.* 13·1 cals. at 25°; and $58\cdot871+15\cdot4T\log T+0\cdot00033T^2-0\cdot0_68T^3-203\cdot7T$ for the free energy of vaporization, *i.e.* 6063 cals. per gram-atom at 25°. The entropy change on fusion is 0·506 cal., and on vaporization 25·5 cals. Hence, from G. N. Lewis and co-workers' value for phosphorus gas, the entropy of phosphorus at 25° is 9·95 units. E. Kordes discussed the changes of entropy on melting phosphorus. For the **heat of dissociation** $P_4=2P_2$, A. Stock and co-workers gave 49·2 to —50·3 Cals. H. Giran gave 4·4 cals. for the **heat of transformation** of white to violet phosphorus.

E. Petersen estimated the difference in the **heat of oxidation** of yellow and of red phosphorus to be less than 100 cals. T. Andrews gave 5747 cals. for the **heat of combustion** of a gram of ordinary phosphorus with oxygen; 4509 cals. per gram of oxygen; or 6479 cals. per litre of oxygen. P. A. Favre and J. T. Silbermann gave 209,476 cals. for the heat of oxidation of yellow phosphorus and 181,230 cals. for red phosphorus. H. Giran gave (2P,5O)=369·4 Cals. for yellow phosphorus, and 365·7 Cals. for the red form. J. J. B. Abria gave 351·48 Cals., and T. Andrews, 356·31 Cals. for yellow phosphorus. L. Troost and P. Hautefeuille found that commercial red phosphorus has a heat of combustion 362·82 Cals. and for samples of red phosphorus prepared at 265°, 360°, and 580° the heats of combustion have the respective values of 367·34, 345·34, and 362·86 Cals. The heat of combustion of ordinary yellow phosphorus is 369·90 Cals. J. C. Thomlinson has made some speculations on the relations between these values and the valency of the phosphorus atom; but the data on which the arguments are based apply to heterogeneous mixtures and not to a definite chemical individual.

The **index of refraction** of solid yellow phosphorus in air at 29·2° was found by B. C. Damien[10] to be 1·8244 for the *D*-line, 2·09300 for the H_α-line, and 2·19885 for the H_γ-line; and at 37·5°, 1·8191 for the *D*-line, 2·08873 for the H_α-line, and 2·19462 for the H_γ-line. He also found for liquid yellow phosphorus in air at 44°, 2·15274 for the *D*-line, 2·11311 for the *F*-line, and 2·05010 for the *C*-line; and at 55·3°, 2·14012 for the *D*-line, 2·09943 for the *F*-line, and 2·03754 for the *C*-line. He also found for the temp. coeff. $d\mu/d\theta$, —0·000051 per degree. J. W. Retgers gave 2·14 for the index of refraction of solid yellow phosphorus. E. Schmidt made some observations on this subject. F. P. le Roux gave 1·001364 for the index of refraction of phosphorus vapour; and C. Cuthbertson and E. P. Metcalfe, 1·001197 for light of wave-length $\lambda=589\cdot3\mu\mu$. They represented their results by $\mu-1=0\cdot001162(1+1\cdot53\times10^{-10}\lambda^{-2})$; and C. and M. Cuthbertson by $76\times10^{27}/(6534\times10^{27}-n^2)$. J. W. Retgers said that the crystals of red phosphorus have a high index of refraction. V. Berghoff found for *D*-light, at 20°, the refraction constants of soln. with 4·762, 13·043, and 20 per cent., *p*, of phosphorus in carbon disulphide, the respective values 0·002761, 0·002929, and 0·002975 for $(\mu-\mu_0)/p$; and H. G. Madan, for a sat. soln. of phosphorus in methylene iodide at 18°, 2·021, 1·984, 1·944, and 1·929 respectively for *G*-, *F*-, *D*-, and *C*-light. A. Haagen gave 0·4816 for the **specific refractory power,** and J. H. Gladstone, 0·590; A. Schrauf gave for the **refraction equivalent,** 0·019406 for phosphorus vapour in red-light —when the value for hydrogen is 0·00405—and 0·075547 for liquid phosphorus; and with the μ-formula, 0·000626 for the vapour, and 0·002437 for the solid. J. H. Gladstone gave 18·3 for the refraction equivalent—when the value for hydrogen is unity—and he also gave 3·0 for the **dispersion equivalent.** F. Zecchini showed that the **atomic refraction** of phosphorus changes with the nature and number of other elements with which it is combined. For temp. ranging from 18·6° to 29·3°, he found for the at. refraction of phosphorus in

	$P(C_2H_5)_3$	$P(C_2H_5)_4I$	PCl_5	$POCl_3$	PBr_3	P_2I_4	$P(C_6H_5)_3$
μ-formula . .	17·24	18·24	16·65	8·92	20·01	24·12	24·34
μ^2-formula . .	9·47	10·29	8·81	4·92	9·72	9·92	11·18

The at. refraction is least in the chlorides of phosphorus and greatest in the iodide, the value deduced from the bromide being intermediate. Hydrogen phosphide gives a much lower value for the at. refraction of phosphorus than do the halogen compounds of the same type. Compounds of phosphorus with the same elements give practically the same values for the at. refraction; this is especially well shown with the tri- and penta-chlorides. The very low refraction eq. of phosphorus oxychloride is remarkable; it gives the at. refraction of phosphorus as less than half that which the element has in the free state or when combined with chlorine alone. The μ-formula gave more consistent results than the μ^2-formula; and the values were greater with the D-ray than with the H_α-ray. W. A. Kowalewsky found 7·71 for the at. refraction of phosphorus in the chloroanhydrides of alkyl phosphates. C. P. Smyth studied this subject; and J. E. Calthrop, the relation between the at. vol. and the index of refraction.

J. Kerr found phosphorus to have a positive double refraction in the electric field. K. Schultz-Sellack showed that an 8-mm. layer of a soln. of 10 parts of phosphorus in one of carbon disulphide absorbs 52 per cent. of the rays emitted from a lampblack surface at 100°; and 57 per cent. of the heat rays from a coal-gas flame.

R. T. Simmler[11] showed that the **flame spectrum** of burning phosphorus is continuous. Burning phosphine gives no line spectrum; and phosphoric acid colours the non-luminous gas-flame blue. J. Plücker observed that the ordinary electric discharge tube filled with hydrogen and phosphorus vapour shows only the spectrum of hydrogen, but with the vapour of phosphorus trichloride he observed lines due both to chlorine and to phosphorus. When phosphorus is introduced into a flame, the inner cone is coloured green; and if hydrogen be passed over phosphorus, or, according to L. Dusart, if phosphorus, hypophosphorous, or phosphorus acids or their salts be introduced into an apparatus generating hydrogen, the gas subsequently burns with an emerald-green flame, and a yellowish-red film is deposited on a piece of cold porcelain held in the flame. The presence of alcohol, ether, or of several organic substances retards the action. The spectrum of a hydrogen flame containing phosphorus shows two green lines, one of which is close to the green barium line. J. Plücker and J. W. Hittorf first obtained the **line spectrum** of phosphorus from a warm evacuated discharge tube containing a little phosphorus. The line spectrum was also observed by G. Salet, A. Ditte, K. B. Hofmann, A. de Gramont, E. Demarçay, A. E. Ruark and co-workers, F. Exner and E. Haschek, A. Hagenbach and H. Konen, P. Geuter, E. Goldstein, and J. M. Eder and E. Valenta. The more important lines are 6506 in the red; 6058 and 6033 in the orange-yellow; 5421, 5403, 5382, 5338, 5307, 5285, and 5244 in the green; 4601 and 4589 in the blue—Fig. 7. M. Curie studied the spark spectrum of liquid phosphorus; and A. de Gramont, the ultimate lines of the spectrum. The **band spectrum** of phosphorus was considered by J. Formanek to be best observed in the flame of burning hydrogen obtained by putting a very small piece of phosphorus in an apparatus generating hydrogen gas. The inner cone appears green. The spectrum shows four bands—a feeble one in the orange-yellow, about 5995; a pale yellowish-green band about 5606; a pale greenish yellow band about 5264; and a feeble green band about 5107—Fig. 8. J. E. Purvis found that the vapour shows no absorption bands in the ultra-violet. G. Salet showed

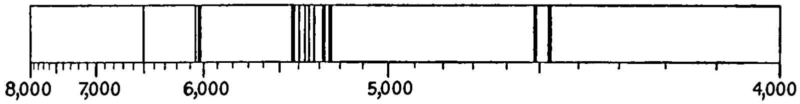

FIG. 7.—The Line Spectrum of Phosphorus.

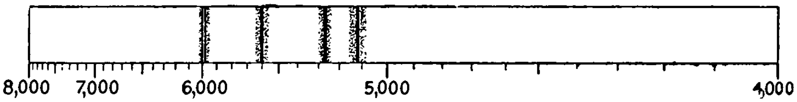

FIG. 8.—The Band Spectrum of Phosphorus.

that this procedure is a very sensitive means of detecting phosphorus in iron, or in cases of phosphorus poisoning. The banded flame spectrum was examined by J. M. Séguin, P. Christofle and F. Beilstein, A. Petrikaln, E. Mulder, A. Mitscherlich, O. S. Duffendack and H. Huthsteiner, W. N. Hartley, F. Exner and E. Haschek, and P. Geuter. The band spectrum was also investigated by G. Salet, L. de Boisbaudran, C. J. Lundström, W. N. Hartley, C. de Watteville, and A. de Gramont and C. de Watteville. The **arc spectrum** was studied by H. Kayser and C. Runge, F. Exner and E. Haschek, M. O. Saltmarsh, A. Hagenbach and H. Konen, and J. M. Eder and E. Valenta. The absorption spectrum was described by J. N. Lockyer; and the emission spectrum of the heated vapour by E. Paterno and A. Mazzuchelli. The effect of *temperature* was examined by G. Ciamician, and A. Schuster; and these investigators also examined the effect of *pressure*. A. de Gramont studied the action of the so-called *self-induction* on the spectrum of phosphorus compounds. R. A. Millikan and I. S. Bowen studied the extreme ultra-violet spectrum. W. W. Shaver measured the spectral lines produced by the electrodeless discharge in phosphorus vapour; F. Holweck, the ultra-violet spectrum; C. R. Crymble, the absorption spectrum of the phosphorus chlorides; and J. J. Dobbie and J. J. Fox, the absorption of light by the vapour of phosphorus. A. Petrikaln, W. Centnerszwer and A. Petrikaln, W. N. Hartley, and H. J. Emeléus and R. H. Purcell discussed the origin of the ultra-violet spectrum of glowing phosphorus; and the last-named concluded that it has its origin in the molecule of an oxide. According to A. Fowler, and W. M. Hicks, no **series spectral lines** have been observed in the phosphorus spectrum; but M. O. Saltmarsh found that the series system in the spectrum of doubly ionized phosphorus is a doublet system in accordance with the spectroscopic displacement law. Three members of the triplet series of the spectrum of trebly ionized phosphorus have been identified. For three groups of elements, each having its own characteristic electron structure, the sharp terms are greater than the diffuse terms with the same Rydberg's number for the neutral and singly ionized element, but for higher stages of ionization the diffuse terms are greater than the sharp. R. B. Lindsay, O. Laporte, N. K. Sur, J. C. McLennan and A. B. McLay, I. S. Bowen, and R. A. Millikan and I. S. Bowen discussed this subject. The general subject was reviewed by H. Kayser. W. W. Coblentz measured the **ultra-red transmission spectrum** of phosphorus. M. Centnerszwer, and A. Petrikaln found the luminous glow of phosphorus in an organic solvent has a continuous spectrum in the visible region, but in the ultra-violet there are fourteen sharp lines and a band near 3252. A. Petrikaln found broad bands covering the fourteen lines between $\lambda=2381$ A. and 2613 A. previously observed. H. J. Emeleus and W. E. Downey did not agree with the latter conclusion. They also found that when phosphorus burns in enriched air with a flame temp. of 800°, there are five bands in the ultra-violet at $\lambda=2390$, 2475, 2530, 3630, and 3275 A.; the same bands occur when phosphorus burns under reduced press. with a flame temp. of 125°, but the bands are resolved into smaller bands; and when phosphorus glows, it emits the same bands as the low temp. flame. H. J. Emeléus found the same spectrum is emitted from glowing phosphorus oxide, and phosphine burning in oxygen. E. Schmidt said that phosphorus is opaque to the ultraviolet rays.

The K-series of the **X-ray spectrum** was examined by H. Fricke,[12] J. Bergengren, M. de Broglie and A. Dauvillier, E. Bäcklin, O. Stelling, D. M. Bose, F. L. Mohler and P. D. Foote, G. Wentzel, E. Hjalmar, O. Lundquist, L. A. Turner, A. E. Lindh, C. D. and D. Cooksey, G. Wentzel. S. K. Allison, F. Holweck, J. C. McLennan and M. L. Clark, studied the L-series of the X-ray spectrum. A. Dauvillier could not find the L_α-ray. According to J. Bergengren, the wave-lengths of the limits of absorption in the X-ray absorption spectra of the different varieties of phosphorus, are different for black phosphorus and for phosphorus in the form of phosphoric acid; that of red phosphorus shows a double limit, one component of which is identical with that of black phosphorus, and the other, attributed to yellow phosphorus, coincides, at least approximately, with that of phosphoric acid. T. E. Aurén found the relative at. absorption coeff. of phosphorus for X-rays is 5·68 when that of lead is 569. O. Stelling studied the effect of radicles bound directly to quinquevalent phosphorus on the *K*-absorption wave-lengths, and also the effect of different valencies of phosphorus with the same radicles. Elements bound directly to quinquevalent phosphorus cause a shift of the *K*-absorption towards a longer wave-length in the order $O<N<H<C<Cl$. These results were discussed by S. Aoyama and co-workers, and M. de Broglie and A. Dauvillier. F. L. Mohler and P. D. Foote[13] gave 5·80 volts for the **resonance potential** of phosphorus vapour, and 13·3 volts for the **ionization potential.** A. E. Ruark and co-workers gave 13·3 volts for the ionization potential and 5·80 volts for the inelastic **collision potential.** K. T. Compton discussed this subject. O. S. Duffendack and H. Huthsteiner gave 10·3 volts for the **arcing potential** of the vapour of red phosphorus at 335°, and they regard this as the ionizing potential of the phosphorus atom. J. E. P. Wagstaff calculated the **vibration frequency** of red phosphorus to be $6·3\times10^{-12}$, and M. Holweck gave 128 volts for the critical potential of the *L*-series of the X-ray spectra. R. N. Ghosh discussed the relation between the ionizing potential and the electronic structure; and S. C. Biswas, and the mol. vol.

The **actinic properties** of the light from burning phosphorus were found by J. M. Eder[14] to be much less than those of burning magnesium or aluminium. The actinic properties of the flame obtained when a soln. of phosphorus in carbon disulphide is burnt, were mentioned by J. Murray. L. Rolla and G. Piccardi studied the ionization of phosphorus in flames.

According to M. Faraday,[15] liquid and solid yellow phosphorus are non-conductors of electricity; G. L. Knox said that the **electrical conductivity** of fused phosphorus is small; A. Matthiessen observed that if the conductivity of silver be 100 at 0°, then that of red and yellow phosphorus is $0·0_5123$ at 20°; and G. Foussereau gave $0·957\times10^{-11}$ mho for the conductivity of solid phosphorus at 11°, and $0·641\times10^{-10}$ mho at 42°, while for liquid phosphorus, he obtained $0·435\times10^{-6}$ mho at 25°, and $0·289\times10^{-5}$ mho at 100°. P. W. Bridgman found the electrical resistances, *R*, of black phosphorus at different temp. and press., *p*, in kgrms. per sq. cm., were:

p . . .		0	3000	6000	9000	10,000	12,000
R	0° . .	1·000	0·492	0·2042	0·0783	0·0565	0·0297
	50° . .	0·662	0·313	0·1371	0·0572	0·0427	0·0238
	100° . .	0·421	0·195	0·0910	0·0425	0·0337	0·0209

The average value of the press. coeff. is —0·000293 at 0° between 0 and 12,000 kgrms. per sq. cm. press.; —0·000277 at 50°; and —0·000250 at 100°; and for the temp. coeff., at 0° the temp. coeff. is —0·000200, and at 12,000 kgrms. per sq. cm. press., —0·000320; the corresponding values at 50° are —0·000231 and —0·000290 respectively; and at 100°, respectively —0·000262, and —0·000249. The sp. resistance was 1000 ohms per cm. cube at 0°. W. R. Grove found that phosphine is formed when a current is passed through ordinary molten phosphorus, but if the occluded gases have been previously expelled by heating the phosphorus in vacuo, no phosphine is formed. P. Walden found that a soln. of phosphorus in phosphorus trichloride is a non-conductor. O. Reichenheim discussed the conductivity of phosphorus vapour. The action of an electrical discharge on phosphorus vapour has been discussed in connection with red phosphorus. O. W. Richardson found that phosphorus vapour discharges a hot positively charged platinum plate, and the vapour is probably adsorbed by the metal. The effect is not due to the oxidation of phosphorus, because, as indicated below, both positive and negative ions are then present. A. Günther-Schulze discussed the conductivity of phosphorus; and K. F. Herzfeld discussed the relation between the refractive index and the conductivity. K. Przibram examined the conductivity of the fumes from phosphorus. P. W. Bridgman found the **thermoelectric force** of black phosphorus and copper from 0° to 21° is 0·000413 volt per degree, a positive current flowing from the copper to the phosphorus at the hot junction. A. Matthiessen found the thermoelectric power of red phosphorus and lead to be 29·9 microvolts. A. Avogadro studied the position of phosphorus in the **electrochemical series**; it probably comes between fluorine and carbon. F. W. Bergstrom found the electrochemical series in liquid ammonia: Pb, Bi, Sn, Sb, As, **P**, Te, Se, S, I. M. le Blanc and D. Reichenstein measured the electrode potential of phosphorus in soln. of potassium hydroxide, and sulphuric acid. R. Schenck found the **potential difference** of the hydrogen-phosphorus couple to be 0·168 volt at 13·6°, so that the phosphorus electrode is negative to that of hydrogen. W. Beetz studied the gas-cell with phosphorus vapour, and platinum with occluded hydrogen; O. S. Duffendack and H. Huthsteiner, the low voltage arc in phosphorus vapour. W. Busse measured the distribution of the sizes of the ions in phosphorus vapour and found that there is a continuous gradation from the largest to the smallest.

According to M. Faraday,[16] phosphorus is diamagnetic; and the subject was examined by J. Plücker, F. C. O. von Feilitzsch, J. Tyndall, F. Zantedeschi, and E. Becquerel. G. Quincke gave for the **magnetic susceptibility** of yellow phosphorus at the m.p., $-1{\cdot}6\times10^{-6}$ vol. units; P. Curie, $-0{\cdot}92\times10^{-6}$ mass units at 19°–71°; P. Pascal, $-0{\cdot}884\times10^{-6}$ mass units; and K. Honda, $-0{\cdot}88\times10^{-6}$ mass units at 18°. For red phosphorus, S. Meyer gave $-0{\cdot}23\times10^{-6}$ mass units at 18°; and P. Curie, $0{\cdot}73\times10^{-6}$ mass units at 20°–275°. P. Pascal gave -274×10^{-7} for the at. magnetization of yellow phosphorus. K. Honda studied the thermomagnetic properties of yellow phosphorus. P. Pascal compared the magnetic susceptibilities of the elements of the family group, and found the logarithm of the susceptibility to be a linear function of the at. wt. H. Schlundt gave for the **dielectric constant** of solid yellow phosphorus, 4·1 at 20°, and for liquid phosphorus, 3·85 at 45°. G. L. Addenbrooke studied the relation between the dielectric constant and the physical properties; and J. H. Jones, the relation between the dielectric constant and the electronic structure. B. H. Wilsdon studied the subject.

§ 6. The Oxidation of Phosphorus

M. van Marum,[1] A. van Bemmelen, and B. Meijlink showed that the oxidation of phosphorus is accelerated if the air is rarefied, and when the phosphorus is at the same time covered with cotton, or powdered resin or sulphur, the phosphorus ignites at the ordinary temp. A. D. Bache said that the phosphorus can be ignited even without these powders, but that the powders—charcoal, boric acid, potassium or barium hydroxide, lime, calcium carbonate, magnesia, ammonium, sodium or calcium chloride, nitre, fluorspar, silica, arsenic, antimony, manganese, etc.—do facilitate the inflammation. Animal charcoal and lampblack are specially favourable, so that phosphorus sprinkled with charcoal ignites at 15·5° in the open air. When yellow phosphorus burns in a limited supply of air, there may be produced a suboxide, corresponding with that described by U. J. J. Leverrier, as well as phosphorus trioxide, phosphorus tetroxide, phosphorus pentoxide, along with some red phosphorus. R. Cowper and V. B. Lewes showed that the product may contain some unchanged yellow phosphorus. When the products of combustion are treated with water, phosphoric, phosphorous, and hypophosphorous acids as well as phosphine may be formed as indicated more particularly in connection with these compounds. U. J. J. Leverrier showed that if water be gradually added to the products of combustion, there is formed a golden-yellow liquid which coagulates at 80°; and if water in excess be added, a colourless soln. and a red precipitate are formed. B. Reinitzer considers that the reaction can be in part represented by $5P_2O_3=3P_2O_5+P_4$. The golden-yellow soln. contains a colloidal substance $mP_2O_3.nH_2O$, which is not phosphorus anhydride, because the aq. soln. is neutral. The red precipitate is considered to be a solid hydride $(P_4H_2)_n$, with more or less hydrogen replaced by oxygen. T. E. Thorpe and A. E. H. Tutton could not confirm these observations.

When yellow phosphorus burns in an excess of oxygen, the main product is phosphorus pentoxide—possibly mixed with a little red phosphorus. When a considerable quantity of air is passed over phosphorus, the slow combustion which first occurs produces a slight elevation of temp. which gradually accelerates the reaction, until finally the phosphorus bursts into flame. Anything which hinders the dissipation of the heat generated during the oxidation, or hastens the rate of oxidation, favours the ignition of the phosphorus at a low temp. Thus, L. Hünefeld found that if the phosphorus be wrapped in blotting paper, or even if a freshly cut surface be in contact with blotting paper, the phosphorus may fuse at the corners, or edges, and ignite at 20°. The discoverers of phosphorus must have noticed the white clouds which are formed when that substance is burned in air; and the product was mentioned by S. A. Frobenius, A. G. Hanckewitz, etc. Again, finely divided phosphorus may ignite in air after it is dried. According to W. A. Lampadius, filter-paper, or, as recommended by O. Ohmann, asbestos-paper, soaked with a soln. of phosphorus in carbon disulphide, ignites as the solvent evaporates and leaves the phosphorus in a fine state of subdivision on the paper—*vide infra*, action of carbon disulphide on phosphorus.

The old *phosphorus boxes* contained preparations which absorbed moisture from the air with the evolution of heat. The resulting rise of temp. favoured combustion. For example, the mixture of yellow and red phosphorus, and phosphoric and phosphorous oxides and acids, obtained by blowing a jet of air into a flask with some warmed phosphorus, may ignite when exposed to moist air. The phosphoric oxides keep the phosphorus in a fine state of subdivision. J. Pelouze obtained a luminous mixture by melting phosphorus with phosphoric oxide, or calcined magnesia, or lime. M. Saltzer melted phosphorus with about one-third its weight of wax; sent a jet of air into the flask until the phosphorus inflamed and then closed the flask. E. Benedix fused a mixture of powdered cork, beeswax, phosphorus, and naphtha. The mass fired spontaneously at 20°, or at a lower temp. if breathed upon.

J. Davy also showed that the inflammation of yellow phosphorus is favoured by the rarefaction of air, and retarded by compression. Thus phosphorus heated until it takes fire in a closed vessel, is soon extinguished by the press. produced by the heat. The flame reappears on opening the vessel. The inflammation temperature is so low that the heat of the body suffices to raise the temperature of the phosphorus above its kindling temperature, and hence phosphorus should always be "handled" with the forceps, never with the bare fingers unless under water. Burns produced by phosphorus are very painful, and heal very slowly. F. H. Eydmann measured the **ignition temperature** of phosphorus submerged in water whose temp. was gradually raised while a current of air or oxygen was bubbled through the fused mass. The ignition was assumed to occur when the temp. of the water increased very rapidly. This was found to be 45·0°–45·2° in air, oxygen, or air diluted with an equal vol. of carbon dioxide. The ignition temp. is thus independent of the conc. of the oxygen. According to F. Molnar, the ignition temp. of ordinary phosphorus in air containing ozone is 4° higher than in purified air; it is higher in dry air than in moist air, and this the more the greater the humidity of the air. Thus, phosphorus inflamed at 30° in air sat. with water vapour at 30·1°; and at 17° in air sat. with water vapour at 38·1°. It inflamed at 47° in air sat. with alcohol; at 82° in air sat. with ether; at 87° in air sat. with carbon disulphide; and at 18° in air sat. with turpentine vapour. Phosphorus at rest can be heated in air to 205° without ignition, but with a slight agitation, it ignites at 45°. H. Rebenstorff said that phosphorus ignites in 20 seconds if in contact with a clean strip of amalgamated aluminium. Numerous lecture experiments have been devised for demonstrating different phases of the combustion of phosphorus.

W. Hittorf [2] said that red phosphorus does not ignite in air at 255°; and A. Schrötter gave 260° for the ignition temp. in air, and H. B. Baker and H. B. Dixon gave 260° for the ignition temp. in moist oxygen. J. Personne observed that red phosphorus is slowly oxidized and acidified by exposure to air, and L. Guerri showed that phosphorous and metaphosphoric acids are produced—*vide infra*. C. F. Schönbein said that unlike ordinary phosphorus, red phosphorus does not ozonize air, and it does not vaporize at ordinary temp. Hence, red phosphorus is not luminescent in air. T. B. Groves said that moist red phosphorus may slowly oxidize in air, and produce ozone without being luminous. H. B. Baker and co-workers showed that neither yellow nor red phosphorus readily ignites in thoroughly dried oxygen.

In the seventeenth century, Robert Boyle was much impressed by the fact that a body like phosphorus was able " to shine in the dark without having been before illumined by any lucid substance, and without being hot as to sense " ; and by the remarkably small amount of phosphorus required to produce a luminous effect. He said :

> A grain of the noctiluca dissolved in alcohol of wine and shaken in water rendered 400,000 times its weight luminous throughout ; at another trial I found that it impregnated 500,000 times its weight ; which was more than one part of cochineal could communicate its colour to. And one thing further observable was that when it had been a long time exposed to the air, it emitted strong and odorous exhalations distinct from the visible fumes.

The strong and odorous exhalation described by R. Boyle is now called ozone. M. van Marum, J. B. de Mons, and J. Davy showed that when phosphorus is exposed to air at ordinary press. and a temp. above 7°, the slow oxidation is attended by a very slight rise of temp., and a pale greenish light visible only in darkness is emitted : at the same time white fumes with an unpleasant garlic-like odour are emitted. In 1681, F. Slare gave an account of one of the most paradoxical phenomena connected with the luminosity of phosphorus, for he showed that the glow is increased by rarefying the air. He said :

> It being now generally agreed that the fire and flame of phosphorus have their pabulum out of the air, I was willing to try this matter in vacuo. To effect this I placed a considerable lump of phosphorus under a glass, which I fixed to an engine for exhausting the air ; then presently working the engine, I found it to grow lighter (*i.e.* the phosphorus to become more luminous), though a charcoal that was well kindled would be quite extinguished at the first exhaustion ; and upon the third or fourth draught, which very well exhausted the glass, it much increased in light, and continued to shine with its increased light for a long time ; on re-admitting the air, it returns again to its former dulness.

The observation was confirmed by F. Hauksbee, and G. Homberg ; while J. Davy, working along the same line, said that in rarefied air, the luminosity increases with the degree of rarefaction, and that the light does not diminish in brightness under the reduced press. attained by the air-pump ; if air be then suddenly emitted, the light disappears. Phosphorus does not glow in vacuo, nor in air at 4 atms. press. C. G. von Helwig also found that in compressed air, phosphorus does not luminesce until the temp. is raised. Some discrepant results have been reported owing to the neglect of certain impurities in the gases employed. J. F. A. Göttling stated that phosphorus does not glow in oxygen prepared from mercuric oxide, but it becomes luminous in nitrogen ; J. B. de Mons, however, showed that the luminescence of phosphorus in nitrogen is due to the presence of traces of oxygen. J. Davy showed that phosphorus can be volatilized in oxygen at a temp. at which it does not luminesce, and luminosity occurs when nitrogen or hydrogen is introduced into the gas. J. Davy, and C. L. Berthollet found that if oxygen be excluded, phosphorus does not glow in inert gases—carbon dioxide, nitrogen, hydrogen, carbon monoxide, hydrogen chloride, etc. According to J. Davy, phosphorus does not glow in pure oxygen at temp. below 16° ; if the press. be increased to 1·5 atms., the glow does not appear until the phosphorus has been heated to its m.p., and then it takes fire ; phosphorescence occurs at ordinary temp. if the gas be slightly rarefied, or its partial press. be reduced by dilution with an inert gas. Hence, *at a given temp., a certain critical pressure of the oxygen is needed to start phosphorescence.* This press. is called by M. Centnerszwer the *Leuchtdruck* or *luminescence pressure.* According to J. S. C. Schweigger, the more oxygen is rarefied, either by diminishing the press., or by admixture with an inert gas, the lower the temp. at which the luminescence of phosphorus occurs. Consequently, at a given press. a certain *critical temperature*—P. Duhem's *le point de réaction*—is needed for the luminescence of phosphorus. P. Duhem considers the phenomenon to be a case of *le faux équilibre*, where the limiting or critical temp. at different press., obtained by J. Joubert, were:

	1·4°	3·0°	5·0°	8·9°	11·5°	14·2°	19·2°
p . .	355	387	428	519	580	650	760 mm.

When plotted, the curve, Fig. 9, divides the plane into two regions; the region above the curve represents systems where phosphorus is undergoing oxidation; and the region below where no oxidation is taking place, and he therefore calls it *le region des faux équilibres.* J. Chariton and Z. Walta also said that the oxidation is inappreciable below a definite critical press., but M. Bodenstein objected that the conclusion is a result of faulty measurements.

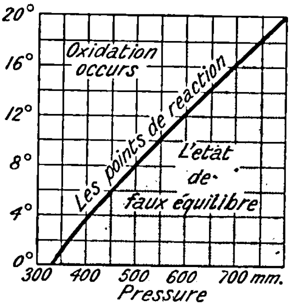

FIG. 9.—J. Joubert's Observations on the Oxidation of Phosphorus.

C. Barus thought that phosphorus actually emitted charged particles of an "emanation" which served as condensation nuclei for water vapour. These were presumably charged ions. W. P. Jorissen, H. E. Armstrong, and G. Bredig and W. Pemsel mention that an emanation from oxidizing phosphorus is able to penetrate opaque substances and affect a photographic plate; but M. Centnerszwer and A. Petrikaln found that the photographic effect is not produced if the products of oxidation are removed as fast as they are formed, and they attribute it to a volatile oxidation product—perhaps hydrogen dioxide. J. Elster and H. Geitel found that whatever be the emanation it is not able to produce an electrical effect on the other side of a quartz plate. A. Blanc observed that the oxidation of phosphorus in air is accompanied by an ionizing radiation of low penetrative power. W. P. Jorissen and W. E. Ringer did not observe any increase in the luminosity by exposing the oxygen to radium radiations, though the light from an electric arc accelerated the process.

At the end of the seventeenth century, R. Boyle noticed that phosphorus is luminous only in the presence of air; and in 1795, W. A. Lampadius showed that phosphorus does not luminesce in dry air. L. J. Thénard found that the slow oxidation of phosphorus ceases in the course of an hour when the air or oxygen is dry. L. Gmelin said that phosphorus does not fume in air dried over sulphuric acid, though it still luminesces feebly in the dark. J. Davy found phosphorus burns as rapidly in air dried by sulphuric acid, as it does in ordinary air. J. J. Berzelius, and E. Marchand inferred that the luminosity of phosphorus at low temp. is not altogether the result of oxidation, but is partly due to vaporization and a mol. change; this hypothesis, however, does not explain the retarding influence of those chemically inactive gases which prevent the oxidation, but not the vaporization of the phosphorus. The ideas of the early workers on the drying of gases are different from those which prevail to-day. H. B. Baker and co-workers showed that if moisture be rigorously excluded phosphorus does not oxidize in air or in oxygen, and no luminescence occurs. The experiments of E. Scharff, E. Mitscherlich, J. Joubert, A. Schrötter, G. Meissner, W. Müller-Erzbach, and E. J. Russell are also decisive in showing that the glow is the concomitant of a chemical process dependent on the presence of oxygen—no oxidation, no glow. H. P. Waran observed periodic flashes on admitting small bubbles of oxygen into a vessel containing phosphorus deposited on the walls by vaporization. E. Q. Adams calculated that the ratio of the production of light to the energy input in the case of phosphorus vapour in nitrogen in contact with air is slightly above one lumen per kilowatt at 25° or at 40°.

R. Boyle observed that the presence of a minute quantity of a number of essential oils—*e.g.* oil of mace or of aniseed—extinguished the glow of phosphorus. J. Davy, H. A. von Vogel, and T. Graham showed that the luminescence is not prevented when the vapour of sulphur, or of acetic acid, hydrogen chloride, or ammonia is present; phosphorus is luminous in hydrogen chloride or carbon dioxide when but a trace of oxygen is present. The luminosity is diminished or stopped by a small proportion of phosphine, hydrogen sulphide, sulphur doxide, carbon disulphide, iodine, chlorine, nitrous oxide, nitric oxide, methane, ethylene, ether, alcohol, naphtha, turpentine, camphor, creosote, and other volatile oils. Thus, T. Graham found that phosphorus is not luminous in air at 21° which contains 0·001 vol. of phosphine (not spontaneously inflammable in air); and H. A. von Vogel said that 0·83 vol. of sulphur dioxide will stop the luminosity of phosphorus in air at 10° but not at 18°; less than 0·001 vol. of turpentine vapour will also extinguish the glow. The effect of numerous other volatile organic substances was examined by M. H. Deschamps, J. Chappius, M. Centnerszwer, K. R. K. Iyer, and E. Scharff.

It is very curious to find that phosphorus will not glow in oxygen at ordinary atm. press. and temp., but if the oxygen be rarefied, the glow at once begins, and ceases immediately the oxygen is compressed. If the luminosity were simply an oxidization process, the converse might have been predicted. According to M. Centnerszwer, and E. J. Russell, luminosity or oxidation commences in moist oxygen when the gas has a partial press. of 500–600 mm., and with dry oxygen, according to T. Ewan, luminosity commences at 20° when the partial press. of this gas is 200 mm. E. J. Russell found a small amount of moisture is necessary for the oxidation of phosphorus by oxygen gas, and that the amount remaining in a gas after treatment with conc. sulphuric acid is most suited for rapid oxidation. W. Busse added that while the oxidation of phosphorus is greatly influenced by the presence of water vapour, and reaches a maximum when the moisture content is so regulated by conc. sulphuric acid that about 10^{14} to 10^{15} mols of water are present per c.c. Extreme drying, however, does retard the oxidation of phosphorus, but does not completely inhibit the process, so that whilst water is a catalyst for the oxidation, it is not essential. Dry phosphorus in the dark becomes coated with a film of oxide, so that a store of oxide accumulates. This undergoes a sudden oxidation to the pentoxide, accompanied by luminescence, when local changes of temp. occur. According to E. J. Russell, the oxidation occurs in two stages: First, a slow oxidation accompanied by a feeble glow, followed by a continuously accelerated process of oxidation when the glow is very bright. Phosphorus pentoxide seems to be formed in the second stage, and an unrecognized oxide in the first stage: R. Schenck and co-workers, L. and E. Bloch, E. Jungfleisch, E. Scharff, H. B. Weiser and A. Garrison, E. Gilchrist, C. C. Miller, and N. Blondlot assume this oxide to be phosphorus trioxide. Consequently, the first stage involves the oxidation of phosphorus to the trioxide without glow; and the second stage, the oxidation of the trioxide (*q.v.*) to the pentoxide with glow. When much moisture is present, the process of oxidation appears to be retarded, possibly owing to the formation of a protective film of moisture on the phosphorus. With moderately dried oxygen, too, measurements of the speed of oxidation are complicated by the formation of a film of oxide on the surface of the oxidizing phosphorus. With moist oxygen, the connection between the rate of oxidation and the press. of the gas is illustrated by the curve, Fig. 10, where the speed of the reaction, zero at 700 mm., increases rapidly as the press. falls, and then varies within narrow limits over press. ranging from about 500 mm. to about 100 mm., and finally decreases rapidly to zero, in vacuo. J. Chariton and Z. Walta found that there is a relation between the vap. press. of the phosphorus and the critical press. of the oxygen below which no oxidation occurs. The critical press. is lowered if argon be present. If the press. of the oxygen be below a *critical pressure*, no rapid reaction occurs. The value of the critical press. is greater the greater the press. of the phosphorus vap. Above the critical press., the reaction is extremely

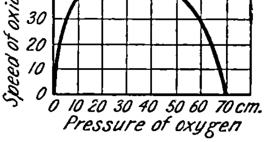

FIG. 10.—The Effect of Pressure on the Oxidation of Phosphorus.

rapid. If oxygen is admitted until its critical press. is nearly reached, and then argon is allowed to enter, the luminescence appears; the effect is as though the press. of the phosphorus had diminished, but the intensity of the light is less. With argon almost at atm. press., the glow made its appearance immediately oxygen was allowed to enter, but its intensity was very feeble. As shown by C. F. Schönbein, H. McLeod, C. T. Kingzett, J. Chappius, A. R. Leeds, etc., ozone and hydrogen dioxide are formed when the moisture is present in excess; these substances are not direct products of the reaction between phosphorus and oxygen. In addition, ammonium nitrate and nitrite, according to C. F. Schönbein, and E. J. Russell, are formed when the oxidation of the phosphorus is effected.

The work of W. Schmid, J. Corne, Lord Rayleigh, W. Müller-Erzbach, E. Scharff, J. Joubert, etc., makes it very probable that the luminosity is produced by the oxidation of the vapour of phosphorus. E. Jungfleisch said that the amount of phosphorus volatilized at ordinary temp. is too small to explain the luminosity, and he thinks it is due to the oxidation of a very volatile oxide of phosphorus. Lord Rayleigh showed that phosphorus may be slowly oxidized under conditions where there is no perceptible glow; the rate of oxidation was found to increase perceptibly with the vol. of the surrounding oxygen; and that the oxidation occurs in the gas as a reaction between oxygen and phosphorus. Phosphorus is slightly volatile at ordinary temp., and the increased volatilization which occurs when the press. of the gas is diminished appears to account for the increased luminescence in a rarefied atm. Hydrogen, carbon dioxide, and nitrogen containing a trace of oxygen become luminous in contact with phosphorus owing to the diffusion of the vapour of phosphorus in these gases. According to J. Chappius, ozone passed into oxygen in contact with phosphorus, at a temp. and press. at which no luminescence occurs, immediately produces a glow which continues so long as ozone is present. As J. Chappius showed, neither ozone nor the glowing is produced in oxygen at ordinary temp. and press., but on warming, both ozone and luminosity are produced. Hence, T. E. Thorpe said that when phosphorus is placed in oxygen, or in an atmosphere containing oxygen, under such conditions that it volatilizes, the phosphorus oxidizes, partly into phosphoric oxide and partly into phosphorous oxide (*q.v.*). Ozone is formed, possibly by the reaction already indicated, and this reacts upon the residual phosphorus vapour and the phosphorous oxide, with the production of the luminous effect to which the element owes its name. The glow itself is nothing but a slowly burning flame, having an extremely low temperature, caused by the chemical union of oxygen with the vapours of phosphorus and phosphorous oxide. By suitable means this glow can be gradually augmented until it passes by regular gradation into the active vigorous combustion which we ordinarily associate with flame. H. Biltz and A. Gross concluded that phosphorus trioxide is the primary product in the oxidation of phosphorus, and that the pentoxide is formed in a subsequent reaction. L. Marino and C. Porlezza said that three different stages are reached in the oxidation of phosphorus according to conditions employed: (i) formation of P_2O_5 when phosphorus vapour burns completely in excess of oxygen; (ii) formation of P_2O_3 and P_4O when phosphorus is burnt in a current of air; (iii) formation of a lower oxide, probably P_4O, when phosphorus is oxidized with highly diluted oxygen. According to J. Chariton and Z. Walta, when phosphorus is oxidized by oxygen at a press. in the vicinity of 10 mm., the reacting mol. is P_2; when this is oxidized, more mols. are formed from P_4 with absorption of heat; this, together with the fact that some of the heat of oxidation is lost as radiation, prevents the rapid action. The higher the press. of the phosphorus vap. the greater is the proportion of P_4 mols. and the higher is the critical press. of the oxygen. The argon diminishes the loss by radiation, receiving energy by collision, which is then communicated to the phosphorus by further collisions and the critical press. is reduced. The subject was discussed by M. Bodenstein.

The glow of phosphorous oxide presents similar features to the glow of phosphorus itself. Consequently, as just indicated, it has been inferred that the glow of phosphorus is due to the phosphorous oxide formed in a preliminary non-luminous oxidation. A. Petrikaln found that the ultra-violet bands in the spectrum of glowing phosphorus have maxima at 3270, 2600, 2530, 2460, and 2390 A., in agreement with the bands in the arc-spectrum of phosphorus pentoxide. The spectral observations of H. J. Emeléus and co-workers show that the light from burning phosphorus, that from glowing phosphorus, that from glowing phosphorous oxide, and that from spontaneously inflammable phosphine burning in oxygen give the same spectrum—*vide supra*, phosphorus. H. J. Emeléus added:

> The fact that the light from glowing phosphorus and that from phosphorus trioxide both give the same spectrum supports the analogy between these two oxidations, already well established in other respects. These observations, however, cannot be taken as proof of the identity of the chemical processes. They indicate rather that there is some radiating system involved in them all, which gives rise to a definite band spectrum. Such a system may well have a connection with the chemical anomalies common to the low temperature oxidation of these phosphorus compounds.

W. E. Downey showed that the action of the light, through windows of quartz or fluorite, on glowing phosphorus, formed ozone. Similarly, it was found that the formation of ozone by glowing phosphorus is proportional to the intensity of the glow, although a fresh phosphorus surface did not show this until it had become acclimatized. The glow of phosphorus trioxide was similar but of less intensity. A. L. Hughes showed that the spectrum of the glow extends within the region λ=1200–1800 A. The glow is capable of ionizing air. These facts, said W. E. Downey, support the idea that *the ozone is formed by the glow of phosphorus.* W. Busse could not repeat the experiment, and he doubted if rays between λ=120 A. and 200 A. are generated at all. W. Busse, and A. Petrikaln also showed that the production of ozone is not a photochemical effect of the glow.

C. F. Schönbein assumed that the ozone formed during the reaction is a necessary catalyst, and that it is destroyed by those agents which inhibit the glow. H. J. Emeléus showed that were this so, the relative effect of different retarders would be that of their reactivity towards ozone. In some cases this is not so—*e.g.* acetone is less readily attacked by ozone than is benzene, and yet it is a stronger inhibitor of the glow. M. Centnerszwer showed that it is not likely to be due to the formation of a protective film on the phosphorus because phosphorus exerts its normal vap. press. in the presence of inhibitors. It is generally supposed that the glow is a process analogous to the passage of flame through a combustible mixture, and that poisons prevent this occurring. Thus, Lord Rayleigh found this to be the case with the inhibition produced by an excess of oxygen; and L. and E. Bloch measured the blast of gas necessary to blow the glow from a given phosphorus surface in various oxygen-nitrogen mixtures, and found that it becomes less as the percentage of oxygen was increased. Assuming that the blast required to maintain the glow in a stationary position downstream is a measure of the virtual rate of propagation upstream, it follows that successive increases in the oxygen conc. decrease the rate of propagation. H. J. Emeléus studied the inhibitory effect of benzene, chloroform, aniline, and ethylene on the glow. A decrease of press. or an increase of temp. favours the glow, while the presence of air increases both the vap. press. and reactivity of the phosphorus. He found that the inhibition with ethylene can occur at 90°, which is much above the normal ignition temp. of phosphorus. Moreover, the "glow temperature" does not depend on whether air or oxygen is used as a diluent for ethylene. When the glow is prevented, the reaction continues; this is shown by the slow non-luminous oxidation which still occurs at 48°. At some stage, depending on the conc. of the ethylene, some kind of impediment is overcome, and a wave of luminosity passes through the mixture, the subsequent oxidation being accelerated by the formation of ozone. Again, on slowly decreasing the press. of a mixture of ethylene and oxygen, the partial press. of the phosphorus will remain constant in the presence of the solid. In effect, therefore, the proportion of combustible vapour in the mixture is being increased, which in itself would be expected to favour flame-propagation. Analogous cases of the retardation of combustion have been reported by A. G. White, H. B. Dixon, M. Delépine, etc. The experiments of H. J. Emeléus showed that the addition to air of typical inhibitors renders it easier to blow the glow from a phosphorus surface, and that increase in temp. diminishes this action. An analogy is thus established between the action of an excess of oxygen and that of the stronger inhibiting agents in that both prevent the propagation of the glow in the gas. A tentative explanation of the mechanism was put forward by Lord Rayleigh, who suggested that in the propagation of the glow products of the reaction in one layer acted as catalysts in the next. These catalytic particles are supposed to be rendered inactive by the adsorption of the mols. of the inhibiting gas, when the reaction stops. A similar view has been adopted by H. B. Dixon to explain the inhibition of the phosphorescent flame of carbon disulphide.

The formation of ozone, takes place in such a way that the amount of ozone formed is proportional to the amount of phosphorus oxidized, and also that the *atomic* ratio of the number of atoms of phosphorus oxidized to the number of molecules of ozone formed is 2 : 1. C. Matteucci showed that air in the vicinity of oxidizing phosphorus becomes charged electrically. Both positively and negatively charged electroscopes in the vicinity of oxidizing phosphorus are discharged showing that both negative and positive ions are produced in air: $O_2=O^-+O^+$. Thus, A. C. Christomanos found that a piece of paper moistened with an ethereal soln. of phosphorus will discharge a positively or a negatively charged electroscope. The subject was studied by J. A. McClelland and P. J. Nolan, etc. N. R. Dhar said that phosphorescence, like fluorescence, is due to molecules which have been activated by ions formed in the oxidation of the phosphorus, returning to the normal state.

The phenomenon is illustrated by the following experiment: A large test-tube *A*, Fig. 11, and a two-necked bottle, *B*, are fitted as indicated in the diagram; the two-necked bottle is connected with a metal cylinder, *C*, fitted with a brass rod attached to the charged electroscope *D*. The metal cylinder is fitted with a rubber stopper and a tube leading to an aspirator. The metal cylinder is put in electrical connection with the earth. The aspiration of air through the system has no appreciable effect on the gold-leaf of the electroscope; but if a little phosphorus be placed in the tube *A*, the electrical conductivity of the air is shown by the movement of the gold-leaf of the electroscope. The attachment *A* can be modified to find if the ambient air becomes electrically conducting during other chemical processes.

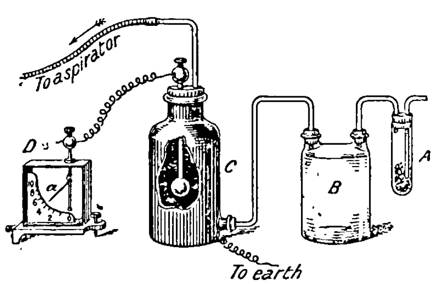

FIG. 11.—Experiment showing the Ionization of Air during the Oxidation of Phosphorus.

It is not clear what actually takes place during oxidation of phosphorus. A number of more or less plausible hypotheses have been proposed. B. C. Brodie, and C. F. Schönbein suggested that during the process of oxidation, the oxygen is split up into two parts which take up electrical charges of opposite sign. As R. Clausius expressed it, " phosphorus resolves the oxygen molecule into two atoms of opposite electrical states, one of which combines with the phosphorus and the other is removed from the sphere of the reaction." The subject was discussed by H. L. F. von Helmholtz, R. von Helmholtz and F. Richarz, J. J. Thomson, J. Elster and H. Geitel, W. Giese, A. Gockel, A. Schuster, E. Bloch, F. Harms, H. Löwy, etc. The general idea is that the conductivity of the ambient air when phosphorus is oxidizing is really due to the ionization of the oxygen molecules; G. C. Schmidt, however, thinks that the conductivity is due to " the convection of electricity by cloud-forming, conducting oxidation-products"; and F. Harms attributed the ionization to a secondary action due to the ozone; he said that, as indicated by F. Richarz and R. Schenck, no ionization occurs during the combustion of phosphorus. On the other hand, G. C. Schmidt said that burning phosphorus makes the air a good conductor, and that the conductivity rapidly decreases with the desiccation of the air. R. Schenck and E. Breuning attribute the ionization to a reaction product, a kind of *phosphorus emanation*, which undergoes complete condensation at —180°, but has an appreciable vapour pressure at —80°. W. Busse showed that phosphorus is luminous when it is undergoing slow oxidation with the concomitant formation of ozone and the appearance of positively and negatively charged ions in the surrounding gas. F. Harms, and E. Bloch studied the mobilities of the ions, and W Busse found that the ions are generated on the oxidizing phosphorus. The two kinds of ions do not at first show different mobilities. There is afterwards a continuous increase in the size of ions, and the presence of a continuous range of sizes can be demonstrated. Consequently, the phosphorus is not the only place at which ions originate; and the rate of growth of the large ions shows that ionization also occurs in the stream of air away from the phosphorus. The high mobilities of the negative ions is ascribed to multiple charges—four to six times as great as those carried by the positive ions. Most of the positive ions carry single charges, and in any case four charges is the maximum carried by a positive ion. On the assumption that the positive ions carry single charges, it can be shown that in the ageing process the positive ions change in size from 5×10^{-8} cm. to from 2×10^{-8} to 4×10^{-8} cm. in 8 seconds. W. Busse found that the ionization-temp. curves show maxima and minima and a noteworthy small peak at temp. between 35° and 40°, *i.e.*, just below the flashing temp. In dry air, ionization occurs only at higher temp. The position and magnitude of the maximum are greatly influenced by the temp. of the air stream. The moisture present favours a rapid rise to maximum ionization. The fact that moisture appears to be essential for the formation of ions, the fact that the negative ions take up multiple charges preferentially, lead to the view that the ionization occurs as a result of the dissociation of an acid formed in the course of the oxidation of phosphorus. The charge which occurs, initially, on passing a stream of air over the phosphorus is, apart from special exceptions, equal to the charge at the stage immediately preceding the ignition. On the other hand, the maximum in the curve corresponds with a charge several times as great as the initial charge. The amount of dissociating acid present remains fairly constant, so that ionization by stages must occur. It is concluded that pyrophosphoric acid must be the dissociating substance responsible for ion-formation.

R. Schenck and co-workers found the conductivity of ozone is not increased by contact with organic substances such as turpentine, amylene, eugenol, caoutchouc, silk, cotton-wool, linen, or wood, whilst that of air is not increased by contact with benzaldehyde, formaldehyde, acetaldehyde, methyl, ethyl, or amyl alcohol, methyl or ethyl ether, phenylhydroxylamine, indigo-white, pyrogallol, or triethylphosphine, or by the slow oxidation of sulphur or of bromoacetylene, which resembles phosphorus in that when slowly oxidized it shows the phenomenon of intermittent phosphorescence and forms a polymeride, tribromobenzene. If the conditions are such that the oxidation of phosphorus is hindered, the increase in the conductivity of air or oxygen is correspondingly slight. Thus, the conductivity of pure oxygen in contact with phosphorus under atm. press. is much less than that of air under the same conditions. The conductivity of air which has been passed through turpentine, alcohol, mesitylene, ammonia, ethylene, or amylene is not increased by bringing the air in contact with phosphorus, but, on the other hand, the conductivity is diminished only slightly if the process is reversed. Mixtures of oxygen with hydrogen or carbon dioxide give the same result as air. The conductivity of air or of ozonized oxygen, but not of pure oxygen, is increased by contact of the gases with red phosphorus. They added that the conductivity of air in contact with glowing phosphorus is connected with the presence of phosphorus trioxide, and may be caused by the interaction of the trioxide and moisture to form phosphorous acid. E. Meyer and E. Müller inquired whether the ionization of the air in contact with oxidizing phosphorus is due to the light emitted in the process or to the oxidation itself. In the presence of substances such as chlorine, ether, and turpentine, which inhibit the glowing of phosphorus, there is no oxidation and no ionization. If phosphorus is allowed to oxidize in thin-walled quartz vessels which are transparent to ultra-violet radiation, no ionization of the air can be detected. The spectrum shows that the radiation emitted by phosphorus undergoing oxidation is free from ultra-violet rays. The ozone produced in the oxidation cannot be the cause of the enormous conductivity imparted to the air; after removal of the ozone, the air retains its conducting power. According to H. Schmidt, when a current of purified hydrogen, carbon dioxide, or nitrous oxide is passed through an emulsion of phosphorus in water or through a solution in benzaldehyde, the luminosity and cloud formation, which are observed in the early stages, gradually diminish in intensity, and disappear when the oxygen has been completely removed. When the inactive gases charged with phosphorus vapour are passed into the chamber of an electroscope, ionization currents are obtained, which are very much larger than the currents obtained when air similarly saturated with phosphorus vapour is passed into the chamber. On passing pure oxygen through the emulsion or solution, the luminosity and cloud formation disappear as the partial pressure of the oxygen rises in consequence of the removal of air.

One form of the ionization hypothesis assumes that *atoms* of oxygen alone take part in the oxidation, and that some of the molecules of oxygen are dissociated into two atoms, each atom acquiring at the same time an electric charge of opposite sign: $O_2=O^++O^-$. The phosphorus combines with the atoms with one kind of electric charge; and the atoms of oxygen with a charge of opposite sign form ozone. The dissociation of the oxygen molecule is not a consequence of the oxidation, but antecedent to it, as suggested by O. Loew, and H. Fudakowsky. This view is confirmed by T. Ewan, who showed that when the partial press. of the phosphorus is less than 100 mm. the rate of oxidation of the phosphorus is proportional to the square root of the partial press., and not to the partial press. itself. J. H. van't Hoff interpreted this to mean that the actual oxidation of the phosphorus is effected by the atoms of the dissociated oxygen molecules; in symbols: $2P+2O_2=P_2O_3+O$, and $O_2+O=O_3$. According to W. Ostwald, this hypothesis cannot be right, because ozone has more available energy than oxygen from which it is derived, and energy must therefore be added to oxygen to produce ozone, the assumption being that the chemical energy of one reaction is not available for another totally different reaction, so that the energy degraded during the oxidation of phosphorus cannot be used for producing ozone. A. Bach assumed that a peroxide is first formed by the direct addition of oxygen to phosphorus, and this, on contact with water, forms an oxide of phosphorus and hydrogen dioxide. W. Ostwald likewise assumed that each atom of phosphorus is first oxidized by direct union with whole molecules of oxygen, forming a higher peroxide, say, P_2O_{2n}. This then decomposes, giving atomic oxygen: $P_2O_{2n}=P_2O_{2n-3}+O_3$. E. J. Bowen and E. G. Pells showed that if phosphoric acid is the final product of the oxidation of phosphorus, and is produced by a series of consecutive reactions of which only one, involving only one mol of oxygen, emits light, then, the ratio of the number of quanta of visible light emitted to the number of molecules reacting in the glow of phosphorus vapour and oxygen shows that at least one in 2000 molecules of phosphorus undergoing oxidation emits a quantum of visible light. The glow of phosphorus is a kind of chemiluminescence in which oxidation at the surface of solid particles of an oxide excites to luminescence the adsorbed molecules of some other oxide. This subject was discussed by H. Kautsky.

When phosphorus is oxidized in darkness in the presence of a solution of indigo, the luminosity, which is a sign that phosphorus is undergoing oxidation, gradually disappears; if the contents of the vessel be now shaken up, the luminosity reappears. Hence something which retards the further oxidation is formed, and this product is destroyed by shaking up with indigo soln. The alternate appearance and disappearance of the luminosity may be produced again and again. At the same time the blue colour of the indigo soln. gradually disappears, showing that the primary product of the oxidation of phosphorus is absorbed by the indigo soln. From this experiment, J. H. van't Hoff thinks that the primary product of the action cannot be ozone, because J. Chappius has shown that the presence of ozone would accelerate the oxidation. Something which retards the oxidation must be present. Merely shaking up the water, without the indigo, will not remove the primary product of the oxidation. He suggested that this product is an excess of positively or negatively charged oxygen atoms. Whatever may be the product which prevents oxidation, it gradually disappears when the flask is left alone, and the luminosity, in consequence, reappears in a few hours; again oxidation ceases, to begin anew on standing a few hours. This explains the *periodic phosphorescence* noticed by J. Joubert in 1874. The subject was studied by Lord Rayleigh, and W. P. Jorissen. K. R. K. Iyer found that the periodic phenomenon occurs in the presence of air when traces of inhibitors like naphthalene, carbon disulphide, turpentine, light petroleum, etc., are present, but not with water alone.

§ 7. The Chemical Properties of Phosphorus

Yellow phosphorus is commonly sold in the form of waxy, transparent sticks which are usually preserved under water, because the element is so readily oxidized and inflamed when exposed to air. Yellow phosphorus fumes in air, and it then appears to have a peculiar odour recalling that of garlic. As remarked by C. F. Schönbein,[1] phosphorus vapour has probably no smell; what is actually perceived is the smell of a mixture of phosphorous oxide and ozone. T. E. Thorpe and A. E. H. Tutton also showed that the fumes of phosphorus consist largely of phosphorous oxide; by drawing air over phosphorus without allowing it to ignite, and passing the fumes through a narrow strongly-cooled tube, a deposit is obtained which melts with the warmth of the hand, and gives the reactions for phosphorous oxide. Moreover, the odour of the product is identical with that of pure phosphorous oxide, and it is also identical with the peculiar smell noticed in a lucifer-match manufactory during the making and handling of the "composition" with which the splints are tipped, and which is present in the neighbourhood of the benches where the "boxers" are at work. Red phosphorus is inert under many circumstances where yellow phosphorus is an active chemical agent; and it has a far smaller tendency to unite with incandescence with other substances. Yellow phosphorus is not very soluble in most of the common solvents; carbon disulphide is considered to be *the* solvent for this element; and, as indicated in detail below, the solubility in other solvents is much smaller—thus, 100 grms. of solvent dissolve approximately:

Carbon disulphide.	Benzene.	Almond oil.	Conc. acetic acid.	Ether.	Alcohol, sp. gr. 0·822.	Glycerol.
25	1·5	1·00	1·00	0·45	0·25	0·17 grm.

W. Ramsay and J. N. Collie [2] observed no reaction between **helium** and phosphorus, although R. J. Strutt observed that a little helium may be absorbed. Lord Rayleigh and W. Ramsay observed no reaction between phosphorus and **argon.** W. Ramsay and F. Soddy observed no reaction between phosphorus and radium emanation or **niton.** M. Guichard examined the gases occluded by phosphorus, and evolved when the element is heated in vacuo. H. Davy was very much impressed by the proportion of **hydrogen** liberated from phosphorus during the passage of an electric current; and H. B. Baker and H. B. Dixon showed that comparatively large quantities of hydrogen are absorbed or occluded by phosphorus. Hydrogen, however, as A. F. Fourcroy and L. N. de Vauquelin showed in 1822, exerts no appreciable chemical action if heated in contact with phosphorus. F. H. Newman observed that hydrogen is absorbed by phosphorus in the electric discharge tube. Although hydrogen *in statu nascendi* is able to unite with phosphorus, once the hydrogen has assumed the gaseous state, combination no longer occurs. I. Langmuir, however, observed that the so-called atomic hydrogen can convert phosphorus into phosphine. J. Davy said that hydrogen becomes charged with phosphorus vapour when in contact with that element. In 1894, J. W. Retgers stated that a stream of hydrogen passed over heated amorphous phosphorus does form hydrogen phosphides, but V. E. Tischtschenko and N. Zawoiko, and A. J. J. Vandevelde showed that there is no direct combination even when the phosphorus is heated to the temperature of sublimation. True enough, if hydrogen be passed over molten phosphorus, the vapour of phosphorus diffuses into the hydrogen imparting to it the odour of garlic, the property of emitting light when it comes in contact with oxygen, or the hydrogen may even ignite when it comes in contact with the air. The formation of a volatile hydrogen phosphide when phosphorus is in the presence of zinc and dil. acid, or conc. alkali generating hydrogen was observed by L. Dusart, and A. R. Leeds. According to J. B. A. Dumas, zinc in contact with dil. acids and phosphorus does not form hydrogen phosphide, and H. Davy was mistaken in supposing that combination occurred, for, if the acid is heated, phosphorus vapour not hydrogen phosphide may be carried along with the hydrogen; but J. Brössler, like H. Davy, considered that combination of phosphorus with the nascent hydrogen occurred under these conditions. V. Ipatieff and V. Nikolaieff observed that phosphine is formed when white phosphorus and hydrogen are heated in a sealed tube at 360°. Red phosphorus was found by V. Ipatieff to pass into the black variety when heated in hydrogen at 200° and 90 atm. press., whereas under milder conditions it furnishes phosphine, etc. V. Kohlschütter and A. Frumkin noticed that hydrogen and phosphorus vapour form solid hydrides when exposed to the luminous electrical discharge. They also found that phosphorus can adsorb argon and helium.

The effect of **oxygen** has been discussed in a special section, and the action of **ozone** is also there indicated. H. Biltz and A. Gross, J. Lang, and K. Brunner described a demonstration experiment for the combustion of phosphorus; N. R. Dhar observed that in the oxidation of phosphorus, by atm. oxygen, the presence of easily oxidizable substances like hydroquinone, sugars, glycerol, sodium arsenite, etc., retard its reaction. A. N. Dey and N. R. Dhar studied some coupled reactions with oxidizing phosphorus as the primary reaction and oxidizing sulphur, nickelous hydroxide, ethyl alcohol, sodium arsenite, or oxalic acid as the secondary reaction. The use of phosphorus for the production of smoke screens was discussed by H. W. Walker; and for the absorption of oxygen in gas analysis, by A. Holmes. N. R. Dhar, and C. Moureu and C. Dufraisse[3] discussed the spontaneous oxidation of phosphorus by free oxygen. A. Schrötter said that red phosphorus can be kept in air for years without change. J. Böeseken, G. Wilson, and J. Personne observed that moist red phosphorus in a finely divided state is slowly oxidized; and T. B. Groves observed that the smell of ozone is produced, but no luminosity occurs. A. Pedler also noted that in hot, moist, tropical atm., phosphine and phosphorous acid are formed. A. Stock and F. Gomolka added that moist red phosphorus, like yellow phosphorus, is oxidized by moist air, the only difference is that the oxidation is much slower. For the burning of phosphorus in air, *vide* the different oxides of phosphorus. L. Gmelin, and B. von Dybkowsky showed that phosphorus and **water** can react chemically at ordinary temp. A. R. Leeds believed that moist phosphorus, in an atm. of carbon dioxide, can form phosphine. A. Oppenheim found that water heated in a sealed tube with red or yellow phosphorus forms phosphine and phosphorous acid. J. J. Berzelius said that yellow phosphorus is very slightly soluble in **water**; and the solubility was also qualitatively observed by R. Phillips, J. Murray, and W. Müller-Erzbach. C. Stich said that 100 grms. of water can dissolve 0·0003 grm. of phosphorus, at 15°; J. Hartmann, 0·000127 grm. at 38·5°; and T. Bokorny said that an aq. soln. can be obtained containing 0·02 grm. of phosphorus in 100 c.c. of water by pouring a soln. of 0·1 grm. of phosphorus in carbon disulphide mixed with ether and hot alcohol, into 500 c.c. of air-free boiling water, and continuing the boiling until the alcohol, ether, and carbon disulphide have been expelled. C. F. Cross and A. Higgin found that only in the presence of air is the water decomposed; in an atm. of carbon dioxide, water can be distilled from phosphorus without forming phosphine, but under ordinary conditions, said T. Weyl, phosphorus decomposes warm water with the evolution of phosphine. C. Stich observed no activation of the oxygen when a soln. of 3 mgrms. of phosphorus in water is kept in intimate contact with air. C. F. Cross and A. Higgin, and J. Böeseken observed that red phosphorus does not react with boiling water, but at a higher temp. a feeble reaction occurs. V. Ipatieff and V. Nikolaieff observed that white phosphorus and water in a sealed tube at 360° yield phosphoric acid and phosphine; and the formation of phosphine starts at about 290° and 40–50 atm. press., and is indicated by a break in the temp.-press. curve. V. Ipatieff observed a little black phosphorus may be formed; and red phosphorus furnishes phosphoric acid and phosphine when heated under press. with water. H. Rebenstorff described a demonstration experiment for the ignition of phosphorus under water. T. Weyl found that a 6 to 30 per cent. soln. of **hydrogen dioxide** attacks phosphorus at about 60°, forming phosphine which does not spontaneously inflame, and phosphorous and phosphoric acids. The action of hydrogen dioxide on red or scarlet phosphorus is much more energetic than is its action on yellow phosphorus, the action being violent with soln. which contain more than 8 per cent. of the dioxide; the products are in this case also hydrogen phosphide, phosphorous acid, and phosphoric acid. Hydrogen phosphide is evolved when red phosphorus is boiled with water; the action is not due to any alkali derived from the glass vessels used. The liberation of phosphine by the action of red or scarlet phosphorus on boiling water or hydrogen dioxide is not due to the presence of yellow phosphorus, but rather to the formation and decomposition of phosphorous acid: $3H_2O_2+2P=2P(OH)_3$; and $4P(OH)_3=PH_3+3H_3PO_4$.

H. Moissan[4] showed that **fluorine** reacts on both red and yellow phosphorus at ordinary temp. The reaction is accompanied by incandescence producing the trifluoride if the phosphorus is in excess, and the pentafluoride if the fluorine is in excess. Ordinary phosphorus burns in **chlorine** gas with a pale greenish light producing, in an analogous manner, phosphorus tri- or penta-chloride. A. Schrötter said that no reaction with liquid chlorine occurs at the temp. of solid carbon dioxide, but, according to J. B. A. Dumas, and F. Donny and J. Mareska, it does react, even at —90°. Red phosphorus was found by A. Schrötter to react with chlorine at ordinary temp., forming first the tri- and then the penta-chloride; red phosphorus inflames in warm chlorine but the flame dies out if the gas be cooled. J. Personne observed that very finely divided red phosphorus inflames spontaneously in chlorine gas at ordinary temp., forming the pentachloride. A. Schrötter found that red phosphorus dissolves in chlorine-water more quickly than does ordinary phosphorus because there are more points of contact. W. Müller-Erzbach said that the affinity of chlorine must be greater than that of bromine for phosphorus because of the increased density of the products. Ordinary phosphorus was found by A. J. Balard, and C. Löwig to react with **bromine** gas with incandescence, forming the tri- or the penta-bromide. H. Rose, and V. Merz and W. Weith observed that when small pieces of yellow phosphorus are thrown into liquid bromine, the phosphorus takes fire and produces dangerous explosions. A. Schrötter found that red phosphorus also unites with bromine, at ordinary temp., with incandescence. Ordinary phosphorus unites with **iodine** at ordinary temp, and, according to C. L. Gazzaniga, at —24°, with the development of heat. The product inflames on contact with air. The reaction was studied by J. L. Gay Lussac, T. S. Traill, R. Boulouch, and K. I. Lissenko. According to A. Schrötter, the reaction does not occur at ordinary temp. with red phosphorus, but when warmed, di- and tri-iodides are formed without incandescence. F. Sestini studied what he called the *chemical adherence* of red phosphorus to the metalloids. He found that the reddish-violet soln. of iodine in carbon disulphide is decolorized by dry red phosphorus. R. N. Traxler and F. E. E. Germann observed that after decolorization, the phosphorus contains hydriodic and phosphorous acids, but no free iodine. N. E. Gordon and J. C. Krantz used benzene, toluene, xylene, carbon disulphide, carbon tetrachloride, and chloroform as solvents for the iodine. G. Gore said that yellow phosphorus is not affected by liquid **hydrogen chloride.** A. Oppenheim found that hot conc. **hydrochloric acid** reacts with red phosphorus in a sealed tube at 200°, forming phosphine, etc.; $2P+3HCl=PH_3+PCl_3$. H. Rose said that several **metal chlorides** give off chlorine when treated with yellow phosphorus. O. Damoiseau found that yellow phosphorus does not react with **hydrobromic acid;** but in a sealed tube at 100°–120°, phosphonium bromide is formed. He also found that **hydrogen iodide** reacts with ordinary phosphorus at room temp., forming both the tetraiodide, and phosphonium iodide. With red phosphorus there is no reaction at temp. below 100°—the little phosphonium iodide which may be produced probably comes from the presence of yellow phosphorus as impurity. A. Oppenheim found that when red phosphorus is heated with **hydriodic acid** in a sealed tube at 160°, crystals of phosphonium iodide are formed. A. J. Balard showed that **hypochlorites** oxidize yellow phosphorus to phosphoric acid. N. A. E. Millon found that ordinary phosphorus reacts explosively with **chlorine trioxide;** and F. Stadion, and H. Davy observed a similar result with **chlorine dioxide.** J. Schiel found that an aq. soln. of **chlorous acid** immediately dissolves red phosphorus. R. Böttger found that if a drop of a soln. of phosphorus in carbon disulphide be placed on some powdered **potassium chlorate,** an explosion occurs as the solvent evaporates. J. W. Slater said that phosphorous and phosphoric acids are formed when phosphorus is boiled with a soln. of potassium chlorate. A. Schrötter found that when red phosphorus is triturated with potassium chlorate there is a vigorous reaction, and under water in the presence of sulphuric acid, there is a vigorous reaction without incandescent phenomena. M. Bengieser, and A. Ditte found that yellow phosphorus reacts with **iodic acid,** forming phosphorus oxides, iodine, phosphoric acid, and possibly red phosphorus; and M. Bengieser showed that **periodic acid** oxidizes phosphorus to phosphoric acid. According to T. F. Buehrer and O. E. Schupp, when either white or red phosphorus is mixed with potassium iodate, and a few drops of water are added, the mixture reacts violently, sometimes even explosively, liberating iodine and evolving a considerable quantity of heat. When more water is initially taken, the rate of the reaction is greatly decreased. Since the reaction starts slowly and gradually speeds up, it appears probable that the iodine formed is responsible for the rapidity of the reaction rather than the iodate ion. Since phosphorous acid is formed to a considerable extent under these conditions, the rate of the entire reaction is determined solely, perhaps, by the rate at which it is oxidized to phosphoric acid. It is possible, however, under suitable conditions, to render this oxidation complete by means of potassium iodate. The reactions involved in the oxidation of phosphorus by potassium iodate have been found to take place as follows: $5P+3IO'_3+3H^{\cdot}+6H_2O=\frac{3}{2}I_2+5H_3PO_3$. This reaction is slow, and goes partially to phosphoric acid. $2P+3I_2+6H_2O=6H^{\cdot}+6I'+2H_3PO_3$. This reaction is quite rapid. $5H_3PO_3+2IO_3'=I_2+3H^{\cdot}+5H_2PO'_4+H_2O$. This reaction is very slow, as is strikingly shown by adding potassium iodate to a phosphorous acid soln. Very little iodine is liberated even on refluxing the soln. for some time. $H_3PO_3+I_2+H_2O=3H^{\cdot}+2I'+H_2PO'_4$. This reaction has been studied by B. D. Steel, who finds that "two distinct reactions occur . . . one of which preponderates in acid soln. and the other in the absence of strong acid," the one in acid soln. being catalyzed by hydrogen ion. This reaction has been shown by others to be slow, and to depend in large measure upon the conc. of the acid. It is probable that the oxidation of the phosphorous acid by iodine determines the rate of the reaction as a whole: $5I'+IO'_3+6H^{\cdot}=3I_2+3H_2O$. This reaction is known to be instantaneous and complete.

According to B. Pelletier,[5] F. Isambert, A. Levol, and R. Böttger, when a mixture of **sulphur** and yellow phosphorus is warmed the two elements unite in all proportions with vivid combustion, and powerful detonations. The reaction is quite complicated, and a series of sulphides is formed—*vide infra.* W. Wicke said that the two elements unite at ordinary temp. when sulphur is in contact with yellow phosphorus under water. A. Schrötter observed no reaction with a mixture of sulphur and red phosphorus until the temp. attained 230°; nor did W. Spring obtain any evidence of combination when the mixture was subjected to great press. J. Davy found that when in contact with phosphorus, **hydrogen sulphide** becomes charged with the vapour of that element. F. Sestini found yellow phosphorus to be soluble in liquid **sulphur dioxide** without chemical action. F. C. Vogel observed that yellow phosphorus inflames at ordinary temp. after it has stood some time in the vapour of **sulphur trioxide,** and sulphur is produced. R. H. Adie obtained a complex $3P_2O_4.2SO_3$ by the interaction of yellow phosphorus and sulphur trioxide. He said that when a piece of phosphorus is dropped into liquid sulphur trioxide, it reduces the latter with violence to sulphur dioxide, and is itself oxidized, forming a white, flocculent solid, $3P_2O_4.2SO_3$, floating in the liquid. When the pieces of phosphorus were large, the heat of combination raised the temp. of the phosphorus sufficiently high to ignite it. Heating phosphorus with sulphur trioxide in a sealed tube not only oxidizes all the phosphorus, but converts it at once into phosphoric anhydride, which forms a clear soln. in the trioxide. A. Oppenheim showed that yellow phosphorus inflames when placed in a capacious flask containing conc. **sulphuric acid** heated to its b.p.; and when yellow phosphorus and the conc. acid are heated in a sealed tube at 200°, sulphur dioxide is formed : $3H_2SO_4+2P=2H_3PO_3+3SO_2$. A. Schrötter, and J. Pelouze observed no reaction between cold conc. sulphuric acid and red phosphorus, but when heated nearly to the b.p., sulphur dioxide is evolved. K. Heumann and P. Köchlin showed that **chlorosulphonic acid** reacts feebly with yellow phosphorus at ordinary temp., but a vigorous reaction begins at 25°–30° with the evolution of sulphur dioxide and hydrogen chloride, and ending with an explosion; with red phosphorus, a higher temp. is needed to start the reaction—it is assumed that phosphoric acid and a phosphorus chloride are first formed, and that these react with the sulphuric acid which is formed at the same time so as to produce phosphoryl chloride. They also found that **sulphuryl chloride** when warmed with yellow phosphorus reacts only feebly, while with red phosphorus the reaction is vigorous: $3SO_2Cl_2+2P=2PCl_3+3SO_2$; and that **pyrosulphuryl chloride** reacts vigorously with red phosphorus, forming phosphorus trichloride, etc. H. F. G. de Claubry found that ordinary phosphorus reacts with **sulphur monochloride,** S_2Cl_2, at 40°, with the development of heat, and the formation of sulphur and phosphorus trichloride. F. Wöhler found that yellow phosphorus readily dissolves in sulphur monochloride, and there is a reaction which M. Chevrier symbolized : $3S_2Cl_2+2P=2PSCl_3+4S$. P. Nicolardot found that yellow and red phosphorus dissolves in sulphur monochloride. J. J. Berzelius[6] found that **selenium** and yellow phosphorus are miscible in all proportions at a temp. near the m.p. of phosphorus ; the reaction is probably a complicated one as in the case of phosphorus and sulphur. E. Baudrimont found that when phosphorus reacts with **selenium monochloride,** Se_2Cl_2, phosphorus trichloride and selenium are formed ; and a similar result is obtained with **selenium tetrachloride,** but if this agent is present in excess, the complex $2PCl_5.SeCl_4$ is formed. L. Rosenstein found that soln. of **selenates** are reduced to the element or a phosphide when boiled a few minutes with red phosphorus; while **tellurates** are but slowly reduced.

Phosphorus does not react directly with **nitrogen.** F. H. Newman[7] found nitrogen is absorbed by phosphorus in the electric discharge tube. J. Davy noticed that in contact with phosphorus, nitrogen becomes charged with the vapour of that element. C. L. Berthollet attributed the faint luminosity of nitrogen charged with phosphorus vapour to the presence of oxygen as an impurity ; he also thought that when the gas is charged with phosphorus vapour it increases by 0·025 part of its vol., but C. Brunner could not verify this—only a milligram of phosphorus is taken up by 1732 c.c. of gas. By passing an electric discharge through a mixture of phosphorus vapour and nitrogen, V. Kohlschütter and A. Frumkin obtained solid nitrides—*vide infra*, phosphorus nitride. F. W. Bergstrom found that both yellow and red phosphorus react readily with **potassium amide,** and with **sodium amide,** W. P. Winter said that sodium phosphide as well as oxyacids of phosphorus, and a phosphorus amide are formed. According to H. Davy, **nitrous oxide** has no action on phosphorus even when that element is touched with a piece of red-hot iron ; but if the iron be still hotter, the phosphorus may inflame, forming phosphorus pentoxide, free nitrogen, and some nitrogen peroxide ; J. Dalton found that feebly burning phosphorus is extinguished in **nitric oxide ;** but at a higher temp., say at the m.p. of phosphorus, there is a vigorous reaction with the formation of nitrogen peroxide, etc. ; P. L. Dulong found that phosphorus ignites when strongly heated in **nitrogen peroxide** and burns vigorously. These results were confirmed by A. Rosenheim and J. Pinsker. R. Weber found that phosphorus also burns vigorously in contact with warm **nitrogen pentoxide.** H. Reinsch showed that phosphorus is but slightly attacked by **nitric acid** in an open vessel, at ordinary temp., because it becomes covered with a film of oxide; if air be excluded, nitric oxide is evolved, and the liquid becomes blue. The boiling acid, out of contact with air, forms nitric oxide, which reacts with the phosphorus, forming nitrogen ; if air be not excluded, the nitric oxide is not decomposed in this way. C. F. Schönbein showed that the heat may be such that phosphorus vapour rises and burns in the vapour of the nitric acid. According to C. Wittstock, hot nitric acid of sp. gr. 1·2 dissolves yellow phosphorus with the evolution of nitric oxide and nitrogen, and the formation of phosphorous and phosphoric acids; when the liquid is evaporated, the phosphorous acid is oxidized, and phosphoric acid is alone obtained. The reaction was studied by C. W. G. Kastner, L. A. Buchner, J. Geiseler, J. von Liebig, C. F. Bärwald, etc. There is some doubt about the nature of the gases evolved. J. Personne, and E. J. Maumené found that ammonia is a product of the reaction; and C. Montemartini showed that on exposing red phosphorus to the action of an excess of 17·3, 28·3, and 68 per cent. nitric acid, at 13°–14°, until all is dissolved, one gram of phosphorus furnishes respectively 0·0739, 0·0824, and 0·0095 grm. of ammonia. The phosphorus requires some days to dissolve in dil. nitric acid, but dissolution is rapid in the conc. acid. A. Schrötter found that red phosphorus is more easily attacked by nitric acid than yellow phosphorus; and J. Böeseken found that with boiling nitric acid of sp. gr. 1·25, half the phosphorus is oxidized to phosphoric acid, and half to hypophosphoric acid. A. Siemens showed that when a soln. of yellow phosphorus in benzene is treated with dil. nitric acid, and warmed to drive off the benzene, phosphorus pentoxide is present in the remaining liquid; with red phosphorus, some picric acid is produced. E. Marchand showed that yellow phosphorus burns in molten **ammonium nitrate,** forming phosphorus pentoxide. J. W. Slater found that a mixture of a **nitrate** with yellow phosphorus detonates by percussion; and a soln. of **barium nitrate** is not affected when boiled with phosphorus. A. Schrötter observed red phosphorus does not detonate when triturated with potassium nitrate, but when warmed together there is a vigorous reaction.

According to C. W. Böckmann,[8] and A. Vogel, ordinary phosphorus forms a dark brown powder in **ammonia** gas, but the earlier observations were made on imperfectly purified phosphorus. T. A. Commaille reported that ammonia gas has no action on phosphorus, though A. F. de Fourcroy found that a mixture of ammonia and phosphorus vapour decomposes into nitrogen and phosphine when led through a red-hot tube. C. Hugot was able to distil phosphorus unchanged in an atm. of ammonia. Aq. ammonia exerts a slight action on yellow phosphorus, particularly if heated, phosphine and a black powder are formed; but, according to F. A. Flückiger, red phosphorus is not soluble in that menstruum. G. Gore, and E. C. Franklin found that yellow phosphorus dissolves slowly in liquid ammonia; while E. C. Franklin, and C. Hugot said that red phosphorus is insoluble in this menstruum. According to A. Stock and co-workers, liquid ammonia blackens scarlet phosphorus. A. Stock and co-workers, R. Schenck, and C. Hugot showed that ordinary phosphorus reacts very slowly with liquid ammonia in a sealed tube at ordinary temp.—the soln. first becomes red, and in a few days it deposits a black powder. The reaction is much more rapid if the temp. be raised. The black product is supposed to be a compound of phosphorus hydride, P_4H_2, with ammonia —either $HP_4.NH_4$, or $P_4H_2.NH_3$—and a similar compound obtained by R. Schenck is formed by warming a mixture of ammonia with the solid hydride. R. Schenck represented the reaction: $14P+7NH_3=3P_4H(NH_4)+2(HN:P.NH_2)$. When the solid hydride is treated with piperidine, $C_5H_{11}N$, an analogous product, $P_4H_2(C_5H_{11}N)$, is formed—*vide supra,* phosphorus amides and imides; and *vide infra,* hydrogen triphosphide. According to C. Hugot, **sodammonium,** $Na.NH_3$, reacts with red phosphorus, forming ammonium and sodamide together with a substance with the ultimate composition, $Na_3P_2H_3$, in yellow needle-like crystals; $6NH_3Na+2P=P_2H_3Na_3+3NaNH_2+3NH_3$. W. P. Winter found phosphorus acts energetically on **sodamide,** forming a chocolate-brown powder which when heated gives off ammonia and phosphine, forming sodium phosphite and hypophosphite. C. A. Lobry de Bruyn found that phosphorus reacts with **hydrazine,** forming a black substance; and it dissolves slowly in **hydrazine hydrate,** forming a soln. which is coloured yellow, red, brownish-violet, and finally black; a little phosphine is given off, and water precipitates brown flecks. According to J. W. Dito, yellow phosphorus slowly dissolves in hydrazine hydrate, and if the mixture be left in vacuo for a couple of months, a black substance mixed with white crystals is formed. The white crystals are either hydrazine phosphite or hypophosphite; and they can be extracted by solution in alcohol in which the black mass is insoluble. When the black mass is exposed to the air it becomes yellow, and when heated in hydrogen to 100° it forms a red product similar to that which is formed by the action of phosphorus on free hydrazine. The black mass is supposed to be a weak phosphorus acid free from nitrogen, and the red substance its hydrazine derivative.

H. Moissan[9] observed that yellow phosphorus heated in contact with **phosphorus trifluoride** *ne produit aucune réaction;* C. Poulenc found that with **phosphorus trifluodichloride,** at 120°, phosphorus trifluoride and trichloride are formed. P. Walden, and J. Böeseken found that yellow phosphorus is soluble in **phosphorus trichloride,** and J. H. Gladstone, that it reduces **phosphorus pentachloride** to the trichloride. B. Reinitzer and H. Goldschmidt reported the formation of a suboxide when yellow phosphorus is heated with **phosphoryl chloride** at 200°. G. S. Sérullas showed that yellow phosphorus dissolves in **thiophosphoryl** chloride; and J. H. Gladstone, in **thiopyrophosphoryl chloride.** C. Löwig found that yellow phosphorus dissolves in **phosphorus tribromide,** and E. Buck showed that the solubility of red phosphorus in that menstruum is diminished by long heating. He gave

	172°	185°	198°	218°
Initial conc. . . .	0·555	0·476	0·592	0·476
Final conc. . . .	0·374	0·397	0·416	0·592
Duration of heating .	34	24	18	17 hrs.

He found that with ordinary commercial red phosphorus with 98 per cent. phosphorus, there dissolved 0·056 and 0·108 per cent. of phosphorus in respectively 10 and 42 hrs., and with a finely-divided sample 0·092 and 0·116 per cent. phosphorus in 10 and 20 hrs. respectively. R. Schenck found that 100 grms. of phosphorus tribromide dissolved 0·2601 grm. of scarlet phosphorus at 172°, and 0·3634 grm. at 184°. E. Baudrimont showed that yellow phosphorus does not attack **phosphoryl bromide** at the b.p. L. Rosenstein found that soln. of **arsenates,** and **arsenic, antimony, or bismuth salts** are not reduced by boiling with red phosphorus; but W. Finkelstein found that a nitrobenzene soln. of arsenic trichloride is reduced by yellow phosphorus and arsenic is deposited. O. Ruff observed that phosphorus reacts with **antimony trichloride** in the presence of a little aluminium chloride. F. E. Brown and J. E. Snyder observed that **vanadium oxytrichloride** is without action on red or white phosphorus.

Moist yellow phosphorus in an atm. of **carbon dioxide** was found by A. R. Leeds[10] to produce some phosphine, but not to react with the carbon dioxide; and G. Gore showed that a sat. soln. of phosphorus in carbon disulphide has no action on carbon dioxide. J. Davy found that when in contact with yellow phosphorus, **carbon monoxide** and dioxide become charged with the vapour of that element; but A. F. de Fourcroy and L. N. Vauquelin thought that this was not the case with carbon dioxide. G. Gore showed that a mixture of **ammonium carbonate** and red phosphorus in a red-hot crucible forms phosphorus pentoxide. J. Davy found that phosphorus does not react with **carbonyl chloride** even at the sublimation temp. of that element.

J. W. Retgers said that yellow phosphorus is very soluble in **methylene iodide,** and red phosphorus insoluble. A. Vogel found that 100 parts of **carbon disulphide** dissolve 5·55 to 5·88 parts of yellow phosphorus; J. B. Trommsdorff said 12·5 parts; and R. Böttger, 5·0 parts. H. Giran also made some observations which E. Cohen and K. Inouye consider to be inaccurate; they found the solubility, expressed in grams of phosphorus per 100 grms. of soln., to be:

	−10°	−7·5°	−5°	−2·5°	0°	5°	10°
Solubility . .	31·40	35·85	41·95	75·00	81·27	86·30	89·80

The soln. sat. at —3·5° separates at —8° into two immiscible liquids. Some properties of soln. of yellow phosphorus in carbon disulphide were described by W. A. Lampadius, D. Brewster, R. Böttger, J. J. Berzelius, J. Murray, J. M. Eder, F. Scriba, E. Brunn, G. Gore, and O. Ohmann. M. Thiele found that when a soln. of yellow phosphorus in carbon disulphide is mixed with alcohol, the soln. remains clear, and in a few days deposits an orange-yellow, crystalline mass; ether forms a turbid liquid and deposits a lemon-yellow precipitate, probably yellow phosphorus. Chloroform, benzene, and ligroïn produce no perceptible change. Red phosphorus was found by A. Schrötter to be insoluble in carbon disulphide—*vide infra.* R. Boyle mentioned that yellow phosphorus dissolves in spirits of wine. According to J. A. Buchner, 100 parts of cold **ethyl alcohol** of sp. gr. 0·799 dissolve 0·312 part of phosphorus, and when warm, 0·417 part; G. F. Schacht gave 0·208 grm. per 100 grms. of absolute alcohol. The soln. has an acid reaction and contains some oxide. The chemical reaction which occurs when a mixture of phosphorus and alcohol is heated in a sealed tube at 250° was investigated by J. Berthaud, and when the mixture is exposed to light, by A. Pedler. J. B. Senderens studied red phosphorus as a catalytic agent in the dehydration of alcohols. A. Schrötter found red phosphorus to be insoluble in alcohol. A. M. Ossendowsky said that 100 grms. of **glycerol** of sp. gr. 1·256, at 15°–16°, dissolve 0·25 grm. of phosphorus. According to C. F. Bucholz, at 20°, 100 grms. of absolute **ether** dissolve 5 grms. of yellow phosphorus and ordinary ether, 0·417 grm.; while L. V. Brugnatelli found at 15·5°, respectively 1·25 and 0·417 grm. A. C. Christomanos found for the solubility of phosphorus in grams per 100 grms. of ether:

	0°	5°	10°	15°	20°	25°	30°	35°
Solubility . .	0·4335	0·62	0·85	0·90	1·04	1·39	1·75	1·9984

The sp. gr. of the soln. sat. at 15°, 20°, and 25° are respectively 0·7257 at 13°, 0·7187 at 19°, and 0·7283 at 19°. A. Schrötter found red phosphorus to be insoluble in ether. In light, the soln. soon becomes turbid, and decomposes. T. Svedberg said that both red and yellow phosphorus are perceptibly soluble in **isobutyl alcohol.** According to A. C. Vournasos, the vapour of yellow phosphorus at 200° acts on **sodium formate** in the presence of hydrogen, producing sodium oxalate, $(COONa)_2$, and phosphine: $2P+6HCOONa=3(COONa)_2+2PH_3$. G. Vulpius found that **acetic acid** dissolves about one per cent. of yellow phosphorus; C. Stich, 100 grms. of 90 per cent. acetic acid dissolves 0·105 grm.; and J. P. Boudet reported that vinegar dissolves phosphorus. G. Vulpius found that phosphorus is freely soluble in **stearic acid**; and C. Stich showed that at 15°, **oleic acid** dissolves 1·06 grm. of phosphorus per 100 grms. of acid. C. B. Mansfield said that yellow phosphorus is slightly soluble in cold and more soluble in hot **benzene**; and A. C. Christomanos, expressing the solubility in grams of phosphorus per 100 grms. of benzene, found:

	0°	5°	10°	20°	30°	40°	50°	60°	70°	81°
Solubility .	1·513	1·99	2·4	3·21	4·601	5·75	6·8	7·9	8·898	10·027

The soln. becomes turbid when exposed to air. A. Siemens said that the vaporization of a soln. of red phosphorus in benzene is quite different from that of a soln. of yellow phosphorus in that solvent. N. T. de Saussure found phosphorus to be soluble in 14 parts of hot **petroleum,** and less in cold; L. Crismer said it is slightly soluble in liquid **paraffin,** and C. Stich found 100 grms. of paraffin at 15° dissolve 1·45 grms. of yellow phosphorus. A. Colson said that ordinary phosphorus dissolves in **turpentine** only in the absence of air; and warm, rectified turpentine freely dissolves the phosphorus, which furnishes snow-white crystals on cooling; in the presence of air, the liquid becomes cloudy, and a white, odorous, colloidal mass is obtained: $(C_{10}H_{16}O_3)_2.H_3PO_4$; red phosphorus does not dissolve in turpentine even at 270°; with boiling turpentine, and other high boiling liquids, the red phosphorus may be partly converted into the yellow form, and it may then pass into soln. A. Schrötter stated that red phosphorus is slightly soluble in turpentine, but A. Colson said that this is not the case. There is no common solvent for yellow and red phosphorus; and since both varieties have the same vap. press., they would become identical in a common solvent. F. Molnar, A. Colson, and S. Minovici studied the chemical reaction between turpentine and phosphorus. As mentioned by R. Boyle, yellow phosphorus dissolves in a number of **essential oils,** and **fatty oils,** particularly when warm—*e.g.* oil of copaiba, oil of mandarin, oil of caraway, oil of aniseed, oil of cloves, oil of mace, etc. C. Stich said that at 15°, 100 grms. of oil of almonds dissolve 1·25 grms. of phosphorus. L. E. Jonas studied the chemical action of phosphorus on heated linseed oil, poppy oil, oil of almonds, and nut oil. F. Krafft and R. Neumann found that the arsenic in **triphenylarsine** is quantitatively displaced by phosphorus in a sealed tube at 300°; likewise also **triphenylstibine.** J. H. Hildebrand and T. F. Buehrer observed that the critical soln. temp. of liquid phosphorus with **decane** is over 300°; with **chlorobenzene,** 264°; **naphthalene,** 202°; **phenanthrene,** 200°; *p*-**dibromobenzene,** 163°; and with **carbon disulphide,** —6·5°. H. Wichelhaus investigated the chemical action of yellow phosphorus on **phenol, naphthol,** etc.; P. Bartolotti, on *rottlerin*—from the dyestuff kamala; and T. Weyl, the action of red phosphorus on **nitrobenzene.**

The slight solubility of yellow phosphorus in several other liquids has been noticed—*e.g.* ethyl chloride, ethylene chloride, chloroform, bromoform, chloral, acetic ether, acetone aldehyde, cacodyl sulphide, allyl thiocyanate, mercury methide, valerianic acid, amyl valerate, fusel oil, benzoyl chloride, stannic chloride, ethyl nitrite, nicotine, coniine, cavutchin, styrene, aniline, quinoline, creosote, etc. J. Hartmann found that 100 grms. of *bile* at 38·5° dissolved 0·02424 grm. of phosphorus, and more at a higher temp.

A. Kemp observed that yellow phosphorus slowly dissolves in liquid **cyanogen** and possibly forms cyanogen phosphide; but H. Hübner and G. Wehrhane observed no formation of that phosphide when cyanogen gas or **cyanogen chloride** is brought in contact with phosphorus vapour; C. Löwig observed a phosphorus bromide is formed by the action of **cyanogen bromide** on warm phosphorus; and F. Wöhler noticed that a phosphorus iodide is formed with incandescence when **cyanogen iodide** is brought in contact with molten phosphorus.

The action of phosphorus on the **metals** is discussed in connection with the phosphides—*vide infra.* According to A. Michaelis and M. Pitsch,[11] when ordinary phosphorus is warmed with an alcoholic soln. of **potassium hydroxide,** phosphine, hydrogen, and hypophosphorous acid are produced. It is maintained that the reaction proceeds in two stages: The phosphorus first dissolves, forming a dark red soln., and evolving a little gas which smells of phosphine; the filtered liquid gives a greenish-yellow precipitate when treated with hydrochloric acid, and this, when dried, consists of phosphorus tetritoxide: $4P+H_2O=P_4O+H_2$, and the nascent hydrogen converts a little phosphorus into phosphine. As the red soln. becomes warm, the tetritoxide passes into the hemioxide, $P_4O+H_2O=2P_2O+H_2$, and the hemioxide reacts with water, forming hypophosphorous acid: $P_2O+3H_2O=2H_3PO_2$—*vide infra,* phosphorus tetritoxide. By boiling an aq. soln. of alkali hydroxide with ordinary phosphorus, spontaneously inflammable phosphine is formed—*vide infra.* According to W. P. Winter, it is probable that sodium phosphide is one of the primary products of the action of phosphorus on sodium hydroxide, and this may, on hydrolysis, be the source of the phosphine. A. Schrötter found that when red phosphorus is boiled with potash-lye, the colour changes to a dark chocolate-brown, and phosphine, not spontaneously inflammable, is evolved. C. H. Burgess and D. L. Chapman said that finely-divided red phosphorus dissolves in an alcoholic soln. of alkali hydroxide; but A. Michaelis and K. von Arend, that red phosphorus is partly transformed into yellow phosphorus by grinding to a fine state of subdivision, and it then becomes soluble in the alcoholic potash-lye. Red phosphorus, whether commercial or prepared by heating phosphorous acid and phosphorus trichloride, is insoluble in aq. alcoholic potash; and when triturated with water for a long time, it is oxidized to the suboxide and acids of phosphorus. I. Guareschi found that **soda-lime** absorbs phosphorus vapour. W. Wicke said that a stick of phosphorus in contact with moist **copper oxide** partially reduces the oxide, forming in a few weeks crystals of copper. A. Schrötter said that copper oxide does not react when triturated with red phosphorus, but when heated together there is a vigorous reaction. There is, however, a vigorous reaction with **silver oxide** when the mixture is triturated or heated. A. Oppenheim found that **zinc oxide** is not attacked when heated with yellow phosphorus in a sealed tube; but B. Renault said that the vapour of phosphorus acts on zinc oxide at a red-heat, forming zinc phosphides, and similarly also with **cadmium oxide.** A. Schrötter found that when red phosphorus is triturated with **mercury oxide,** or one of the **lead oxides,** there is a vigorous reaction and likewise also when the mixture is warmed; **manganese dioxide** does not react by trituration, but it does so when warmed with red phosphorus. A. Thiel and H. Kölsch found phosphorus vapour reacts with **indium trioxide,** In_2O_3.

F. Wöhler found that when phosphorus was placed in a soln. of **copper sulphate,** phosphorus was deposited on the copper wire in contact with phosphorus, and W. Wicke obtained analogous results with **silver nitrate.** A. Vogel, and R. Böttger observed that ordinary phosphorus reduces copper from soln. of the **copper salts,** forming a small quantity of phosphide; and J. Nicklès found that a soln. of phosphorus in carbon disulphide precipitates the metal from soln. of copper salts. J. H. Gladstone noted the formation of phosphorus trichloride when yellow phosphorus acts on cupric chloride. T. Sidot showed that copper and copper phosphide are precipitated by yellow phosphorus from soln. of copper sulphate, and when all the copper has been precipitated from the soln., some hydrogen appears. J. W. Slater also observed the formation of copper, copper phosphide, and phosphoric acid when phosphorus acts on a soln. of copper nitrate. According to W. Straub, when phosphorus is placed in an aq. soln. of copper sulphate, it becomes black, and when removed from the soln. it does not react with the atm. oxygen. In the soln., the black coating becomes red on account of the deposition of metallic copper. Copper continues to be deposited as long as phosphorus is present, but in all cases the black deposit is first formed. This black substance is a copper phosphide, but its composition could not be accurately ascertained. As the reaction proceeds, the quantity of phosphoric acid in the solution continuously increases. The quantity of phosphorus which enters into reaction stands in a constant relationship to the amount of reduced copper sulphate only if the reaction is not carried to an end or if atm. oxygen is rigorously excluded. At the point where the reaction is just complete, the soln. contains sulphuric acid and phosphoric acid in the proportion 1 : 0·5, and consequently 1 mol. of phosphorus separates 2 mols. of copper from the copper sulphate soln. The oxygen which oxidizes the phosphorus must come from the water because the amount of sulphuric acid undergoes no diminution. The reduced copper is not acted on by the sulphuric acid, but is oxidized by the atm. oxygen, and the copper oxide dissolves to form copper phosphate, which is then reduced to phosphide. The dark film on the phosphorus is produced in a soln. containing only 1 gram-mol. of crystallized copper sulphate in 100,000 litres of water, and at a dilution 10 times as great the film is produced in the course of two months. F. Tauchert found hypophosphorous acid among the products of the reaction. J. B. Senderens found red phosphorus forms copper phosphide when in contact with a soln. of copper nitrate; and A. Granger, with a soln. of copper phosphite at 130°; and it also reacts with a soln. of copper chloride.

R. M. Bird and S. H. Diggs said that the main reaction of phosphorus on copper sulphate consists in the transfer of positive charges from copper ions to the phosphorus: $5Cu^{\cdot\cdot}+2P=2P^{\cdot\cdot\cdot\cdot\cdot}+5Cu$, and the immediate reaction of the phosphorus ions to form phosphoric acid. They found the ratio of the number of atoms of copper precipitated to those of phosphorus oxidized approximates 5 : 2. The phosphorus present as lower acids and phosphide is produced by secondary reactions. O. J. Walker showed that when a stick of phosphorus is placed in a soln. of a copper or silver salt, a reaction proceeds in two distinct stages. The first process is the formation of a black phosphide on the surface of the phosphorus; at the same time, the soln. is found to contain phosphorous acid. After a layer of the phosphide has been formed, metal begins to be deposited in a bright crystalline state, and phosphorus is oxidized to phosphorous and phosphoric acids. During this stage, approximately 4 eq. of the metals are deposited for every atom of phosphorus oxidized. The formation of a phosphide is due to the prior production of phosphine by the action of phosphorus on water, another portion of the phosphorus being simultaneously oxidized to phosphorous acid. This is evidenced by the exact parallelism which exists between the actions of phosphorus and phosphine on salt soln. of the heavy metals; only those metallic salt soln. which give phosphides by the action of phosphine are able to react with phosphorus. In confirmation, C. F. Cross and A. F. Higgins found that boiling water was decomposed by phosphorus, which was partly reduced to phosphine and partly oxidized to oxy-acids, and that, in the absence of oxygen, decomposition of the water took place only in the absence of certain metallic salts. O. J. Walker therefore suggests that the first stage in the action of phosphorus on the metallic salt takes place as follows (M and X representing an eq. of the positive and negative radicals, respectively): $2P+3H_2O=PH_3+H_3PO_3$, followed by $PH_3+3MX=PM_3+3HX$. The appearance of a deposit of the metal evidently depends on the preliminary formation of the phosphide. It has already been shown that the phosphides of silver and of other metals are capable of reacting with excess of the metallic salt to give the metal and phosphoric acid. The second stage, therefore, appears to be $M_3P+5MX+4H_2O=8M+5HX+H_3PO_4$. According to these equations, 4 eq. of the metal should be deposited for every atom of phosphorus oxidized, and this was the ratio actually obtained with silver and copper salts. The amount of phosphorous acid, however, was somewhat greater than that required by these equations. It is quite possible that this may be due to the following reaction proceeding to a small extent: $M_3P+3MX+3H_2O=6M+3HX+H_3PO_3$. This reaction consists essentially in the discharge of positive metal ions while phosphorus becomes oxidized, *i.e.* loses electrons. The ionic process may be represented as $M_3P+5M^{\cdot}=8M+P^{\cdot\cdot\cdot\cdot\cdot}$, the positive phosphorus ions reacting immediately with water to form phosphoric acid. According to this view, the $P^{\cdot\cdot\cdot\cdot}$-ions constitute an intermediate stage in the transition from phosphide to phosphoric acid. The discharge of $M^{\cdot}$-ions and the formation of $P^{\cdot\cdot\cdot\cdot\cdot}$-ions may occur at points widely separated from one another, provided that a metallic conducting path be available for the passage of the necessary electrons.

F. Wöhler, A. Vogel, W. Wicke, and R. Böttger found that ordinary phosphorus reduces soln. of **silver salts** to the metal, and W. Wicke, that a stick of phosphorus wrapped with silver wire and placed in a conc. soln. of silver nitrate gives in the course of a few weeks crystals of silver, while the phosphorus acquires a film of silver phosphide. J. Philipp showed that if phosphorus and silver nitrate soln. acidified with nitric acid be boiled, phosphorous and phosphoric acids and silver subphosphate are formed. T. Poleck and K. Thümmel found red phosphorus does not act on a conc. soln. of silver nitrate like yellow phosphorus, but it forms free acid and silver phosphide; J. B. Senderens represented the reaction: $2P+10AgNO_3+8H_2O=10Ag+2H_3PO_4+10HNO_3$—*vide supra*, for O. J. Walker's observations with copper and silver salts. L. Rosenstein found silver salts soln. are reduced to phosphide in a few minutes when boiled with red phosphorus. A. Granger observed no reaction between silver chloride and red phosphorus, similarly also with **gold chloride**; but L. Rosenstein found a few minutes' boiling with red phosphorus forms insoluble gold phosphide. B. Renault found that phosphorus vapour at a red-heat transforms **zinc carbonate** into zinc phosphides, and that it acts in an analogous way on **cadmium carbonate.** J. Nicklès also showed that a soln. of phosphorus in carbon disulphide precipitates zinc phosphide from soln. of **zinc salts.** L. Rosenstein found that cadmium salt soln. are not reduced by boiling with red phosphorus. A. Granger observed that red phosphorus does not react with **cadmium chloride** or with **mercuric chloride**; but if the soln. of a mercuric or mercurous salt is boiled a few minutes with red phosphorus, L. Rosenstein found that the salt is reduced to mercury. According to J. L. Gay Lussac and L. J. Thénard, yellow phosphorus forms phosphorus trichloride when it reacts with mercuric chloride; and C. Löwig observed that phosphorus bromide is formed when the vapour reacts with **mercurous or mercuric bromide.** F. Venturoli found that a yellow precipitate is formed when phosphorus acts on an alcoholic soln. of **mercuric iodide**: $6P+8HgI_2=4PI_3Hg_2+2PI_2$. A. J. Cenedella observed that yellow phosphorus becomes hot when mixed with **mercuric cyanide,** and, if an explosion does not occur, a white sublimate may be formed. A. Granger observed that when heated with **stannous sulphide,** red phosphorus forms the complex $SnP.2SnS$; analogous compounds are not produced with the sulphides of gold, cadmium, lead, or antimony. Red phosphorus does not react with **stannous chloride.** L. Rosenstein found **stannic salts** are partially reduced to stannous salts by a few minutes' boiling with red phosphorus; *but stannous salts* are not reduced. F. Wöhler, A. Vogel, W. Wicke, and R. Böttger found that **lead salts** are reduced by phosphorus to lead, and lead phosphide. W. Wicke found that when lead wire is wrapped on a stick of phosphorus, and immersed in a soln. of lead nitrate, a black film is deposited on the phosphorus, and lead crystals are formed. J. H. Gladstone observed no phosphorus trichloride is formed when phosphorus acts on lead chloride; and J. W. Slater found that when phosphorus is boiled with a soln. of lead nitrate, some lead phosphate is formed. L. Rosenstein found that soln. of lead salts are not reduced by boiling with red phosphorus.

G. Dragendorff showed that phosphorus reduces fused **borax** to boron; H. Moissan, that phosphorus reacts vigorously with **boron iodide**; W. Ramsay and R. W. E. MacIvor, that soln. of phosphorus and **antimony trichloride** in carbon disulphide form antimony phosphide. L. Rosenstein found that soln. of **permanganates** are reduced to manganous salts by a few minutes' boiling with red phosphorus; J. W. Slater observed that potassium permanganate soln. is reduced by yellow phosphorus to manganese dioxide; **potassium chromate and dichromate** at ordinary temp. slowly form chromium phosphate; **copper chromate** forms copper, copper phosphide, chromium phosphate, and phosphorous and phosphoric acids; but **lead chromate** is scarcely affected when boiled with phosphorus. E. Kopp noticed that potassium dichromate soln. is reduced by phosphorus in sunlight, or by warmth; and A. Stiassny found that when phosphorus is burnt under a bell-jar in the presence of a soln. of potassium dichromate, some of the dichromate is reduced, possibly owing to the formation of hypophosphorous acid. A. Schrötter said an aq. soln. of potassium dichromate does not act on red phosphorus; but combustion occurs when the dry salt is triturated or heated with red phosphorus. L. Rosenstein also found that soln. of dichromates are reduced to chromic salts by a few minutes' boiling with red phosphorus; under similar conditions, **molybdates** form quadrivalent molybdenum salts; and **vanadates,** tervalent vanadium salts. A. Granger found that red phosphorus reacts with **nickel chloride, cobalt chloride,** and with **ferric chloride**; and J. H. Gladstone showed that with yellow phosphorus, ferric chloride forms phosphorus trichloride. I. W. Schmoss found that on boiling an alcoholic soln. of **nickel nitrate,** sat. at 20°, with yellow phosphorus, a pale green precipitate of nickel triphosphate, $NiH_3P_3O_{10}.3H_2O$, is formed. L. Rosenstein found ferric salt soln. are reduced to ferrous salts by a few minutes' boiling with red phosphorus; **palladium salts** and **osmium salts** are reduced to metal or phosphide; **iridic salts** to iridous salts; but **chloroplatinates** are but slowly reduced.

The physiological action of phosphorus.—Yellow phosphorus was formerly used largely in the preparation of lucifer matches, and the workman exposed to the fumes suffered from necrosis or rotting of the bones of the upper and particularly of the lower jaw—*phossy-jaw*. The use of red phosphorus and improved hygienic conditions have done much to minimize the risks of chronic phosphorus poisoning.

Phosphorus vapour or rather that of phosphorus oxide—*vide supra*—acts locally on bone tissue wherever it is exposed; so long as it is covered with mucous membrane, the bone is not attacked. The vapour finds its way to the bone through decayed teeth, or the space left where a tooth is absent. The bone is first attacked with periostitis, and then with necrosis, which may spread far from the point originally attacked. The general health is then broken down. In healthy subjects, apart from its action on exposed bone, phosphorus vapour in the atm. of a match factory is not considered to be a toxic agent; the phosphorus absorbed is largely eliminated with the urine, and there may be slight albuminuria with no other perceptible pathological disturbance.

Acute phosphorus poisoning occurs when mixtures containing phosphorus are swallowed—*e.g.* vermin-killers or rat-pastes; and match-heads made with yellow phosphorus—through an accident, as when children suck and swallow the heads of matches, when a phosphorus rat-paste, or a mixture of match-heads and water is swallowed as a means of committing suicide, or with the object of procuring abortion by pregnant women. Finely-divided phosphorus can be absorbed as such without previously being oxidized. Immediately after swallowing, a disagreeable taste may be experienced; there may be intense pains in the throat, gullet, and stomach; retching and vomiting may follow; the throat and tongue may swell; and the breath may become phosphorescent. These preliminary symptoms may be delayed a number of hours. Gastro-intestinal irritation occurs—nausea, abdominal pain, and vomiting; the vomited matters may smell of phosphorus and be luminescent. There may be general depression; diarrhœa is rare. The subject may die of collapse, or may apparently recover; but in a few days, jaundice appears. General prostration follows, the liver is enlarged, and the abdomen distended. There may occur frequent vomiting of altered blood, diarrhœa with bloody stools, skin affections, retention of urine, sleeplessness, and headache. There may follow acute delirium and fever, coma, and death, or coma may set in and death follow in sleep without delirium. A. Tardieu[12] said that acute poisoning by phosphorus is sometimes rapid, sometimes slow; and the symptoms may take three distinct forms—a common form, a nervous form, and a hæmorrhagic form. In certain cases, these three forms may succeed each other, and may only constitute periods of poisoning; but each may show itself alone, and occupy the whole course of the illness produced by the poison. In the nervous form, there are strange creeping sensations about the limbs, painful cramps, repeated faintings, great somnolence, jaundice, acute delirium, lockjaw, convulsions, and death. In the hæmorrhagic form there is a great effusion of blood—nose, mouth, bladder, kidneys, and bowels. The liver swells, and is painful; there is great bodily weakness, and death may occur months after the poison has been taken. Recovery from phosphorus poisoning has occurred after 4–6 grains have been taken in the form of rat-poison, but 1½ grains have proved fatal.

In phosphorus poisoning, the proportion of blood corpuscles is increased. Numerous investigations have been reported on the subject. In general, the phosphorus stimulates metabolic changes as shown by the increased proportion of sulphates, phosphates, and nitrogen in the urine. The nitrogen comes from the excess of ammonia formed in the protein tissues; and appears in the blood neutralizing the lactic and acetone acids which appear in the blood because the phosphorus prevents the complete oxidation of glycogen, fat, and other non-nitrogenous products from the breaking down of the proteins. The fat is partially deposited in the liver and muscles and leads to fatty degeneration of the tissues. R. Schenck found that scarlet phosphorus is not poisonous; and M. de Vrij, and A. Postans, that dark red phosphorus is likewise non-toxic. H. Köhler and H. W. Schimpf, and L. E. Jonas said that turpentine is an antidote for phosphorus poisoning because it produces an inert complex, but V. Plavec denied the effectiveness of the alleged antidote. J. Stoklasa[13] and co-workers, O. Loew, H. Schmidt, T. Bokorny, M. Tsvett, and F. Scurti studied the action of phosphorus on plants.

The uses of phosphorus.—Phosphorus is employed in making bronzes, and for hardening alloys,[14] when it is added in the form of copper phosphide; it is used in gas analysis; and it has been used to a small extent medicinally as *oleum phosphoratum*—a soln. of one part of phosphorus in 98 of almond oil—and as *pilula phosphori*—a mixture of china clay, fat, and theobroma oil with one per cent. of phosphorus. Yellow and red phosphorus are chiefly employed in making matches. H. W. Walker discussed its use in making smoke screens.

§ 8. The Atomic Weight and Valency of Phosphorus

Phosphorus behaves both as a tervalent and as a quinquevalent element. As with nitrogen in ammonia, NH_3, phosphorus in phosphine, PH_3, is clearly tervalent, and all attempts to isolate phosphonium, PH_4, analogous with ammonium, NH_4, have proved abortive. In phosphorus trichloride, PCl_3, the element is tervalent, but F. A. Kekulé[1] argued that in phosphorus pentachloride, PCl_5, phosphorus is still tervalent, and that the pentachloride is a molecularly associated compound, $PCl_3.Cl_2$, because when heated, the molecule is dissociated: $PCl_5 = PCl_3 + Cl_2$. A. Wurtz, however, showed that if an excess of trichloride be present, the pentachloride can be vaporized without decomposition: and H. B. Baker's work showed that if the thoroughly dried pentachloride were vaporized its dissociation would be inappreciable. All this means that F. A. Kekulé's hypothesis is untenable, and that the phosphorus is quinquevalent in the pentachloride, as T. E. Thorpe showed to be the case with the pentafluoride which can be vaporized without decomposition. Following on the same argument, phosphorus appears to be septavalent in E. Baudrimont's hexachloroiodide, PCl_6I, and in A. Michaelis' trichlorotetrabromide, PCl_3Br_4; and undecivalent in M. Prinvault's and Michaelis' trichloroctobromide, PCl_3Br_8. The difficulty is here overcome by assuming, as in the analogous case of nitrogen, that the valencies of the halogens are greater than unity, so that the maximum valency of phosphorus is five. From the thermochemical data, J. C. Thomlinson argued that phosphorus is quadrivalent. A. A. Blanchard assumed that the non-polar valency of phosphorus in its pentachloride is five. A. Bilecki, A. P. Mathews, T. M. Lowry, H. Goldschmidt, and R. De discussed the valency of phosphorus.

The molecular formulæ of the tri- and pent-oxides are respectively P_4O_6 and P_4O_{10} as shown respectively by T. E. Thorpe and A. E. H. Tutton, and by W. A. Tilden and R. E. Barnett. It is assumed that the phosphorus in the trioxide is tervalent because hydrogen chloride converts the oxide into phosphorous chloride, PCl_3, and phosphorous acid, $P(OH)_3$; while phosphorus in the pentoxide is assumed to be quinquevalent because water converts the oxide into phosphoric acid, $O : P(OH)_3$. Since water converts phosphorus tetroxide, P_2O_4, into a mixture of phosphorous and phosphoric acids, it has been argued that one phosphorus atom is tervalent, and the other quinquevalent. In the alleged phosphorus tetritoxide, P_4O, of A. Michaelis, the phosphorus is assumed to be tervalent:

$$\begin{array}{c}P-P\\ \vdots\quad\vdots\\ P-P\end{array}\!>O$$

Two isomers with the empirical formula $(C_6H_5)_3PO$, were prepared by A. Michaelis and W. la Coste. The properties of neither agree with the formula $P(C_6H_5)_2.C_6H_4.OH$. The one—phenoxydiphenylphosphine—prepared by the action of diphenylchlorophosphine on phenol, $(C_6H_5)_2PCl+C_6H_5OH=HCl+(C_6H_5)_2P.O.C_6H_5$, is a thick, oily liquid; and the other—triphenylphosphine oxide—prepared by the action of water on triphenylbromophosphine bromide, $(C_6H_5)_3PBr_2+H_2O=2HBr+(C_6H_5)_3P : O$, is solid with the m.p. 153·5°. With this interpretation, phosphorus is tervalent in the one case and quinquevalent in the other. In the *cyclo*-tetramethylenephenyl phosphine

$$\begin{array}{l}CH_2.CH_2\\ CH_2.CH_2\end{array}\!>P-C_6H_5$$

of E. Krause, the phosphorus forms the fifth member of a heterocyclic system.

Assuming that the sp. vol. of phosphorus is constant, T. E. Thorpe argued that the phosphorus in phosphoryl chloride, $POCl_3$, must be tervalent, and the molecule unsymmetrical, $Cl.O.PCl_2$, and not $O : PCl_3$; but W. Ramsay and D. O. Masson showed that the assumption is not justified, for evidence, deduced from other elements, indicates that there is a change of sp. vol. in passing from singly to doubly linked atoms. R. M. Caven tried to demonstrate that the three valencies of tervalent phosphorus lie in one plane as in the analogous case of nitrogen; and he inferred that the centres of gravity of the three chlorine atoms lie at the angles of an equilateral triangle; and if an imaginary line is drawn through the centre of this triangle and at right angles to its plane, the centres of gravity, both of the phosphorus atom and of the oxygen atom are situated in this line. The question whether the phosphorus atom lies in the same plane as the three chlorine atoms remains undecided. The expectation that phosphorus should yield optically active derivatives, as in the case of nitrogen, has not been realized. R. M. Caven, and A. Michaelis were unable to obtain activity with compounds of the type: $PR_1R_2R_3R_4X$—and the latter thinks it possible that the failure was due to the poisonous action of the compounds on the ferments employed; but L. Lichtenstadt obtained $(CH_3)(C_2H_5)(C_6H_5)(C_6H_5.CH_2)PI$, as a bromocamphor sulphonate, which was dextrorotatory. J. Meisenheimer and L. Lichtenstadt prepared optically active phenylmethylethylphosphine oxide, $O : P(CH_3)(C_2H_5)(C_6H_5)$.

A. L. Lavoisier's[2] measurement of the increase in weight which occurs when phosphorus is fully oxidized corresponded with an at. wt. 28 (oxygen, 16); H. Davy's, 26·2; T. Thomson's, 24·5; and V. Rose's, 35. J. J. Berzelius at first gave 26·8, and later 31·36. The value approximating 31 is in harmony with the gas density law, the sp. gr. rule, the law of isomorphism, and the periodic law. J. J. Berzelius' value 26·8 was obtained from the analysis of the phosphates; and from the ratio 3P : 5Au obtained by precipitating gold from soln. of its salts by phosphorus he calculated the at. wt. 31·56, and from the ratio P : 5Ag, 31·32. P. L. Dulong obtained the erroneous result 27·3 from the ratio P : PCl_3; J. Pelouze, 32·3 from the ratio PCl_3 : 3Ag obtained by titrating phosphorus trichloride with a standard soln. of silver nitrate, while V. A. Jacquelain did even worse, obtaining from 19·7 to 48·7—results which A. Schrötter proved to be quite valueless. A. Schrötter burnt phosphorus in oxygen, and from the ratio 2P : P_2O_5, calculated 31·03 for the at. wt. of phosphorus; J. B. A. Dumas titrated phosphorus trichloride with silver nitrate, and calculated from the ratio PCl_3 : 3Ag, 31·04; J. D. van der Plaats from the ratio P : 5Ag, obtained by treating a soln. of silver nitrate with phosphorus, calculated 30·93; from the ratio Ag_3PO_4 : 3Ag, 30·99; and from the ratio 2P : P_2O_5 obtained by oxidizing phosphorus, he calculated 30·98. G. P. Baxter and G. Jones calculated 31·02 from the ratio 3AgBr : Ag_3PO_4, with the at. wt. of silver 107·86. G. Ter-Gazarian measured the density of phosphine, and hence calculated for the at. wt. of phosphorus 30·098. Considering all the available reliable determinations, F. W. Clarke gave 30·925 as the best representative value; B. Brauner, 31·0; while the International Table for 1925 gives 31·027.

The **atomic number** of phosphorus is 15. According to F. W. Aston,[3] there is only one **isotope** of phosphorus with an at. mass 31. E. Rutherford and J. Chadwick, F. Chalfin, G. Kirsch, and G. Kirsch and H. Pettersson, found evidence of **atomic disintegration** when the atoms of phosphorus are bombarded by α-particles from radium. N. Bohr represents the **electronic structure** of the atom, to show the number of electrons in the different orbits thus: (2) (4, 4) (2, 2, 1). C. G. Bedreag, H. Collins, L. Brüninghaus, T. M. Lowry, J. H. W. Booth, J. H. Jones, H. G. Grimm and A. Sommerfeld, H. Lessheim and R. Samuel, C. D. Niven, M. L. Huggins, B. Rosen, R. H. Ghosh, S. C. Biswas, and H. Burgarth made observations on the electronic structure of the phosphorus atom.

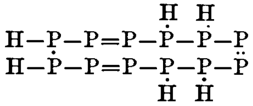
§ 9. Hydrogen Tritaphosphide, or Phosphorus Trihydride, or Phosphine

The action of hydrogen on phosphorus, and I. Langmuir's[1] observation that activated or atomic hydrogen reacts directly with phosphorus, forming phosphine, have been previously discussed. In 1783, P. Gengembre discovered that when phosphorus is boiled with a soln. of sodium or potassium hydroxide, a gas is evolved which is spontaneously inflammable when exposed to air; he called it *gas phosphorique inflammable.* Soon afterwards, but independently, R. Kirwan obtained the gas in a similar way; he called it *phosphatic hepatic air;* and considered it to be "phosphorus in an aerial state." In 1792, J. M. Raymond prepared it by heating phosphorus with slaked lime; and next year, G. Pearson obtained it by the action of water on the calcium phosphide obtained by heating quicklime with phosphorus in a luted vessel. In 1790, B. Pelletier had obtained a gas not spontaneously inflammable in air by the action of heat on phosphorous acid. There were thus two "phosphatic airs," and the text-books about that time—*e.g.* C. Girtanner, *Anfangsgrunde der antiphlogistischen Chemie* (Berlin, 1792)—called the gases *phosphuretted hydrogen.* The nature of the gas was established by H. Davy, who showed that its composition is analogous with that of ammonia. The compositions of the spontaneously inflammable gas, and the one which does not so inflame, were the same. P. Thénard showed that the cause of the spontaneous inflammability of the gas in air is due to the presence of a different phosphorus hydride as impurity. This constituent is liquid at ordinary temp. In 1826, J. B. A. Dumas showed that while the non-spontaneously inflammable gas has the empirical composition PH_3, or **hydrogen tritaphosphide**—commonly called **phosphine**—the empirical composition of the spontaneously inflammable constituent is PH_2, or **hydrogen hemiphosphide,** P_2H_4, *i.e.* $(PH_2)_2$. U. J. J. Leverrier in 1835 discovered a solid phosphorus hydride, which he represented by the formula PH, but P. Thénard showed that it is a **hydrogen diphosphide,** P_4H_2, or $(P_2H)_2$, or, according to A. Stock and co-workers, $P_{12}H_6$, *i.e.* $(P_2H)_6$, and H. Henstock assumed that this compound contains tervalent phosphorus, alternately + and —, with the ring structure:



$$\begin{array}{ccccccccccccc} &&&&&&&&\mathrm{H}&&\mathrm{H}&& \\ &&&&&&&&\cdot&&\cdot&& \\ \mathrm{H}&-&\mathrm{P}&-&\mathrm{P}&=&\mathrm{P}&-&\mathrm{P}&-&\mathrm{P}&-&\mathrm{P} \\ &&\cdot&&&&&&&&&&\cdot\cdot \\ \mathrm{H}&-&\mathrm{P}&-&\mathrm{P}&=&\mathrm{P}&-&\mathrm{P}&-&\mathrm{P}&-&\mathrm{P} \\ &&&&&&&&\cdot&&\cdot&& \\ &&&&&&&&\mathrm{H}&&\mathrm{H}&& \end{array}$$

These workers also obtained **hydrogen hemienneaphosphide,** P_9H_2, by the action of heat on the diphosphide. L. Hackspill also reported the solid **hydrogen hemipentaphosphide,** P_5H_2, to be formed by heating the hemienneaphosphide in vacuo at 80°, or by the action of dil. acetic acid on the corresponding alkali phosphides.

Some other hydrogen phosphides have been reported. Thus, T. A. Commaille[2] supposed *hydrogen triphosphide,* P_3H, to be formed by the action of aq. ammonia of sp. gr. 0·971, on ordinary, but not on red phosphorus; but this has not been confirmed—*vide supra*, action of aq. ammonia on phosphorus. N. Blondlot said that red phosphorus is produced by the action of ammonia on ordinary phosphorus; and F. A. Flückiger, that an ammine of phosphorous oxide is formed. G. Janssen also reported a crystalline *hydrogen ditritaphosphide*, P_2H_3, to be formed in hexagonal prisms when phosphorus is boiled with milk of lime. This report has not been verified.

The curious natural phenomenon known as *ignis fatuus* (*ignis*, fire; *fatuus*, wild, silly), or in France *feux follets*, often manifests itself as a more or less transient, flickering, " light, spirituous flame dancing on the heath," and it has been frequently reported to appear in darkness over peat-bogs, swamps, marshy districts, lagoons, damp cemeteries, recent battle-fields, stagnant waters, etc. The *ignes fatui* were at one time thought to be manifestations of the supernatural, and were called in Scotland *elf-candles* or *elf-fire*—in allusion to the elves or mischievous sprites which the superstitious believe haunt the wild places where the phenomenon usually occurs; in Wales, *corpse-candles*—in reference to their frequent appearance in cemeteries; and in England, *Jack-o'lanterns* or *Will-o'the-wisps*—in allusion to rustic fairy tales. Some rather brilliant displays have been reported at various times. The phenomenon is not to be confused with the light from luminous insects hovering over marshy grounds. The general idea is that the *ignes fatui* are due to the spontaneous ignition of bubbles of gas containing traces of phosphuretted hydrogen evolved, along with other gases, during the decomposition of animal substances under water or in damp soils. Bubbles of gas no doubt escape in the day as well as at night, but the feeble light which is emitted when a gas bubble containing a little phosphuretted hydrogen comes in contact with the air, is visible only in dusk or in darkness. In support of this B. von Dybkowsky [3] said that phosphine is produced when dried blood or gastric juice is kept at 35°–41° for a long time; and A. Gautier and A. Étard, that it is produced during the putrefaction of proteins. E. Pozzi-Escott observed that the hydrogenation of phosphorus to phosphine occurs when hydrogenases act by diastatic fermentation on the element. J. N. Lockyer found phosphine amongst the gases expelled when some minerals are heated in vacuo. W. Steffens reported that the mortar in one part of an old building gave phosphine on treatment with water. The phosphine is said to have been derived from calcium phosphide thought to have been formed from the calcium phosphate originally present, being reduced electrolytically from a short circuit.

The formation and preparation of phosphine.—The modes of preparation are sometimes divided into (i) those which furnish the spontaneously inflammable gas, *i.e.* the gas inflames when it comes in contact with air at ordinary temp. and press.; and (ii) those which furnish the non-spontaneously inflammable gas which takes fire only at an elevated temp. or under a reduced press. Since these divergent qualities are determined by the presence or absence of traces of hydrogen hemiphosphide, $(PH_2)_2$, and since this impurity may or may not be removed from the gas by suitable treatment, there are no essential differences in the modes of preparation of the spontaneously accendible and non-accendible forms of the gas. T. Graham [4] made a special study of the conversion of the spontaneously inflammable gas into the non-accendible form. He said:

> The accendible form of the gas passes into the other one when it is confined over water containing air—no phosphorus is produced during the conversion—the presence of cork or gypsum with air in their pores suffices for the conversion. The presence of about 5 vols. of hydrogen; 2 vols. of carbon dioxide; 1 vol. of ethylene; 0·5 vol. of hydrogen sulphide; 0·2 vol. ammonia; 0·1 vol. nitric oxide; 0·05 vol. hydrogen chloride per vol. of phosphine destroys the spontaneous inflammability of the gas—the mixture with 0·1 vol. of nitric oxide gives red fumes in air, and a mixture with 0·05 vol. of nitric oxide takes fire with a kind of detonation while the bubble is rising in air. When the sides of the containing vessel are moistened with conc. phosphoric, sulphuric, or arsenic acid, the conversion occurs in 2–3 minutes and the change is attended by a mutual decomposition. Arsenious acid acts quickly, so does mercurous oxide; but potash-lye requires some hours to do the work. Potassium alone, or in the form of an amalgam with one part of

potassium in 350,000 parts of mercury, destroys the spontaneous inflammability in a few minutes. Freshly ignited charcoal quenched in mercury, not water, adsorbs a large proportion of the gas but renders the remainder not spontaneously inflammable in half an hour ; when the charcoal is heated, the evolved gas is the non-accendible form ; burnt clay acts similarly. Spongy platinum, mercuric oxide, and a soln. of ferrous sulphate do not destroy the quality.

J. B. A. Dumas thought that the gas which is readily accendible has the composition PH_3, and that which is not so, the composition PH_2 ; but H. Rose showed that this hypothesis is wrong ; the density and composition of both gases are the same. T. Graham concluded that the spontaneous inflammability is due to the presence of some impurity—probably a lower oxide of phosphorus, not nitrogen trioxide. U. J. J. Leverrier said that the impurity is probably another hydrogen phosphide—P_2H_4—and P. Thénard proved that this hypothesis is probably correct, although M. Bonet y Bonfil tried to show that the inflammability is probably due to the presence of phosphorus in both gases but in different states. J. W. Retgers, D. Amato, etc., established the original suggestion of U. J. J. Leverrier, and P. Thénard.

The most difficult impurity to eliminate is hydrogen, which is nearly always formed simultaneously with the phosphine. G. Ter-Gazarian found the most effective method of purifying the gas from traces of other hydrogen phosphides, and from hydrogen is repeated liquefaction and fractional distillation of the liquid. F. M. G. Johnson recommended alumina, dehydrated at a low temp., as a desiccating agent for the gas.

The impure, spontaneously inflammable gas was prepared by P. Gengembre by boiling a conc. soln. of potassium hydroxide with yellow phosphorus. A similar process was employed by R. Kirwan, J. B. A. Dumas, T. Weyl, T. A. Commaille, R. Schenck, H. Rose, and F. Brandstätter. The reaction was studied by H. Rose, who found that some gas is given off even at 15°. The main reaction taking place when yellow or red phosphorus is boiled with potash-lye results in the formation of potassium hypophosphite and phosphine: $4P+3KOH+3H_2O=3KH_2PO_2+PH_3$, some hydrogen hemiphosphide is formed by a side reaction: $6P+4KOH+4H_2O=4KH_2PO_2+P_2H_4$; part of the hemiphosphide may decompose into the diphosphide, $15P_2H_4=P_{12}H_6+18PH_3$. Much free hydrogen is associated with the phosphine. According to J. B. A. Dumas, it is difficult to make phosphine by this process without, say, 60 per cent., or, according to A. W. Hofmann, 55 per cent. of hydrogen : $2P+2KOH+2H_2O=2KH_2PO_2+H_2$; less hydrogen is formed the greater the conc. of the alkali-lye. According to P. L. Dulong, near the end of the reaction, more hydrogen is formed by the oxidation of the hypophosphite to phosphate : $KH_2PO_2+2H_2O=KH_2PO_4+2H_2$, and to pyrophosphate: $2KH_2PO_2+3H_2O=4H_2+K_2H_2P_2O_7$. It has also been suggested that potassium phosphide, K_3P, and phosphorous acid, $P(OH)_3$, are first produced : $4P+6KOH\rightarrow 2K_3P+2P(OH)_3$; and that the phosphorous acid reacts with the excess of potassium hydroxide always present, forming potassium monohydrogen phosphite : $2P(OH)_3+4KOH\rightarrow 2K_2HPO_3+4H_2O$, while the potassium phosphide reacts with water: $2K_3P+7H_2O\rightarrow PH_3KH_2PO_2+5KOH+2H_2$. The main action of phosphorus on boiling potash-lye is then symbolized by combining these equations into one: $4P+5KOH+3H_2O\rightarrow PH_3+2H_2+KH_2PO_2+2K_2HPO_3$. T. von Grotthus regarded the mixture of gases produced by the action of potash-lye on phosphorus as a special gas which he called *Phosphorkohlenwasserstoff gas*. Other alkali hydroxides can be used. W. R. Hodgkinson said that the reaction is not hindered by glycerol. In place of alkali-lye, J. M. Raymond used dry calcium hydroxide, but H. Rose showed that a greater proportion of hydrogen is then formed ; and J. B. A. Dumas, using milk of lime in place of alkali-lye, obtained a gas with 89–90 per cent. of free hydrogen. Hydroxides of the other alkaline earths, or of zinc or iron (ous), can be used. The following is a modernized form of P. Gengembre's experiment :

A conc. soln. of sodium or potassium hydroxide and yellow phosphorus is placed in the flask fitted with delivery tube, etc. A current of an inert gas—coal gas, hydrogen, or carbon dioxide—is first led through the apparatus to drive out the air; or, as recommended by F. Brandstätter, a few drops of ether are introduced into the flask, and as this vaporizes it drives out the air. If the temp. of the mixture be raised very slowly the expulsion of the air in this way is not necessary since the oxygen is removed by the first bubbles of phosphine. E. Löwenhardt fills the generating flask to within "4 c.c." of the stopper. The mixture in the flask is then heated. The phosphorus reacts with the alkali-lye, forming alkali hypophosphite, and gaseous phosphine, associated with some impurities. The mixture of gases so prepared is sometimes called *phosphuretted hydrogen.* Each bubble of gas rises to the surface of the water, and, when it comes in contact with the air, ignites with a slight explosion and burns with a brilliant flash of light, forming a vortex ring of phosphorus pentoxide.

The degree of the spontaneous inflammability of phosphine depends upon the conditions under which the gas has been prepared. In all methods for making phosphine, excepting the phosphonium halide process, A. W. Hofmann found that the gas may contain up to 90 per cent. of hydrogen, while the action of potash-lye on yellow phosphorus gave a gaseous mixture of phosphine with 60 to 90 per cent. of hydrogen, conc. alcoholic potash-lye gave a mixture with 55 per cent. of hydrogen. It does not appear possible to prepare a gas with more than 50 per cent. phosphine by the action of aq. or alcoholic potash-lye on phosphorus. H. Rose showed that the gas obtained by the action of alcoholic potash-lye on yellow phosphorus is mixed with hydrogen and alcohol, and is not usually spontaneously inflammable; and W. R. Hodgkinson showed that an alcoholic soln. of sodium ethoxide acts on yellow phosphorus, giving a fairly pure gas which is not spontaneously inflammable. P. Thénard, and D. Amato showed that phosphuretted hydrogen loses its property of spontaneously inflaming in air if it be treated with conc. hydrochloric acid, or exposed to sunlight. The contained hemiphosphide is thereby decomposed.

Phosphine is obtained by the action of water or dil. acids on the phosphides of the alkalies or alkaline earths. P. Thénard made phosphine by the action of water or dil. acids on the phosphides of the alkalies; and A. Joannis, by the action of water or heat on the dihydromonophosphides, *e.g.* KPH_2 or $NaPH_2$. The reaction between water and, say, sodium phosphide is probably more complex than is represented by the equation: $Na_3P+3H_2O=PH_3+3NaOH$, because some hypophosphite and phosphite appear among the products of the reaction; W. P. Winter suggested the complex equation: $4Na_3P+14H_2O=2PH_3+NaH_2PO_2$. The formation of the spontaneously inflammable gas is explained by assuming that the normal phosphide is contaminated with some of the hemiphosphide. C. Hugot obtained phosphine by the action of water or dil. acids on sodium trihydrodiphosphide, $Na_3H_3P_2+3H_2O=3NaOH+2PH_3$, or $Na_3H_3P_2+3HCl=3NaCl+2PH_3$; or by heating the same substance to 100° under reduced press. At higher temp. more hydrogen and less phosphine is produced until at 200°–300° only phosphine appears. W. P. Winter found that phosphine is produced by the action of water on the chocolate brown substance obtained by treating sodamide with yellow phosphorus. G. Pearson, P. Thénard, C. Matignon and R. Trannoy, B. König, T. Thomson, and R. Lüpke prepared phosphine by the action of water or dil. acid on calcium phosphide. H. Moissan found that calcium phosphide made by heating calcium phosphate in an electric furnace yields a fairly pure phosphine. As H. Rose has shown, some solid hydrogen phosphides are produced when the phosphides of the alkalies or alkaline earths are treated with acids. J. B. A. Dumas said that when barium phosphide is used, 43 per cent. of hydrogen may be present; with calcium phosphide and water, 13 per cent.; and with calcium phosphide and dil. hydrochloric acid, 7 per cent. of hydrogen is present at first, and later, 13 per cent. H. Buff obtained a similar result with calcium phosphide and water; and A. W. Hofmann said it is very difficult by this process to obtain a gas free from hydrogen. R. Lüpke found that phosphine is obtained by the action of water or dil. acids on magnesium phosphide;

H. Schwarz, P. Jolibois, F. Brandstätter, H. Rose, and R. Lüpke used zinc, tin, or iron phosphide and dil. sulphuric or hydrochloric acid; P. Kulisch used cadmium phosphide and dil. acids; P. Kulisch, cadmium phosphide; H. Fonzes-Diacon, C. Matignon, and F. Bodroux, aluminium phosphide; and R. Lüpke, *copper phosphide*, and iron phosphide—in both cases the reaction is slow, but R. Böttger used an alcoholic soln. of potassium cyanide and obtained a larger yield. A. W. Hofmann found that the gas is accompanied by variable amounts of hydrogen. According to F. Bodroux, temp. is a controlling factor in determining the amount of hydrogen obtained from the decomposition of the phosphides by water. Magnesium and aluminium phosphides, when decomposed by iced water, slowly give off phosphine with hydrogen; but when the temp. exceeded 50° or if acids were employed, the phosphine was contaminated with much hydrogen. H. Blumenberg obtained the nascent hydrogen, for the production of phosphine, electrolytically.

W. Ipatieff and W. Nikolaieff observed the formation of phosphine when white phosphorus is heated with hydrogen in a sealed tube at 360°; and when water-gas at 400 atm. press. acts on lead phosphate. J. Brössler said that if white phosphorus be added to a mixture of zinc and dil. sulphuric acid, in a short time, spontaneously inflammable phosphine will be produced; and if a conc. soln. of alkali hydroxide and zinc be mixed with yellow phosphorus, the spontaneously inflammable gas will be given off at about 60°; if the temp. be below 20°, the gas evolved is not spontaneously inflammable. H. Davy, and L. Dusart showed that the gas obtained by the action of zinc and dil. acids on yellow phosphorus contains phosphine, although J. B. A. Dumas questioned the fact. D. Vitali observed that the presence of mercuric chloride retards the formation of phosphine. J. Brössler obtained phosphine by the action of hydrochloric acid and a few drops of nitric acid on tin in the presence of yellow phosphorus. The formation of phosphine during the action of ammonia, and of water on yellow phosphorus has been indicated in connection with the chemical reactions of phosphorus.

According to A. Oppenheim, phosphine is formed when red phosphorus is heated in a sealed tube with conc. hydrochloric acid at 600°, possibly by the reactions $3HCl+2P=PH_3+PCl_3$; and $PCl_3+3H_2O=H_3PO_3+3HCl$. Hydrobromic acid acts more slowly than hydrochloric acid; and with hydriodic acid, the sealed tube can be heated to 160°. A. Oppenheim also heated phosphorus with syrupy phosphoric acid in a sealed tube at 200°, and found that hypophosphorous acid is formed which passes into phosphine and phosphoric acid. T. Weyl represented the action of hydrogen dioxide on red phosphorus by $6H_2O_2+4P=4P(OH)_3$; and $4P(OH)_3=PH_3+3H_3PO_4$; and C. A. Lobry de Bruyn noticed the smell of phosphine when hydrazine hydrate acts on yellow phosphorus. W. B. Grove also obtained a little phosphine by passing an electric current through moist molten phosphorus; if under reduced press., no phosphine is formed, presumably owing to the removal of the moisture. U. J. J. Leverrier observed that phosphine is formed when phosphorus tetritoxide is treated with conc. potash-lye; and B. Reinitzer and H. Goldschmidt, H. Biltz, and A. Michaelis and M. Pitsch obtained a similar result. B. Pelletier, and H. Davy obtained phosphine by heating phosphorous acid, and P. L. Dulong, H. Rose, J. B. A. Dumas, and A. W. Hofmann by heating hypophosphorous acid: $4H_3PO_2=2PH_3+2H_3PO_4$. According to J. J. Berzelius, phosphine is also formed when aq. soln. of phosphites are reduced by zinc or iron; F. Wöhler used zinc with a mixture of phosphorous and sulphuric acids. A. W. Hofmann found that pure phosphorous acid gave a gas with 6 per cent. of hydrogen. R. Lüpke obtained phosphine when phosphites or hypophosphites are reduced by nascent hydrogen. H. Rose said that when alkali hypophosphite is heated the spontaneously inflammable gas evolved may be readily inflamed or it may inflame with difficulty—this, said C. F. Rammelsberg, depends on *ganz zufälligen Umständen.* H. Rose added that the gas is accompanied by hydrogen and the vapour of phosphorus. Contrary to W. Herapath's statement, R. Fresenius said that the phosphates are not reduced by nascent hydrogen, but W. A. Ross maintained that metaphosphates are reduced to phosphine when heated with zinc.

According to G. S. Sérullas, the gas obtained by decomposing phosphonium bromide with water is of a high degree of purity ; and, according to A. W. Hofmann, the best process for phosphine of a high degree of purity is to treat phosphonium iodide with water :

Phosphine is made by mixing pieces of phosphonium iodide the size of a pea with pieces of glass in a flask. The flask is closed with a 2-hole rubber stopper carrying a stoppered-funnel and a delivery tube. A soln. of potassium hydroxide in twice its weight of water is added from the stoppered funnel very slowly. No heating is necessary. If the potash-lye be added too quickly the gas may be self-accendible owing to its containing some liquid hydride ; the gas at the end of the operation is also liable to be self-accendible. The reaction is symbolized: $PH_4I+KOH \rightarrow H_2O+KI+PH_3$. Ten grams of phosphonium iodide will give from 1·3 to 1·4 litres of the gas. Water can be added instead of potash-lye ; a 100 c.c. gas generating flask containing 20 grms. of phosphonium iodide, is fitted with a two-holed rubber stopper. One tubulure holds a stoppered funnel with a capillary tube bent so as to direct the stream of water to the side of the flask, and not directly on the iodide. The gas passes through conc. hydrochloric acid to remove liquid phosphide ; through conc. potash-lye to remove hydrogen chloride and iodide ; over calcium chloride and phosphorus pentoxide to dry the gas. J. Messinger and C. Engels say that it is best to mix the phosphonium iodide with ether, and add water from the separatory-funnel.

M. Bretschger, and B. Lepsius prepared the gas by this process; and C. F. Rammelsberg reported that even here the product may be spontaneously inflammable in air. P. de Wilde found the gas among the products of the action of phosphonium iodide on phosphorus tribromide ; E. and P. Fireman, among the products of the action of antimonic or stannic chloride on phosphonium iodide ; and R. Boulouch, among the products of the action of conc. potash-lye on phosphorus tetritaiodide. A. Stock and co-workers said that small quantities of fairly pure phosphine can be readily obtained by heating the diphosphide, $P_{12}H_6$, under reduced press. T. E. Thorpe and A. E. H. Tutton obtained phosphine by dissolving diamidophosphorous acid, $P(OH)(NH_2)_2$, in dil. hydrochloric acid. A. C. Vournasos showed that phosphine can be prepared by heating sodium formate at 200° in an atm. of hydrogen and phosphorus vapour: $6HCOONa+2P=2PH_3+3(COONa)_2$; and also by heating sodium formate with sodium phosphite or phosphate. M. E. Pozzi-Escott observed that phosphorus is hydrogenized by the hydrogenases—*e.g.* philothion.

The physical properties of phosphine.—At ordinary temp., phosphine is a colourless gas, which can be condensed to a colourless liquid, or frozen to a white solid. H. Rose[5] gave 1·146 for the **relative density** (air unity) ; J. B. A. Dumas, 1·1214 ; and H. Buff, 1·165. The theoretical value for PH_3 is near 1·175, and the lowered values are due to the presence of admixed hydrogen. G. Ter-Gazarian obtained for the purified gas the relative density 1·1829. The early determinations of the weight of a litre of gas are vitiated by the contamination of the phosphine with hydrogen ; G. Ter-Gazarian gave 1·5295 grms., and M. Bretschger, 1·5293 grms., for the **weight of a litre** of the gas under normal conditions. The literature was reviewed by M. S. Blanchard and S. F. Pickering. D. McIntosh and B. D. Steele gave 0·744 for the **specific gravity,** *D*, of the liquid at its b.p. $-86·2°$; and

	−107°	−101°	−97°	−91°	−87°	−81°	−79°
Sp. gr. . .	0·761	0·756	0·753	0·748	0·745	0·740	0·739

The **molecular volume** at the b.p. is 45·7 ; E. Rabinowitsch gave 47 for the mol. vol. R. Lorenz and W. Herz studied this subject. A. O. Rankine calculated $0·911 \times 10^{-15}$ sq. cm. for the mean collision area of phosphine. The sp. gr.,

D, at the temp., T° K., is $D=0{\cdot}744+0{\cdot}0005952(186{\cdot}8-T)$. D. McIntosh and B. D. Steele gave:

	−105·9°	−101·2°	−97·6°	−93·1°
Sp. gr. of liquid . .	0·760	0·756	0·753	0·746
Sp. gr. of vapour . .	0·00079	0·00101	0·00122	0·00151

S. Skinner gave for liquid phosphine:

	49·4°	44·4°	39·4°	29·4°	24·6°	18·4°	8·4°	2·4°
Press. .	62·4	56·1	50·8	41·3	37·1	32·6	27·2	23·4
Sp. gr. .	0·417	0·469	0·502	0·536	0·545	0·559	0·595	0·618

The **surface tension** of liquid phosphine was found by D. McIntosh and B. D. Steele to be:

	−105·9°	−101·2°	−97·6°	−93·1°
Surface tension, σ . . .	22·783	22·095	21·553	20·798 dynes per cm.
Mol. surface energy, $\sigma(MV)^{\frac{2}{3}}$.	287·2	279·6	273·4	265·4 ergs.

A. O. Rankine and C. J. Smith gave for the **viscosity** of phosphine gas 0·0001070 at 0°, 0·0001129 at 15°, and 0·0001450 at 100°; and for the constant C, 290. They calculated the area presented by the molecules for mutual collision to be $0{\cdot}911\times10^{-11}$ sq. cm. E. Briner measured the **compressibility** as represented by the relative values of pv at different temp. and press. He found:

24·6°	p .	1	10	15	20	25	30 atm.
	pv .	1	0·97	0·98	0·80	0·75	0·70
33·6°	p .	1	10	15	20	30	40 atm.
	pv .	1	0·94	0·89	0·85	0·77	0·62
46·2°	r .	1	30	35	40	45	50 atm.
	pv .	1	0·79	0·75	0·71	0·66	0·61
54·4°	p .	1	15	35	45	55	65 atm.
	pv .	1	0·92	0·80	0·72	0·61	0·47

According to M. Faraday, phosphine can be condensed to a transparent, colourless liquid by cooling it in a bath of carbon dioxide, when under a press. of 2–3 atm.; and K. Olschewsky cooled the gas to −75° by a mixture of solid carbon dioxide and ether, but no liquefaction occurred; at −90°, the gas condensed to a liquid which did not freeze at −110°. The gas can be readily liquefied in a tube cooled by liquid ethylene to −102·5, and it can then be frozen at −133·5° to a transparent, crystalline solid. S. Skinner found that the gas can be readily liquefied at ordinary temp. when under 30 atm. press. K. Olschewsky gave −85° for the **boiling point**; F. Henning and A. Stock, −87·43° at 760 mm.; and D. McIntosh and B. D. Steele, −86·2°. K. Olschewsky gave −132·5° for the **melting point.** D. McIntosh and B. D. Steele found the **vapour pressure** of the liquid to be:

	−105·9°	−101·2°	−97·7°	−93·1°	−86·6°
Vap. press.	237	319	393	498	719 mm.

F. Henning and A. Stock found rather smaller values, $\log p=-845{\cdot}57T^{-1}+1{\cdot}75\log T-0{\cdot}0061931T+4{\cdot}61480$. E. Briner gave 38·5 atm. at 25°; 46·5 atm. at 35°; 57 atm. at 45°; and 64·5 atm. at 51·3°. A. Stock and co-workers gave data between −87° and −111°. The **heat of vaporization** is $17{\cdot}2\times10^{10}$ ergs. S. Skinner gave 54° for the **critical temperature,** and 70·5 atm. for the **critical pressure;** corresponding data by A. Leduc and P. Sacerdote are respectively 52·8° and 64 atm.; by E. Briner, and P. A. Guye, 51·3° and 64·5 atm. S. Skinner gave 4·6 for the **critical volume.** J. Ogier gave for the **heat of formation,** (P,3H) = −36·6 Cals.; and for gaseous phosphine, −11·6 Cals. M. Berthelot and P. Petit obtained a similar result; while R. de Forcrand gave $(P_{gas},3H)-9{\cdot}1$ Cals.; and P. Lemoult gave for yellow phosphorus, and gaseous phosphine, −5·8 Cals.; he also gave for the **heat of combustion,** 310 Cals. at constant vol., and 311·2 Cals. at constant press. D. H. Drummond calculated for the **free energy** of the reaction $\frac{3}{2}H_{2gas}+\frac{1}{4}P_{4gas}=PH_{3gas}$, $-16486{\cdot}5+3{\cdot}72T\log T+0{\cdot}0004T^2+0{\cdot}0_67T^3+2{\cdot}52T$, or

$-RT \log K$, where $K = p_{PH_3}/p_{H_2}^{\frac{3}{2}} p_{P_4}^{\frac{1}{4}}$. The free energy of the formation of phosphine from hydrogen and solid phosphorus at 25° is −3296·0 cals. The entropy change in the reaction calculated from the free energy equation is −27·72; so that the **entropy** of phosphine at 25° is 52·4 units. J. C. Thomlinson compared the heats of formation of the trihydrides of the nitrogen-antimony family of elements.

Phosphine is decomposed by **heat** into phosphorus and hydrogen. D. M. Kooij [6] measured the progress of the reaction $2nPH_3 = 2nP + 3nH_2$ from the change in the press. of the gas after different intervals of time. If p_0 denotes the original press. of the gas with a mols of PH_3 in unit vol.; and p the press. of the mixture when x mols of a have decomposed, since for every 2 vols. of phosphine which disappear, 3 vols. of hydrogen remain, when ax mols of phosphine have decomposed, $\frac{3}{2}ax$ mols of hydrogen remain. Hence $a - ax$ mols of phosphine and $\frac{3}{2}ax$ mols of hydrogen remain at the time t. Consequently, $p_0 = a$, and $p = (1-x)a + \frac{3}{2}ax$. If the reaction is unimolecular, $PH_3 = P + 3H$, and

$$\frac{dx}{dt} = k(a - ax)\,; \quad k = \frac{1}{t}\log\frac{a}{a-ax}\,; \quad k = \frac{1}{t}\log\frac{p_0}{3p_0 - 2p}$$

In one experiment, D. M. Kooij found that when $p_0 = 715{\cdot}21$:

t	7·83	24·17	41·25	63·17	89·67
p	730·13	759·45	786·61	819·96	856·50
k	0·00236	0·00237	0·00235	0·00238	0·00241
Percentage decomposition	4·17	12·37	19·97	29·29	39·23

The constancy of k is in close agreement with the assumption that the reaction is unimolecular; and not so closely with assumptions that the reaction is bi-, ter-, or quadri-molecular. This may mean that the slow reaction: $PH_3 = P + 3H$, is followed by the very rapid formation of molecules of hydrogen and phosphorus; or it may mean that the reaction actually proceeds only in the adsorbed film of gas on the surface of the containing vessel, and that the velocity of the reaction in the adsorbed system is proportional to the press. of the gas in the interior of the vessel. The effect of the nature of the surface of the containing vessel must therefore be of importance, and D. M. Kooij found that the velocity coefficient k in a new vessel was 0·0023, in an old vessel it was 0·0064. He also measured the effect of temp. on the velocity constant k, and found :

	310°	367°	440°	512°
k	0·00021	0·00067	0·0025	0·0081

and he represented his results by the equation $\log k = -3595T^{-1} + 2{\cdot}4884$. M. Trautz and D. S. Bhandarkar measured the velocity in a porcelain vessel between 845° and 956°—above 956° the velocity was too rapid for measurement. Above 945°, the reaction is uninfluenced by the walls of the containing vessel, and takes place in the body of the gas. The reaction is retarded by water vapour, and accelerated by copper. According to C. N. Hinshelwood and B. Topley, the rate of decomposition of phosphine in a quartz bulb is affected by some activating influence, which, after a time, decreased to a constant minimum. Similarly also with a porcelain container. The addition of powdered fused silica of approximately known surface area caused an increase of velocity corresponding with the increased surface, so that, up to at least 771°, the reaction is to a large extent localized on the walls of the containing vessel, and not in the body of the gas—it is hence called a *wall-reaction.* This does not agree with M. Trautz and D. S. Bhandarkar's results. The rate of the reaction observed by C. N. Hinshelwood and B. Topley is unimolecular over the press. range 37·5 to 707 mm. The heat of activation is approximately constant between 40,000 and 50,000 cals. when the value calculated for a gas-reaction is 86,719 cals. between 940° and 960°. There is no evidence that the wall-reaction becomes a gas-reaction at higher temp. The reaction was studied by S. Dushman, D. H. Drummond, and E. Yamazaki.

B. H. Wilsden studied the energy involved in the electronic shifts during the dissociation of phosphine.

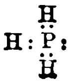
L. Bleekrode[7] gave 1·317 for the **index of refraction** of liquid phosphine at 17·5° for Na-light, and 1·323 at 11° for white light. P. L. Dulong gave for the gas at 0° for white light, 1·000789; and J. W. Brühl compared the results obtained with the μ- and the μ^2-formulæ.

The **spectrum** of the green flame of gases containing phosphine was found by P. Christofele and F. Beilstein, and G. Salet to have two intense green lines, one of which almost coincides with one of the green lines of barium. The spectrum of the burning gas is quite different from that furnished by free phosphorus; it can scarcely be attributed to the molecules PH_3 because at that temp., phosphine is dissociated into its elements. K. B. Hofmann attributes the spectrum to the chemical process in the inner mantle generating rays of a special refrangibility. J. N. Lockyer gave a photograph of the spectrum of phosphine. H. J. Emeléus found the spectrum of the flame of spontaneously inflammable phosphine burning in oxygen is the same as that of burning phosphorus (*q.v.*). J. E. Purvis observed no absorption bands in the ultra-violet.

H. Rose[8] said that spontaneously inflammable phosphine remains unaltered if confined over mercury or well-boiled water, and exposed to **light,** provided no vapour of phosphorus is present; and T. Graham made a similar observation with respect to the non-spontaneously inflammable gas. P. Thénard, however, showed that there is something wrong with H. Rose's experiment, for sunlight transforms the spontaneously inflammable gas into the other form, while the contained hydrogen hemi- and di-phosphides furnish an orange-red deposit, showing that some phosphine is decomposed. L. N. Vauquelin, U. J. J. Leverrier, and A. Vogel also found that the spontaneously inflammable gas gives a reddish deposit when exposed to sunlight. D. Amato, however, observed that dry but impure phosphine suffers no perceptible alteration when exposed to direct sunlight provided the temp. exceeds 10°. M. Trautz and D. S. Bhandarkar calculated the limit of photosensitiveness of phosphine to be about a wave-length of $329\mu\mu$. S. C. Roy studied the reaction from the point of view of the radiation hypothesis. Y. K. Sirkin found that the radiation theory fitted in with the decomposition of phosphine. R. Robl observed no fluorescence occurs with phosphorus in ultra-violet light.

J. Dalton,[9] H. Buff and A. W. Hofmann, and A. W. Hofmann found that phosphine is decomposed by the **electric discharge,** forming red phosphorus, and a vol. of hydrogen 1·5 times the original volume of the gas. T. Graham found that the electrification of the non-spontaneously inflammable gas converts it into the spontaneously inflammable gas. P. and A. Thénard said that the condensed electric discharge decomposes phosphine incompletely, for it first produces the hemiphosphide, then the diphosphide, and finally a red substance—red phosphorus. M. Berthelot also noted the formation of the diphosphide under these conditions, and he represented the reaction: $4PH_3=5H_2+P_4H_2$. B. Lepsius said that with the electric arc in phosphine, there is a dazzling red light, and the red clouds of phosphorus which are formed condense on the walls of the containing vessel as a mixture of red and yellow phosphorus.

The chemical properties of phosphine.—H. Davy[10] analyzed the gas, but his sample must have been mixed with so much hydrogen as to render his result useless for determining the composition of the gas. The analyses of H. Rose, J. B. A. Dumas, and U. J. J. Leverrier agree with the empirical formula PH_3; and the vapour density determinations previously indicated show that this is also the mol. formula. A. O. Rankine discussed the structure of the molecules of the family of trihydrides; H. Remy, and H. Henstock, the electronic structure; and G. W. F. Holroyd gave



$$\begin{array}{c}\mathrm{H}\\ \mathrm{H}:\overset{\cdot\cdot}{\underset{\cdot\cdot}{\mathrm{P}}}:\\ \mathrm{H}\end{array}$$

According to J. Meisenheimer and L. Lichtenstadt, when phosphine oxide, $O:PH_3$, has its hydrogen atoms replaced by three different radicles, the asymmetric compounds are optically active—*e.g.* $O:P(C_6H_5)(C_2H_5)(CH_3)$. P. Pascal also said that the magnetic properties are in agreement with the formula $O:PH_3$.

The gas has an odour suggesting a mixture of stinking fish and garlic; it is irrespirable. As shown by G. Maclean, it has no action on vegetable colours. The effects of heat, light, and the electric discharge have been indicated above. The gas has no perceptible effect on **hydrogen.** The gas does not support combustion, but when traces of hydrogen hemiphosphide are present, the gas may ignite spontaneously in **air** or in **oxygen**—Fig. 12; and H. Rose found that the inflammation occurs even if the temp. of the gas be near the f.p. of mercury, and the air at —15°. H. Davy gave 149° for the **ignition temperature** of the gas; P. Thénard, 100°; and A. W. Hofmann said that the ignition temp. of the purified gas exceeds 100°, because the gas can be bubbled through boiling water without the bubbles burning as they burst in air; on the other hand, the friction of the glass stopper of a glass vessel containing the gas may produce inflammation, K. Olschewsky found that the flame of the burning gas is not extinguished at —78°. but it is at —90°. H. Davy added that the inflammation of single bubbles of the gas is attended by a vivid light, and the formation of a thick, white, vortex ring of phosphoric acid; while in oxygen gas, the combustion is so brilliant as to resemble flashes of lightning. The products of combustion are phosphoric acid and water, as well as a little phosphorus pentoxide which is deposited as a film on the walls of the containing vessel. J. Dalton, and H. Buff found that the combustion of one vol. of the spontaneously inflammable gas consumes two vols. of oxygen. When a mixture with an excess of air or oxygen is exploded, one vol. of phosphine consumes two vols. of oxygen: $2PH_3+4O_2=3H_2O+P_2O_5$; but if self-accendible phosphine be bubbled into an excess of oxygen, some phosphorus is deposited as a yellowish-red film, and less oxygen is then consumed. To obtain complete combustion, J. B. A. Dumas recommended mixing the spontaneously inflammable gas with an equal vol. of carbon dioxide, and then with oxygen, but on igniting the mixture at 120°, he still found only 1·83 vols. of oxygen were consumed instead of two vols. H. Davy, and J. B. A. Dumas suggested that when less than 2 vols. of oxygen are consumed per vol. of phosphine, some phosphorus escapes combustion altogether, but H. Rose considered this to be improbable. H. Davy maintained that when the amount of oxygen associated with phosphine is insufficient for complete combustion, there is a preferential combustion of the phosphorus, and that free hydrogen remains unburnt. J. B. A. Dumas showed that the ignition by an electric spark of a mixture of one vol. of phosphine and 1½ vols. of oxygen contained in a narrow tube yields no phosphorus, but forms water and phosphorous acid, while the residual gas contains sometimes hydrogen, sometimes hydrogen and oxygen with some unoxidized phosphine. If a mixture of one vol. of phosphine with half a vol. of oxygen be exploded by rarefaction, phosphorus may be deposited, and the residual gas contains hydrogen and unconsumed phosphine.

A mixture of the non-accendible gas with oxygen does not ignite at ordinary temp. unless rarefied. According to J. J. Houton de la Billardière, if a glass tube surrounded by a wire-gauze be inclined over a mercury pneumatic trough, and partly filled with the mixture of oxygen and phosphine, an explosion immediately occurs if the gas-tube be raised into a vertical position so as to rarefy the gas a little; and, added J. B. A. Dumas, the explosion by alteration of level takes place with greater facility when an excess of phosphine is present. H. Rose found that a mixture of phosphine and air invariably explodes if kept at the ordinary press. over mercury for a few hours; and H. Davy showed that spontaneously inflammable phosphine can be mixed in a narrow glass tube—8 mm. diameter—without combustion owing to the cooling effect of the sides of the tube. T. Thomson showed that there is here a slow oxidation while phosphorous acid and hydrogen are formed.

The self-accendible gas loses its spontaneous inflammability when this slow oxidation is in progress a little while.

H. J. van de Stadt found that when phosphine and oxygen are mixed at low press., they rapidly combine with the emission of light, to form phosphorous acid: $2PH_3+3O_2=2H_3PO_3$. When the gases are brought in contact very slowly, there is an intermittent greenish-blue light, and equal vols. of oxygen and phosphine interact to form hydrogen and metaphosphorous acid which is deposited as a deliquescent, crystalline film on the walls of the containing vessel: $PH_3+O_2=H_2+HPO_2$. The slow oxidation of phosphine at greater press. proceeds nearly in accord with the equation $4PH_3+5O_2=2HPO_2+2H_3PO_3+2H_2$; does not increase the rate of oxidation continuously; but when a limiting low press. is attained an explosion suddenly occurs. Fig. 12 shows the rate of oxidation in press. decrease per hour, when the press. is expressed in millimetres of mercury at 50°. The limiting press. for explosion depends greatly on the amount of moisture present which retards or prevents oxidation. This is not a case opposing the need for the presence of moisture before certain chemical actions can take place. The effect of the superdrying of the reacting components has not been tried. P. Duhem considers that these experiments are analogous with those given for the oxidation of phosphorus in Fig. 12. H. J. Emeléus made a spectroscopic study of the light emitted by the low temp. combustion of phosphine.

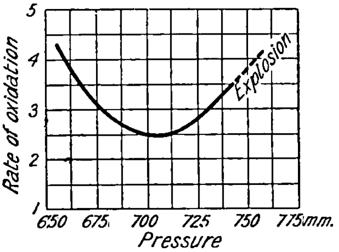


FIG. 12.—The Effect of Pressure on the Rate of Oxidation of Phosphine.

The solubility of phosphine in 100 vols. of **water** was found to be 1·8 vols. by P. Gengembre; 2·14 vols. by W. Henry; 2·5 vols. by H. Davy; 11·22 vols. by B. von Dybrowsky; 12·5 vols. by J. Dalton; and 25·0 vols. by J. M. Raymond. These deviations are great enough to render all the results of little value. A. Stock and co-workers found 100 vols. of water at 17° dissolve 26 vols. of phosphine. The aq. soln. of the gas smells like the gas itself, and, according to T. Thomson, tastes bitter. When the aq. soln. is boiled, the dissolved gas is expelled; the aq. soln. is not luminescent; when exposed to air, it gives off hydrogen gas, and forms phosphoric acid; and when it is exposed to light, red phosphorus is deposited. The aq. soln. does not react alkaline like the aq. soln. of ammonia. S. Skinner said that phosphine may be liquefied in contact with water, and it forms crystalline *hydrated phosphine.* No analyses of the crystals are available, but they are supposed to be *phosphonium hydroxide*, PH_3H_2O, *i.e.* PH_4OH—*vide infra.* They can be distilled from one part of the tube to another by gently warming them. L. Cailletet and L. Bordet found that the compressed gas condenses and floats on the surface of water present in the containing vessel, and a part dissolves. If the press. be suddenly released, a white crystalline product is formed which dissociates when the press. has reached 2·8 atm. at 2·2°; 3 atm. at 4°; 5·1 atm. at 9°; 9·8 atm. at 15°; and 15·1 atm. at 20°. The crystalline hydrate could not be formed above 28°.

In 1788, A. F. de Fourcroy and L. N. Vauquelin[11] said:

> Un petit morceau de phosphore attaché au bout d'un fil de fer, plongé dans le gaz acide muriatique oxygéné, s'allume en décrépitant, brûle rapidement et avec une véritable déflagration. Cette combustion a paru si rapide à M. Vauquelin, qui le premier l'a aperçue, et à M. de Fourcroy qu'ils ont pensé qu'elle pourrait être employée avec avantage pour faire l'acide phosphorique.

Phosphine takes fire in **chlorine** at ordinary temp. and press., burning with a brilliant greenish-white flame, and combining with four times its vol. of chlorine —T. Thomson said 3 vols. of chlorine; and H. Davy, 4 to 5. A. W. Hofmann obtained a similar result with phosphine of a high degree of purity. A. Stock found that phosphine and chlorine react at low temp. According to A. J. Balard, **bromine** decomposes the spontaneously inflammable gas, forming phosphorus and hydrogen bromide; and A. W. Hofmann observed that purified phosphine inflames on making contact with bromine water. T. Thomson found that when **iodine** is introduced into the spontaneously inflammable gas, phosphorus and hydrogen iodides are formed; and A. W. Hofmann observed that with the dried gas and a suitable temp., phosphonium iodide is produced, $5I_2+8PH_3=2PI_2+6PH_4I$—*vide infra.* J. Ogier found that when a mixture of equal vols. of phosphine and **hydrogen chloride** is compressed to 20 atm. at 14°, phosphonium chloride is formed; and the union occurs at lower press. by cooling—thus, the combination occurs at ordinary press., and —30° to —35°. S. Skinner mixed 3·7 vols. of liquid hydrogen chloride, and 4·6 vols. of liquid phosphine—near its critical temp.—and obtained approximately half the vol. of phosphonium iodide —*vide infra.* Phosphine also unites with dry **hydrogen bromide** to form phosphonium bromide; and, as shown by J. J. Houton de la Billardière, with dry **hydrogen iodide** to form phosphonium iodide—*vide infra.* A. J. Balard found that **chlorine monoxide** detonates in contact with phosphine; and **hypochlorous acid** forms phosphoric and hydrochloric acids—J. Dalton obtained a similar result with **calcium hypochlorite.** L. Moser and A. Brukl represented the reaction with soln. of **iodic acid** by $8HIO_3+5PH_3=5H_3PO_4+4I_2+4H_2O$.

As shown by H. Davy, F. Jones, etc., when **sulphur** is heated in phosphine gas, phosphorus sulphide and hydrogen sulphide are formed—one vol. of phosphine furnishing 1·5 vols. of hydrogen sulphide—T. Thomson, L. N. Vauquelin, J. B. A. Dumas, and H. Davy did not obtain the theoretical proportion of hydrogen sulphide, but, without a doubt, they used impure phosphine. F. Jones said that phosphine is decomposed by sulphur more slowly than is the case with arsine or stibine. L. Delachaux observed that if phosphine be heated with more sulphur than is needed to convert all the hydrogen into hydrogen sulphide, the reaction can be symbolized: $2PH_3+nS=3H_2S+P_2S_{n-3}$, and above 450°, the ratio of the press., p, to the absolute temp., T, is constant, showing that the reaction is complete. With relatively smaller proportions of sulphur, this ratio continues to increase for some time, even at 500°, and the gaseous phase consists of a mixture of hydrogen sulphide and phosphine, and the solid phase of phosphorus, which is gradually covered with phosphorus sulphide formed by interaction between the constituents of the gas phase. The reaction between **hydrogen sulphide** and phosphine does not occur with any appreciable velocity below 320°, and above this temp. the ratio p/T increases continuously with the time, no equilibrium being reached. The products are hydrogen and a variable mixture of phosphorus sulphides. A. W. Hofmann found that triethyl phosphine readily reacts with sulphur, forming the sulphide, $(C_2H_5)_3PS$, but it has no action on hydrogen sulphide. J. Dalton, and A. J. Balard found that **sulphur dioxide,** and **sulphurous acid** react at ordinary temp. with phosphine, forming water and phosphorus sulphide. A. Cavazzi represented the reaction between phosphine and sulphurous acid at 60°–70° by the three equations: (i) $PH_3+H_2SO_3=H_3PO_2+H_2O+S$; (ii) $2H_3PO_2+H_2SO_3=2H_3PO_3+H_2O+S$; and (iii) $2H_3PO_3+H_2SO_3=2H_3PO_4+H_2O+S$; and in the presence of mercury the reaction progresses: $PH_3+H_2SO_3+Hg=H_3PO_2+H_2O+HgS$. H. Rose found that when phosphine is passed over dried **sulphur trioxide,** at ordinary temp., red phosphorus and sulphur dioxide are formed; G. Aimé's observations indicate that a yellow cloud of sulphur is produced, and a blue liquid appears in the vessel next day—the blue liquid was thought to be a soln. of sulphur in sulphur trioxide—A. J. Balard reported the formation of both sulphur and phosphorus, as well as of sulphur dioxide. A. Stock and co-workers found that 100 vols. of 50 per cent. **sulphuric acid** dissolve 5 vols. of phosphine at 17°; and H. Buff said that cold conc. sulphuric acid absorbs phosphine without chemical action, but if heated, phosphine acts as a powerful reducing agent on sulphuric acid. A. J. Balard also said that with conc. sulphuric acid, sulphur, phosphorus, and hydrogen sulphide are produced ; and H. Rose, sulphur, phosphoric acid, and sulphur dioxide. The reaction was studied by T. Humpert. W. R. Hodgkinson added that the gas is at first rapidly absorbed by the conc. acid without any visible change, but when the acid is saturated, and the passage of the gas is continued, the acid rapidly becomes hot enough to ignite the gas. If the acid be kept cool, while an excess of gas is passed into it, it is reduced to sulphur dioxide with the separation of sulphur: $3H_2SO_4+2PH_3=2SO_2+S+2H_3PO_4+3H_2$; if hydrogen sulphide is produced, it is at once decomposed by the sulphur dioxide. If the gas be passed for a sufficient length of time, while the acid is kept cool, it becomes so thick and viscid with the separated sulphur, that the containing vessel may be inverted without the contents escaping. At low temp., A. Besson found that sulphuric acid furnishes a syrupy liquid which forms a white deliquescent solid, supposed to be *phosphonium sulphate—vide infra.* H. W. F. Wackenroder said that **pentathionic acid** is not decomposed by phosphine. A. Besson reported that **sulphuryl chloride** reacts with phosphine in the cold. precipitating a brownish-red mixture of phosphorus trisulphide and phosphorus, and hydrogen chloride ; the liquid contains phosphoryl chloride, phosphorous acid, and some undecomposed sulphuryl chloride. Phosphine was also found to react with **thionyl chloride**, forming a reddish precipitate consisting of phosphorus and phosphorus trisulphide; the liquid separates into two layers. The upper one contains thionyl chloride, and phosphoryl and thiophosphoryl chloride. No definite compound was obtained from the residue left on distilling the upper layer in vacuo at 200° ; nor could any definite compound be isolated from the lower layer. R. Böttger observed that when phosphine is passed into a soln. of a **tellurium salt**, tellurium phosphide is precipitated.

For the action of **nitrogen** on phosphorus, *vide* phosphorus nitride. According to T. Graham,[12] the gas which is not spontaneously inflammable becomes so if it be admixed with a trace of the vapour of **nitrous acid** or **nitrogen trioxide**—one vol. of this compound in 10,000 of the non-spontaneously inflammable gas can make it accendible ; a drop of nitric acid on the mercury confining the phosphine will produce enough gas to effect the transformation ; sulphuric acid fresh from the lead chambers contains enough nitrous anhydride so to convert phosphine bubbled through the acid ; hydrogen prepared from zinc and sulphuric acid fresh from the lead chambers when mixed with phosphine makes it spontaneously inflammable. Washed nitric oxide does not transform phosphine, but the unwashed nitric oxide may do so. Phosphine rapidly attacks fuming **nitric acid**, but an acid of sp. gr. 1·34 is not attacked. H. H. Landolt, and A. W. Hofmann made purified phosphine spontaneously inflammable in air by bubbling the gas through nitric acid containing a trace of nitrous anhydride. A. Besson found that phosphine can reduce conc. nitric acid so as to impart the necessary amount of nitrous anhydride to make it spontaneously inflammable provided the temp. exceeds —25°. T. Graham found that anything which destroys the nitrous anhydride makes the spontaneously inflammable gas non-accendible. J. Dalton found that phosphine at ordinary temp. reduces **nitric oxide** to nitrous oxide in a few hours ; and a mixture of nitric oxide and phosphine can be detonated by an electric spark to form nitrogen, water, and phosphoric acid ; P. Thénard found that **nitrous oxide** and phosphine—say in the vol. proportions of 3 : 1—can be detonated by the electric spark, to form, according to T. Thomson, 3 vols. of nitrogen, phosphoric acid, and water. J. B. A. Dumas said that 21 vols. of nitrous oxide are needed for 4 vols. of phosphine. The equation can be written: $2PH_3+8N_2O=P_2O_5+3H_2O+8N_2$. T. Graham said that phosphine is scarcely affected by **nitrogen peroxide**.

According to T. E. Thorpe and A. E. H. Tutton, **phosphorous oxide** has no action on phosphine either cold or hot. H. Rose, and R. Mahn found **phosphorus trichloride** reacts with phosphine, forming hydrogen chloride and phosphorus, but A. Besson said that at ordinary temp. hydrogen diphosphide, not phosphorus, is formed. A. Stock said that the reaction does not occur, notably at —20°, while it does occur slowly with **phosphorus tribromide** at —20°. P. de Wilde also said that the reaction with the tribromide is faster than with the trichloride. J. H. Gladstone represented the reaction $PBr_3+PH_3=2P+3HBr$, but this will be wrong if A. Besson is right. R. Mahn symbolized the reaction with **phosphorus pentachloride**: $3PCl_5+PH_3=4PCl_3+3HCl$, and, as H. N. Stokes pointed out, this is not analogous with the reaction with ammonium chloride, $PCl_5+NH_4Cl=4HCl+PNCl_2$, which corresponds with $PCl_5+NH_3=3HCl+PNCl_2$. J. H. Gladstone represented the reaction with **phosphorus pentabromide,** $3PBr_5+PH_3=4PBr_3+3HBr$. T. Graham found that arsenic acid is decomposed by phosphine, forming arsenic and water; and A. Cavazzi found that a soln. of **arsenic trioxide** in hydrochloric acid acts on phosphine, forming arsenic phosphide. A. Besson observed that phosphine does not form a complex with the **arsenic halides** —fluoride, chloride, bromide, or iodide—but there is a vigorous reaction with the evolution of the hydrogen halide and the formation of a brown solid which, by elutriation, can be separated into two substances with compositions $PAsO_3$ and $PAsO_6$. H. Buff found that when **antimony** is heated in the gas, antimony phosphide is formed, and 1·5 vols. of hydrogen per vol. of phosphine. R. Böttger observed no precipitation when phosphine is passed into soln. of **antimony salts,** nor did P. Kulisch obtain any precipitation with soln. of potassium antimonite, or of tartar emetic. H. Rose said that an addition product is formed by the action of phosphine on **antimony pentachloride,** but R. Mahn could obtain no complex salt, and represented the reaction: $4SbCl_5+PH_3=4SbCl_3+PCl_5+3HCl$. R. Böttger obtained no precipitate by passing phosphine into soln. of **bismuth salts**; on the contrary, P. Kulisch found that bismuth phosphide is deposited. A. Cavazzi said that phosphine at 100° forms with **bismuth trichloride** what is probably black bismuth phosphide; a black precipitate—$Bi_5Cl_2P_4$—is produced when phosphine acts on an aq. dil. soln. of bismuth trichloride; and with a hydrochloric acid soln., there is no precipitate. A. Cavazzi and D. Tiroli found that phosphine acts on an ethereal soln. of **bismuth tribromide,** forming a black hygroscopic substance with the composition Bi_3Br_7P.

J. Hunter[13] found that one vol. of fresh cocoanut **charcoal** absorbs at ordinary temp. 69·1 vols. of phosphine—reduced to n.p. θ; and one vol. of campechy wood charcoal, 27·5 vols. of phosphine. T. Graham's observations on this subject are indicated above. A. Frank studied the action of phosphine on the **metal carbides.** M. Berthelot passed a mixture of **carbon dioxide** and phosphine through a hot glass tube, but could not establish the formation of either methane or of any hydrocarbons, C_nH_n. L. Cailletet and L. Bordet compressed a mixture of equal vols. of phosphine and carbon dioxide in the presence of water, and obtained a white crystalline mass which decomposed at 22°—it was thought to be a *hydrated carbon phosphinodioxide;* or possibly a complex of phosphonium hydroxide and octohydrated carbon dioxide. By treating a mixture of **carbon disulphide,** water, and phosphine in a similar way, they obtained a *hydrated carbon phosphinodisulphide.* A. W. Hofmann found that phosphine is not acted on by carbon disulphide at ordinary temp., but triethylphosphine reacts violently with carbon disulphide producing $(C_2H_5)_3P.CS_2$; while it has no action on **mercaptan.** H. Davy said that phosphine is soluble in alcohol, ether, and volatile oils. J. Messinger and C. Engels found that phosphine does not act on **aldehyde** unless a hydrogen halide is present. C. Schultz-Sellac found a yellow substance, not zinc phosphide, is formed when phosphine acts on an ethereal soln. of **zinc ethide.** A. W. Hofmann obtained triethyl phosphine by the action of phosphine on ethyl iodide under press. Like ammonia, phosphine forms a series of **alkyl phosphines** analogous with the amines; these compounds are less basic than the ammonia derivatives. The tertiary phosphines were discovered by P. Thénard in 1846, and A. W. Hofmann established the existence of the primary and secondary products in 1871. Phosphine, and the primary aliphatic phosphines are weak bases, and form salts unstable in water; the introduction of alkyl groups strengthens them so that the secondary phosphines are decomposed only by alkalies. The tertiary phosphines react like well-defined bases. The aromatic phosphines are less basic than the amines, and are all decomposed by water. P. and A. Thénard obtained a substituted phosphine by the action of **ethylene** on phosphine. J. de Girard obtained a compound of phosphine and **chloral hydrate.** A. Hoffman showed that when phosphine is passed into a warm soln. of **formaldehyde** acidified with hydrochloric acid, *tetramethylphosphonium chloride*, $P(CH_3)_4Cl$, of m.p. 151°, is formed. G. Cauquil found that **cyclo-hexanol** dissolves 2856 c.c. of phosphine per litre at 25° and 766 mm. B. von Dybkowsky found that **blood** takes up more phosphine than water; for putting the solubility of phosphine in water at 0·1122 at 15°, the value for arterial blood is 0·2673, and for venous blood 0·13.

A. Besson found that phosphine does not act on **boron trifluoride** at ordinary temp., but at −30°, or better at −50°, a complex is formed—**boron hemiphosphinotrifluoride,** $2BF_3.PH_3$; below 20°, **boron trichloride** forms **boron phosphinotrichloride,** $BCl_3.PH_3$; and at ordinary temp., **boron tribromide** forms **boron phosphinotribromide,** $BBr_3.PH_3$. At ordinary temp., **silicon tetrafluoride** does not react with phosphine; at −50°, much gas is absorbed, but no crystals are formed even at −60°; if, however, the mixture be compressed at 20 atm. and 10°, crystals of presumably a **silicon phosphinotetrachloride** which decompose at 15 atm., are formed. An analogous **silicon phosphinotetrabromide** appears to be formed by the action of phosphine on **silicon tetrabromide.** H. Rose reported the formation of a **titanium phosphinotetrachloride** by union with **titanium tetrachloride.** J. Gewecke discussed the action of phosphine on silicon and titanium tetrachlorides, and also on zirconium and thorium tetrachlorides—*vide* the corresponding phosphides.

J. L. Gay Lussac and L. J. Thénard [14] showed that **potassium** or **sodium** decompose phosphine *promptement*, when it is heated in the gas, forming metal phosphide, and, according to H. Davy, and J. Dalton, liberating about 1·5 vols. of hydrogen per vol. of phosphine employed—when allowance is made for the impure nature of the gas they must have used. H. Buff, and J. B. A. Dumas obtained a similar result with **copper**; H. Buff with **zinc**; and J. B. A. Dumas with **iron.** E. Rubenovitch found that with copper the reaction begins at 180°–200°—*vide* the metal phosphides. Compounds formally analogous with the amides by replacing one hydrogen atom in the phosphine molecule with an alkali metal have been prepared by A. Joannis. Thus, **sodiophosphine,** with the empirical formula, $NaPH_2$—called by A. Joannis *phosphidure de sodium*—is obtained by treating a soln. of sodium in liquid ammonia with phosphine. Towards the end of the reaction the compound in question floats on the surface of the liquid as brownish-red globules of fluid which freeze to a solid when slowly cooled. When the solid is heated to about 65°, the excess of ammonia is expelled and sodiophosphine remains as a white solid. **Potassiophosphine,** KPH_2, is obtained in slender needle-like crystals in a similar manner. If these compounds be heated, they form the corresponding phosphide: $3KPH_2=2PH_3+PK_3$; they are also decomposed by water with the evolution of phosphine. When treated with nitrous oxide, the alkali phosphines yield a vol. of nitrogen equal to the vol. of nitrous oxide employed.

B. Franke represented action of **potassium hydroxide** in dil. soln. by the equation: $4PH_3+4KOH=4PH_2OK+4H_2$; and $4PH_2OK=P_4H_2+H_2+4KOH$, *vide infra*, the alkali phosphides. I. Guareschi found that spontaneously inflammable phosphine loses this quality if passed over **soda-lime.** According to P. Kulisch, phosphine exerts no perceptible chemical action on **potassium or sodium chloride** or **sodium carbonate**—hot or cold; the same remark applies to **calcium and barium chlorides**; but A. Winkler showed that aq. soln. of the salts of the alkalies, alkaline earths, on the earthy metals, furnish the corresponding phosphites or hypophosphites. P. Kulisch found that soln. of the lighter metal salts are not affected by phosphine hot or cold, but with soln. of salts of the heavy metals, either the salt is reduced to the metal, or a metal phosphide is formed; in some cases both the metal and the phosphide are produced. The reduction probably proceeds in stages; with cupric sulphate, for instance, cuprous sulphate is probably formed: $8CuSO_4+PH_3+4H_2O \rightarrow H_3PO_4+4H_2SO_4+4Cu_2SO_4$; and by the further action of phosphine, cuprous phosphide: $3Cu_2SO_4+2PH_3 \rightarrow 3H_2SO_4+2Cu_3P$, and free copper: $4Cu_2SO_4+PH_3+4H_2O \rightarrow H_3PO_4+4H_2SO_4+8Cu$, are formed. M. Bretschger examined soln. of cupric sulphate, and of cuprous chloride as absorbents of phosphine in gas analysis. H. Rose added that with some halides, a phosphide is formed and hydrogen halide is set free, in other cases, phosphonium salts analogous to those of ammonium are formed. J. M. Raymond, T. Thomson, and H. Rose found that **copper salts** are decomposed by phosphine, but, according to R. Böttger, this is not so. H. Rose said that phosphine decomposes soln. of cupric chloride; P. Kulisch, that the cupric chloride is reduced to cuprous chloride; and E. Rubenovitch, that there is no reaction. The last-named added that the action proceeds in a different way with the different salts of copper—aq. soln. of cupric sulphate give a phosphide, $Cu_5P_2.H_2O$; soln. of cupric formate and acetate give an oxygenated phosphide, Cu_2PO; and ammoniacal soln. of copper salts in the absence of air yield copper tritaphosphide. L. Moser and A. Brukl found that a copper sulphate soln. is a slower absorbent for phosphine than soln. of mercuric, silver, or gold salts. The reaction is symbolized: $3CuSO_4+PH_3+3H_2O=H_3PO_3+3Cu+3H_2SO_4$; $4CuSO_4+PH_3+4H_2O=H_3PO_4+4Cu+4H_2SO_4$; and $3CuSO_4+2PH_3=Cu_3P_2+3H_2SO_4$, accompanied by $Cu_3P_2+3Cu=2Cu_3P$. Red **cuprous oxide** is rapidly blackened by phosphine, forming the tritaphosphide. J. Riban found that phosphine is rapidly absorbed by hydrochloric acid soln. of phosphine, forming **cuprous phosphinochloride,** $CuCl.PH_3$, or $Cu_2Cl_2.2PH_3$, and, according to P. Kulisch, some phosphide is formed at the same time. The copper phosphinochlorides were also studied by M. Bretschger. J. M. Raymond, T. Thomson, H. Rose, P. Kulisch, and R. Böttger found that aq. soln. of **silver salts** are decomposed by phosphine, and, according to R. Böttger, dry silver nitrate is likewise decomposed. According to T. Poleck and K. Thümmel, when filter-paper moistened with a drop of silver nitrate soln. is exposed to phosphine the wet spot is coloured egg-yellow and the periphery acquires a dark brown ring which slowly broadens towards the centre until the whole spot becomes black as in the analogous case of arsine. The yellow spot is not changed by nitric acid, but when wetted with water or aq. ammonia it is immediately blackened. If phosphine be passed into a conc. soln. of silver nitrate, the first few bubbles give a deep lemon-yellow coloration, and the liquid acquires an acid reaction—no precipitate is formed. The coloration remains for one or two days, and then becomes colourless—silver is precipitated, and the soln. contains phosphorous and phosphoric acids. If a rapid stream of phosphine be passed into a conc. soln. of silver nitrate at 0°, the whole liquid solidifies to a yellow crystalline mass which rapidly blackens owing to the separation of silver. The yellow precipitate is considered to be **silver trinitratophosphide,** $Ag_3P.3AgNO_3$. It is best to dilute the phosphine with carbon dioxide or hydrogen since otherwise each bubble of gas in the conc. soln. of silver nitrate produces a flash of light. D. Vitali said that an explosion sometimes occurs. With a dil. soln. of silver nitrate, the black precipitate is formed at once, and the soln. contains a mixture of nitric, nitrous, phosphoric, and hypophosphorous acids. The action is represented $PH_3+6AgNO_3=Ag_3P.3AgNO_3+3HNO_3$, followed by $Ag_3P.3AgNO_3+3H_2O=6Ag+3HNO_3+H_3PO_3$. L. Moser and A. Brukl represented the reaction with an excess of silver nitrate: $3AgNO_3+PH_3=PAg_3+3HNO_3$; and $PAg_3+AgNO_3+2H_2O=H_3PO_2+4Ag+HNO_3$, as well as $H_3PO_2+2AgNO_3+H_2O=H_3PO_3+2Ag+2HNO_3$ and $H_3PO_3+2AgNO_3+H_2O=H_3PO_4+2Ag+2HNO_3$. The resultant reaction is therefore represented: $8AgNO_3+PH_3+4H_2O=H_3PO_4+8Ag+8HNO_3$. J. M. Raymond, H. Rose, R. Böttger, P. Kulisch, and T. Thomson found that aq. soln. of **gold salts** are reduced to gold or gold phosphide by phosphine; but R. Böttger said that dry gold chloride is not affected by the gas. A. Cavazzi represented the action with a dry ethereal soln. of gold chloride by: $AuCl_3+PH_3=AuP+3HCl$. The reaction with 0·2N-$AuCl_3$ is represented by L. Moser and A. Brukl by $2AuCl_3+PH_3+3H_2O=2Au+H_3PO_3+6HCl$; $4AuCl_3+PH_3+4H_2O=H_3PO_4+4AuCl+8HCl$; $3AuCl+PH_3=Au_3P+3HCl$; $3Au_3P+AuCl_3+6H_2O=10Au+3H_3PO_2+3HCl$; $3H_3PO_2+2AuCl_3+3H_2O=2Au+3H_3PO_3+6HCl$; and $3H_3PO_3+2AuCl_3+3H_2O=2Au+3H_3PO_4+6HCl$. The resultant reaction is therefore represented $8AuCl_3+3PH_3+12H_2O=8Au+24HCl+3H_3PO_4$.

J. M. Raymond, T. Thomson, A. Brukl, and R. Böttger found that soln. of **zinc or cadmium salts** are not affected chemically by phosphine, but soln. of **mercury salts** are decomposed. H. Rose said that mercuric sulphate and nitrate give white precipitates which are compounds of mercury phosphide with the metal salt, with mercuric chloride, the yellow precipitate is a mixture of mercurous chloride and mercury phosphide. J. B. A. Dumas heated dry mercuric chloride in phosphine and obtained three vols. of hydrogen chloride per vol. of phosphine, and a yellowish-red powder. W. R. Hodgkinson found that an alcoholic soln. of mercuric cyanide forms a precipitate which is extremely sensitive to light, and which contains mercury cyanide and phosphide. The reactions were also studied by T. Thomson, D. Vitali, and A. Brukl. L. Moser and A. Brukl represented the reaction with soln. of mercuric chloride: $6HgCl_2+2PH_3=3HgCl_2.P_2Hg_3+6HCl$; $6HgCl_2+PH_3+3H_2O=H_3PO_3+6HCl+6HgCl$; and $8HgCl_2+PH_3+4H_2O=H_3PO_4+8HCl+8HgCl_2$. P. Lemoult said that mercuric chloride and bromide form respectively **mercury chlorophosphide,** Hg_3Cl_3P, and **mercury bromophosphide,** $Hg_5Br_4P_2$; and that both salts can be used as absorbents for phosphine in analytical work. Similarly with mercuric iodide which forms **mercury iodophosphide,** Hg_3I_3P. K. A. Aschan obtained three chlorophosphides, $3Hg_3P_2.7HgCl_2$, by the action of phosphine on an aq. soln. of mercury chloride. The first is yellow, $3Hg_3P_2.7HgCl_2$—H. Rose reported $2PHg_2Cl.HgCl_2.3H_2O$; second, red, $4Hg_3P_2.5HgCl_2$; and third, brown, $Hg_3P_2.HgCl_2$. According to H. Rose, the reaction between phosphine and mercuric nitrate furnishes the complex **mercury nitratophosphide,** $P_2Hg_3\{Hg(NO_3)_2HgO\}_2$, where the mercury is all bivalent. This explosive substance was examined by K. A. Aschan; and S. Hada believes that it is a mercurous salt related to his mercurous nitratohypophosphite. T. Graham found that phosphine slowly decomposes dry **mercurous oxide,** but not **mercuric oxide**; and P. Kulisch found that **thallous oxide** is reduced to thallium. R. Böttger observed no precipitate is produced by the action of phosphine on soln. of **tin salts.** H. Rose obtained a yellow addition product with a tin tetrachloride, but R. Mahm represented the reaction: $3SnCl_4+2PH_3=Sn_3Cl_6P_2+6HCl$. J. M. Raymond, A. Brukl, and T. Thomson observed that soln. of **lead salts** are decomposed by phosphine, but R. Böttger said that no precipitate is formed, while H. Rose said that the precipitation occurs very slowly. The results with arsenic, antimony, and bismuth salts are indicated above. W. P. Winter observed that phosphine reduces a soln. of **ammonium molybdate** to a blue soln. which becomes colourless when warmed or allowed to stand. H. Rose found that **chromic chloride** is decomposed by phosphine with the liberation of much heat. J. M. Raymond, and T. Thomson observed no reaction when phosphine is passed into soln. of **manganese salts.** F. Jones represented the reaction with potassium permanganate: $6KMnO_4+4PH_3=3Mn_2O_3+2K_2HPO_3+2KH_2PO_3+3H_2O$, in agreement with the effect of ammonia, arsine, and stibine on this liquid. A. Cavazzi represented the reaction: $2KMnO_4+PH_3=K_2HPO_3+H_2O+2MnO_2$, and by $2KMnO_4+PH_3=K_2HPO_4+H_2O+Mn_2O_3$. J. M. Raymond, T. Thomson, and R. Böttger observed no precipitation occurs when phosphine is passed into soln. of **iron salts,** though H. Rose said that ferric chloride is decomposed, or, according to P. Kulisch, reduced to ferrous chloride. R. Böttger said that soln. of **cobalt and nickel salts** are not decomposed by phosphine; H. Rose said that the chlorides are decomposed. R. Schenck found that nickel phosphide is formed when phosphine is passed into a soln. of nickel chloride containing enough tartaric acid to prevent the precipitation of nickel hydroxide by alkali-lye. R. Böttger said that soln. of **platinum, rhodium, and iridium salts** are not precipitated by phosphine, but H. Rose said these soln. are rapidly decomposed. According to R. Böttger, soln. of **palladium salts** give a precipitate of the phosphide; but phosphine does not react with dry palladium monoxide. A. Cavazzi represented the reaction with a neutral aq. soln. of platinum atetrchloride: $PtCl_4+2PH_3=PtCl_2+2HCl+P_2H_4$; and $PtCl_2+P_2H_4=PtP_2H_2+2HCl$.

The physiological action of phosphine.—Experiments on pigeons, rats, and other animals, and a few observations on men show that phosphine has an exciting action on the respiratory mucous membranes, and a secondary action on the nervous system. It is possible that the phosphine acts on the oxyhæmoglobin, forming phosphorous acid. The spectrum of the blood of animals poisoned by phosphine has an absorption band in the violet. The subject has been investigated by J. Clark and T. B. Henderson,[15] J. Brilliant, M. Koschlakoff and H. Popoff, B. von Dybkowsky, etc. Cases of phosphine poisoning have been reported on board ships laden with ferrosilicon containing phosphides as impurities; when moistened by rain, the phosphide gives off phosphine which penetrates into the cabins, and when respired by sailors, etc., has caused a number of deaths—*vide* ferrosilicon, 6. 40, 13. According to M. Jokote, one part of phosphine in 100,000 parts of air is poisonous in 16 to 30 hrs.; air with 2·5 in 100,000 is poisonous in 8·5 to 10 hrs.; and air with 1 : 10,000 proved fatal in 2·5 to 3·5 hrs. M. Brenner thus described a pharmaceutist who is supposed to have been for a long time in an atmosphere contaminated with a minute proportion of phosphine:

> The man was engaged for two and a half years in the preparation of hypophosphites; his illness commenced with spots before the eyes, and inability to fix the attention. His teeth became very brittle, and pieces broke from healthy as well as diseased teeth from very slight causes. Finally, a weakness of the arms and limbs developed in the course of nine months into complete locomotor ataxy.

§ 10. The Phosphonium Compounds

When phosphine is brought in contact with hydrogen chloride, bromide, or iodide under suitable conditions, a series of phosphonium compounds are formed in which the PH_4-radicle plays the same part as the ammonium radicle in the ammonium compounds. The possible existence of **phosphonium-amalgam,** analogous to ammonium amalgam, was indicated by A. Besson,[1] who electrolyzed a soln. of the so-called phosphonium sulphate in sulphuric acid, at —25° to —40°, by means of a platinum anode and a mercury cathode. Bubbles of gas were developed in the mercury, showing that if phosphonium forms an amalgam with mercury, it is very unstable even at that low temp. The possible formation of an unstable **phosphonium hydroxide,** PH_4OH, analogous with ammonium hydroxide, NH_4OH, was indicated in connection with the experiments of L. Cailletet and L. Bordet, and of S. Skinner on the action of press. on water and phosphine. Of the three halides which have been prepared, the iodide is relatively stable, the chloride is very unstable.

According to H. Rose,[2] hydrogen chloride and non-accendible phosphine do not react perceptibly on one another even in sunlight, and borax or water absorbs the hydrogen chloride from the mixture, but if the mixture be passed through aq. ammonia, the unabsorbed gas acquires the property of inflaming spontaneously in air. A. Bineau suggested that this circumstance favours the assumption that the gases combine without condensation to form **phosphonium chloride,** PH_4Cl, just as phosphine and hydrogen bromide or iodide unite without condensation, but the compound with hydrogen chloride does not liquefy at —12°. J. Ogier found that when equal vols. of the mixed gases are compressed by 20 atm. press. at 14°, union occurs and crystals of the salt are formed ; if lower press. are used, the temp. must be reduced to the temp. of liquid sulphur dioxide. G. Lemoine found 2 atm.

press. was sufficient to make the gases unite; and, according to S. Skinner, the temp. and press. required for the combinations are:

	−30°	7°	13°	18°	21°	24°	28·5°	45°
Press. .	1	11·6	19·3	27·3	33·6	39·1	47·2	85·3 atm.

J. H. van't Hoff compared the phenomenon of dissociation with that of evaporation. He compressed a mixture of equal vols. of phosphine and hydrogen chloride until the tube was half filled with phosphonium chloride crystals. The tube was now heated by means of a water-bath. Fusion occurred at 25°, and at 50°–51° and a press. of 80–90 atm., the line of demarcation between liquid and gas disappeared; whilst on cooling, the thick clouding which characterizes the critical point was observed. F. E. C. Scheffer represented the press.-temp. relations, more or less diagrammatically by Fig. 13. *G* represents the m.p. curve of phosphonium chloride; the plait-point represents *H*, the critical temp. of that salt; *AC*, the vap. press. curve of hydrogen chloride; *BD*, the vap. press. curve of phosphine; and *GI*, the sublimation curve of phosphonium chloride. The double curve *GH* represents the boiling and dew curves, Fig. 7, of **1.** 4, 8. E. Briner gave for the compressibility, represented by the relative values of pv:

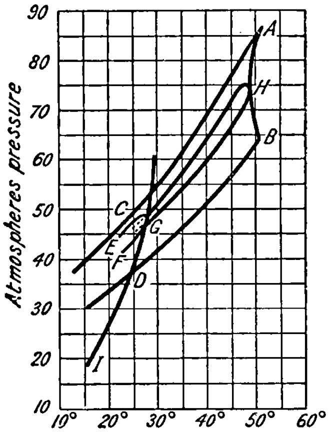

FIG. 13.—Pressure-Temperature Relations of Mixtures of Phosphine and Hydrogen Chloride.

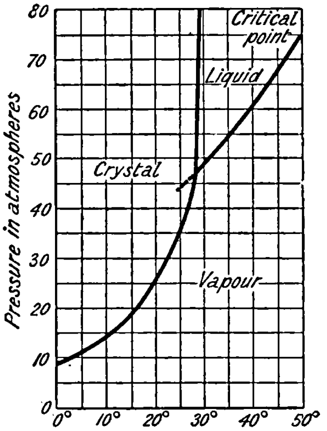

FIG. 14.—Vapour Pressures of Phosphonium Chloride.

33·5°	p	1	40	45	50 atm.
	pv	1	0·69	0·65	0·58
54·4°	p	1	45	60	80 atm.
	pv	1	0·72	0·61	0·38

These values fall between those for hydrogen chloride and phosphine. He also gave for the vap. press. of phosphonium chloride:

	25°	30°	35°	40°	45°	50°
Vap. press. . .	38·5	42·5	46·5	51·5	57	63

and these values fall between the corresponding values for the component gases—hydrogen chloride and phosphine. The white crystals of phosphonium chloride were found by S. Skinner to melt at 26°; and he gave 48° for the critical temp., 96 atm. for the critical press., and 3·5 for the critical vol. G. Tammann gave for the critical temp. and press. respectively 48·8°–50·1° and 74·2–75·0 atm. His values for the vap. press. are shown in Fig. 14. F. M. G. Johnson's estimate of the dissociation press. of phosphonium chloride is indicated in Fig. 13. E. Briner found the critical temp. to be 49·1°; the critical press., 72·7 atm.; the heat of formation of a mol of gas 16·4 Cals.; the temp. at which the dissociation press. is one atm., 253°; and the number of mols produced by the dissociation of a mol of phosphonium chloride, 2. He also gave the heat of formation, $HCl_{gas}+PH_{3gas}=PH_4Cl_{solid}+43{\cdot}4$ Cals., hence the heat of sublimation is 43·4–16·4=27·0 Cals. per mol.

G. S. Sérullas[3] made **phosphonium bromide,** PH_4Br, in 1831 by mixing equal volumes of phosphine and bromine; by bringing a vessel containing a little silicon tetrachloride and water under a globe filled with phosphine; and by the action of phosphonium iodide on mercuric bromide. Hydrogen bromide and phosphine do not interact at ordinary temp., but A. Besson showed that a reaction occurs if dry phosphine be passed into a soln. of hydrogen bromide in phosphoryl chloride or other indifferent solvents. J. Ogier obtained it by passing a stream of phosphine through a cold conc. soln. of hydrogen bromide, filtering off the precipitate, drying by press., etc., and subliming the product in a sealed tube. A. Damoiseau prepared it by heating a mixture of yellow phosphorus and hydrogen bromide in a sealed tube between 100° and 120°. According to A. Richardson, some phosphonium bromide is formed when a mixture of hydrogen bromide and moist red phosphorus is exposed to sunlight: $2P+3H_2O+HBr=PH_4Br+H_3PO_3$. Phosphonium bromide is a mass of white or colourless cubic crystals which, according to A. Bineau, sublime at about 30°. The vap. density given by A. Bineau is 1·906 in agreement with the dissociated mol PH_3+HBr. The value required for PH_4Br is 1·987. The compound readily dissociates: $PH_4Br\rightleftharpoons HBr+PH_3$. F. Isambert studied the reaction at different temp., and found the results to be in accord with the law of mass action, both for phosphonium bromide alone, and when an excess of either component is present. If p_1 and p_2 denote the partial press. of the respective components ammonia and phosphine, and p the dissociation press. of phosphonium bromide, then, for equilibrium, $p_1p_2=\frac{1}{4}p$. The following is a selection from F. M. G. Johnson's measurements of the dissociation press:

	−80°	−36°	−14·2°	0°	14·4°	23·0°	38·8°
Pressure .	1	4	17	56	159	291	794 mm.

or the dissociation press. is one atm. at 38°. A demonstration experiment was devised by G. S. Newth. J. H. van't Hoff compared the phenomenon of the dissociation of the solid with the phenomenon of evaporation, but he did not obtain anything analogous to the critical state as was observed with phosphonium chloride. J. Ogier found the heat of formation to be $PH_{3gas}+HBr_{gas}=PH_4Br_{solid}+23{\cdot}03$ Cals.; $Br_{liquid}+4H+P_{solid}=PH_4Br+44{\cdot}1$ Cals. Phosphonium bromide is closely analogous with the corresponding iodide. G. S. Sérullas showed that it may inflame spontaneously in air, and is very deliquescent; it decomposes in contact with water, forming phosphine and hydrogen bromide: $PH_4BrAq.=PH_{3gas}+HBrAq.-3{\cdot}03$ Cals. A. Besson found that phosphonium bromide does not react with phosphoryl chloride at ordinary temp., but in a sealed tube at 50°, the reaction, $POCl_3+PH_4Br=3HCl+HBr+P_2O$, occurs; there is also a slow reaction with carbonyl chloride at 0°, but at 50°, in a sealed tube, the reaction, $6PH_4Br+5COCl_2=10HCl+6HBr+5CO+2PH_3+P_4H_2$, proceeds vigorously.

The best-known member of the series of phosphonium halides is **phosphonium iodide,** PH_4I. It was discovered by J. J. Houton de la Billardière[4] in 1817, who found that when dried phosphine and hydrogen iodide are mixed together, colourless crystals are formed. It is true that about four years earlier J. L. Gay Lussac obtained a white sublimate consisting of cubic crystals by the action of iodine on phosphorus in the presence of a little water, but he paid no further attention to the product; G. S. Sérullas showed that in the reaction, $2P+I_2+4H_2O=H_3PO_4+HI+PH_4I$, which occurs when the mixture of iodine, phosphorus, and a little water is heated in a retort, the hydrogen iodide is first evolved, and the phosphonium iodide then sublimes. H. Rose found that a mixture of phosphorus, iodine, with a little hydroiodic acid gave rather better results than G. S. Sérullas' mixture. A. Oppenheim heated a mixture of red phosphorus and conc. hydriodic acid in a sealed tube at 160° and obtained a sublimate of crystals of phosphonium iodide. A. Damoiseau passed hydrogen iodide over heated phosphorus: $2P+HI+3H_2O=PH_4I+H_3PO_3$; and A. Richardson exposed moist red phosphorus to the action of hydrogen iodide in sunlight, and observed that phosphonium iodide is probably formed. A. Holt and J. E. Myers, and A. von Bäyer evaporated the solvent from a soln. of 100 grms. of phosphorus and 175 grms. of iodine in carbon disulphide in a current of carbon dioxide; he then gradually added 50 grms. of water, and obtained approximately 120 grms. of a thick crust of a sublimate of phosphonium iodide resembling ammonium chloride : $(4P+I_2)+7H_2O=2PH_4I+H_3PO_3+H_3PO_4$. A. W. Hofmann also made it by the action of water on phosphorus triiodide or a mixture of phosphorus and iodine :

Place 100 grms. of phosphorus in a retort, *A*, and add an equal weight of carbon disulphide, and then 170 grms. of pure iodine. Keep the retort well cooled during the mixing. Distil off the carbon disulphide by attaching a condenser to the retort, and placing the retort in a dish of warm water. The retort is then connected with a wide tube, *B*, which may be fitted with a glass bottle, *R*, as shown in Fig. 15, and then, in the fume closet, with a wash-bottle containing water to absorb any hydrogen iodide formed by the decomposition of the phosphonium iodide. Connect the retort with an apparatus, *C*, for generating carbon dioxide, dried by passage through a tube, *D*, charged with pumice-stone soaked with sulphuric acid, and keep a slow stream of carbon dioxide passing through the apparatus all the time an experiment is in progress. Let 85 grms. of water fall slowly, drop by drop, on to the residue in the retort. The heat of the reaction suffices to sublime the phosphonium iodide into the wide tube, but towards the end of the operation, the retort may be warmed. When the operation is completed, loosen the phosphonium iodide which has collected in the wide tube by means of a piece of wire, and transfer the salt to the bottle used as a receiver. The bottle is then closed with its stopper, *S*. The reaction is represented : $5I_2+18P+32H_2O=10PH_4I+8H_3PO_4$.

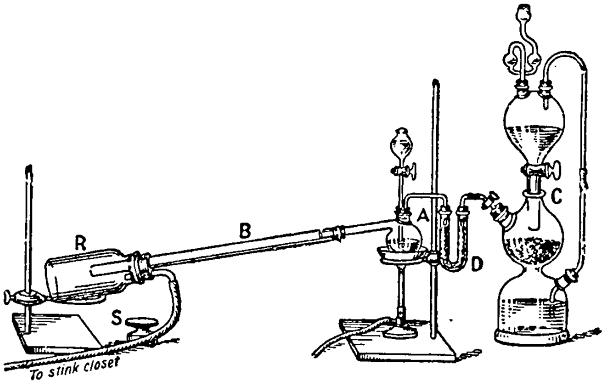

FIG. 15.—The Preparation of Phosphonium Iodide.

A. W. Hofmann made phosphonium iodide by the action of phosphine, dried by quicklime, on iodine: $8PH_3+5I_2=P_2I_4+6PH_4I$. A. L. Ponndorf obtained phosphonium iodide by the action of hydrogen iodide on hypophosphorous acid : $3H_3PO_2+HI=2H_3PO_3+PH_4I$; and K. Lissenko, by saturating molten hypophosphorous acid with hydrogen iodide and cooling the mass while in the presence of the gas. On warming the product in an atm. of carbon dioxide, phosphonium iodide, iodine, and hydrogen iodide were given off, while phosphoric acid remained. J. J. Houton de la Billardière thought that spontaneously inflammable phosphine and the non-accendible form furnished different varieties of phosphonium iodide, but H. Rose, and U. J. J. Leverrier showed that the products are identical.

The analyses of H. Rose agree with the formula just assigned to phosphonium iodide, namely, PH_4I. According to J. L. Gay Lussac, and J. J. Houton de la Billarbière, the clear, transparent crystals are cubic, while H. Rose described them as square prisms with terminal edges and truncated angles. L. Wagner found the crystals, though cube-like in appearance, really belong to the tetragonal system, and the axial ratio for methyl phosphonium iodide is $a:c=1:0{\cdot}7310$. R. G. Dickinson gave for phosphonium iodide $1:0{\cdot}729$, and he found the X-radiograms in agreement with a unit-cell of the dimensions $6{\cdot}34\times6{\cdot}34\times4{\cdot}62$ A. He showed that the space-lattice of the low temp. form of ammonium chloride is very similar to that for phosphonium iodide if the halogen atoms of the former are a little displaced. The arrangement of the atoms is indicated in Fig. 16, and that for low temp. form of ammonium chloride in Fig. 17. The black circles represent phosphorus or nitrogen atoms, and the circles halogen atoms. The hydrogen atoms may be grouped about the phosphorus tetrahedrally, but not necessarily so that all the atoms are equivalent. In the diagrams *OA*, *OA*, and *OC* are the axes of the unit. L. Wagner gave 2·860 for the sp. gr. of phosphonium iodide; H. Rose said that the crystals can be sublimed backwards and forwards in a sealed tube without melting. A. Bineau gave 80° for the sublimation temp. H. Rose said that the crystals deposit phosphorus and acquire a yellow tinge when they are gently heated, but G. S. Sérullas found that the vapour can be passed without decomposition through a red-hot tube containing fused borax. A. Smith and R. P. Calvert found the dissociation press. of solid phosphonium iodide to be :

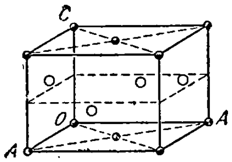

FIG. 16.—Space-lattice of Phosphonium Iodide.

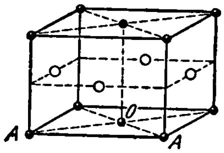

FIG. 17.—Space-lattice of the Ammonium Chloride.

	15°	30°	40°	50°	60°	62·6°	66°
Pressure .	36	107·8	199	368·1	660	760	917·3

The results are in agreement with those of F. M. G. Johnson, which are illustrated by Fig. 18, where the dissociation press. of one atm. is at 62°. A. Holt and J. E. Myers have concluded that, in carefully dried phosphonium iodide vapour, there occurs a secondary reaction in which the hydrogen iodide and phosphine give some free hydrogen and phosphorus iodide. Such a change was indicated in the experiments of A. Smith and R. P. Calvert by a slow, uniform increase in the press. with the time. A. Holt and J. E. Myers state that phosphorus iodide is not formed if a trace of moisture is present. For this reason, perhaps, F. M. G. Johnson obtained no evidence of its formation. According to J. Ogier, the heat of formation is $PH_{3gas}+HI_{gas}=PH_4I_{solid}+24{\cdot}17$ Cals.; and $P_{solid}+I_{solid}+4H=PH_4I_{solid}+29{\cdot}5$ Cals. J. J. Houton de la Billardière found that the salt is not decomposed by **oxygen.** H. Rose said that the crystals fume in **air,** and they gradually deliquesce in moist air giving off phosphine; and H. Rose, and J. J. Houton de la Billardière found that the salt is hydrolyzed by **water** and aq. soln. of ammonia or alkali hydroxide giving off phosphine—*vide supra,* preparation of phosphine. J. Ogier gave for the heat of decomposition $PH_4I+Aq.=PH_{3gas}+HIAq.+4{\cdot}77$ Cals.

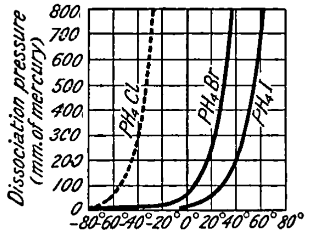

FIG. 18.—Dissociation Pressures of the Phosphonium Halides.

Phosphonium iodide is a reducing agent, which A. W. Hofmann considered to produce more satisfactory results in many cases than hydrogen iodide. It is also used in the preparation of organic phosphines. According to J. C. Cain, **chlorine** and water convert phosphonium iodide into a mixture of red phosphorus and hydrogen diphosphide. A. Stock saw that at —100° phosphonium chloride and chlorine react to form phosphorus pentachloride if chlorine be in excess; and with phosphine in excess, the reaction is slower, and on gradually warming the mess to room temp., yellow hydrogen diphosphide is formed which changes to reddish hemienneaphosphide, or red phosphorus. Hydrogen hemiphosphide is formed from the intermediate product, $PH_2Cl+PH_3=P_2H_4+HCl$, as in the case of ammonia. R. Hanslian found phosphonium iodide is decomposed by **iodine,** forming phosphorus and hydrogen iodides. J. J. Houton de la Billardière said the salt is not decomposed by **hydrochloric acid** ; and G. S. Sérullas found that the salt at ordinary temp. is inflamed by **chloric, bromic or iodic acid,** while **perchloric acid** acts only slowly even when warmed. The dry **chlorates, bromates, and iodates** also inflame phosphonium iodide at ordinary temp.; **potassium perchlorate** decomposes it slowly even when warmed. J. J. Houton de la Billardière found that **hydrogen sulphide** is without action on the salt; while G. S. Sérullas showed that **sulphuric acid** is reduced by phosphonium iodide, forming hydrogen sulphide and sulphur dioxide, which react so that the result of the reaction is to produce sulphur, phosphorus, iodine, a phosphorous acid, and hydrogen iodide. H. Rose, J. J. Houton de la Billardière, A. W. Hofmann, C. F. Rammelsberg, and J. Messinger and C. Engels found that with a conc. soln. of **ammonia,** phosphine is given off and ammonium iodide is formed. G. S. Sérullas found that with **nitric acid** at ordinary temp., phosphonium iodide bursts into flame; while dry **potassium nitrate** decomposes it only slowly even when warmed. According to E. and P. Fireman, **phosphorus pentachloride** acts but slowly at ordinary temp., and only at the points of contact: $3PCl_5+3PH_4I=PI_3+PCl_3+12HCl+4P$. P. de Wilde observed that much heat is developed by the action of **phosphorus trichloride** on phosphonium iodide, forming hydrogen chloride, phosphine, hydrogen diphosphide, phosphorus tetraiodide, etc. A. Besson found that **phosphoryl chloride** reacts vigorously at about 100°, forming hydrogen chloride, phosphorus tetraiodide, red phosphorus, and metaphosphoryl chloride; while when heated with **thiophosphoryl chloride,** there was no sign of the formation of phosphorus thiodiiodide, P_2SI_2. E. and P. Fireman represented the action of **antimony pentachloride** at 100°–110° in a sealed tube, by the equation: $3SbCl_5+3PH_4I=SbI_3+2SbCl_3+9HCl+PH_3+2P$; at ordinary temp. the reaction proceeds with explosive violence. J. J. Houton de la Billardière, and H. Jahn found that **carbon dioxide** has no action on phosphonium iodide. G. S. Sérullas said that it is decomposed by **alcohol,** forming ethyl iodide and phosphine. G. S. Sérullas showed that the iodide is not decomposed by hot **acetic acid.** J. de Girard examined the action of phosphonium iodide on **aldehyde ;** and S. Litthauer, on **benzaldehyde.** E. Drechsel said that phosphonium iodide does not react with **carbon disulphide** below 140°, but above that temp. trimethyl-phosphonium iodide is formed: $3CS_2+4PH_4I=P(CH_3)_3HI+CH_2S+3PSI$. H. Jahn observed a number of other products—phosphine, methane, and traces of other hydrocarbons, hydrogen sulphide, and a dark red substance with the composition $C_5H_6S_7P_6O_{12}$. A. Besson represented the reaction with **carbonyl chloride :** $4PH_4I+8COCl_2=16HCl+8CO+P_2I_4+2P$; and J. Traube found that it does not react with moist **cyanogen chloride.** According to G. S. Sérullas, **mercuric cyanide,** or **potassium cyanide,** reacts with phosphonium iodide, forming mercuric or potassium iodide, hydrogen cyanide, and phosphine.

J. J. Houton de la Billardière found phosphonium iodide has no action on **mercury.** G. S. Sérullas showed that dry **silver nitrate** reacts vigorously with phosphonium iodide with the development of much heat, forming silver iodide and phosphate; **silver oxide** forms silver iodide and spontaneously inflammable phosphine; **mercurous chloride** gives mercuric iodide, hydrogen chloride, and phosphine; and **mercurous bromide** forms mercuric iodide, and phosphonium bromide. E. and P. Fireman represented the reaction with **tin tetrachloride** at about 100° in a sealed tube: $4SnCl_4+4PH_4I=SnI_4+3SnCl_2+10HCl+2PH_3+2P$; and at 250° to 260°, $6SnCl_4+6PH_4I=3SnCl_2+3SnI_2+18HCl+2PH_3+4P$.

H. Rose,[5] H. Buff, A. Stock and co-workers, A. J. Balard, and W. R. Hodgkinson made observations on the action of phosphine on sulphuric acid. According to A. Besson, when hydrogen phosphide is passed into sulphuric acid at the ordinary temp., there is considerable development of heat, sulphur separates, and sulphurous acid is formed. If the acid is previously cooled by means of ice and salt, the gas is somewhat largely absorbed, and the liquid remains limpid. After a time, however, it begins to decompose in the manner indicated, the temp. rises, and decomposition becomes very rapid. If the acid is cooled to —20° or —25° by the rapid evaporation of methyl chloride, a syrupy liquid is obtained, from which a white, crystalline, highly deliquescent solid separates; this seems to be **phosphonium sulphate.** When thrown into water at the ordinary temp., it dissolves with a strident noise, and hydrogen phosphide is evolved, but the sulphuric acid is not reduced. When exposed to air at the ordinary temp., the phosphorus is oxidized to phosphoric, phosphorous and hypophosphorous acids, whilst the sulphuric acid is reduced to sulphurous acid and sulphur, with a small quantity of hydrogen sulphide. For the electrolysis of the soln., *vide supra*, phosphonium-amalgam.

§ 11. The Lower Hydrogen Phosphides

The history of these phosphides has been reviewed in connection with phosphine. The so-called *liquid hydrogen phosphide*, or **hydrogen hemiphosphide,** P_2H_4, was obtained by P. Thénard[1] in 1845 by passing the gases obtained by the action of water on calcium phosphide, Ca_3P_2, through a U-tube immersed in a freezing mixture. Ten years earlier, U. J. J. Leverrier had suggested that some hydrogen phosphide other than phosphine was contained in spontaneously inflammable phosphuretted hydrogen. The first action of water on the calcium phosphide is supposed to result in the formation of this compound: $Ca_3P_2+6H_2O=3Ca(OH)_2+P_2H_4+H_2$; and much of the hydrogen hemiphosphide so formed is at the same time decomposed into hydrogen diphosphide and phosphine: $5P_2H_4=6PH_3+P_4H_2$. A. W. Hofmann prepared the gas by this process; and L. Gattermann and W. Hausknecht recommended the following modification:

A 3-necked Woulfe's bottle, *A*, about 3 litres capacity, is fitted up as shown in Fig. 19 One tube, *H*, is for the introduction of hydrogen; a second tube (about 2·5 cms. bore) serves for the introduction of the calcium phosphide. Both these tubes dip beneath the surface of the 1·5 litres of water contained in the bottle. A third tube for the exit gases is fitted with a vertical condenser, *B*, so that most of the moisture may be removed from the gas. The liquid hydrogen phosphide condenses in a suitable tube, *C*, cooled by a freezing mixture. The gas then passes to a second Woulfe's bottle, *D*, containing conc. hydrochloric acid in which any liquid phosphide in the gas is converted into a yellow solid; the gas passes on and is ignited in the flue. After the air has been expelled from the apparatus by the current of hydrogen, and the large Woulfe's bottle heated to about 60° by means of a water-bath, fragments of calcium phosphide about the size of a pea are introduced at the rate of about 50 grms. in 15–20 minutes. When about a quarter of this amount has been added, liquid phosphide begins to collect in the condenser. A yield of between 3 and 4 c.c. of liquid is obtained for every 100 grms. of calcium phosphide.

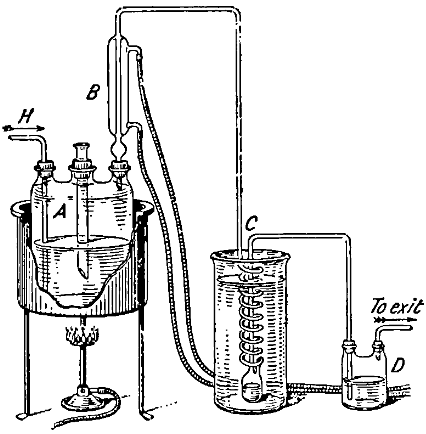

FIG. 19.—The Preparation of Liquid Hydrogen Phosphide.

A. Michaelis and M. Pitsch said that this same phosphide is formed when acetyl chloride reacts with hypophosphorous acid, in a side reaction involving: $4H_3PO_2=H_3PO_4+H_3PO_3+H_2O+P_2H_4$.

Hydrogen hemiphosphide at ordinary temp. is a colourless, strongly refracting liquid which, according to L. Gattermann and W. Hausknecht, has a sp. gr. 1·007 at 16°, and 1·016 at 12°; and a vap. density 74·73 to 77·0 in agreement with the value 76 required for the formula P_2H_4—formally analogous with hydrazine, N_2H_4; and if the phosphorus be here tervalent, the graphic formula is probably $H_2=P-P-H_2$. M. Croullebois also found the vap. density in agreement with this formula, which is based on the analyses of L. Gattermann and W. Hausknecht, and P. Thénard. No reliance can be placed on the vapour density determinations because the vapour is probably the decomposition products of the hemiphosphide. P. Thénard said that the liquid does not solidify at —20°, and it vaporizes between 30° and 40°, and at the same time is more or less decomposed. L. Gattermann and W. Hausknecht gave 57° to 58° for the b.p. at 735 mm. press. No residue remains provided the temp. does not exceed 80°. The distilled liquid is even less stable than the original. Sealed tubes containing the liquid should not be kept for any length of time since, owing to decomposition: $5P_2H_4=6PH_3+P_4H_2$, the internal press. may reach the bursting point. No deposition of any solid occurs when the liquid is kept for some time, but the liquid becomes yellow, presumably owing to the solubility of the solid diphosphide in the liquid hemiphosphide. P. Thénard found that the liquid decomposes when exposed to light, forming about 38 per cent. of the solid diphosphide, and 62 per cent. of phosphine: $5P_2H_4=6PH_3+P_4H_2$. This is in agreement with the observations of L. Gattermann and W. Hausknecht.

P. Thénard said that the liquid is spontaneously inflammable in air, and the presence of a trace of the vapour—1 : 500—makes phosphine and other combustible gases spontaneously inflammable in air. The white flame furnishes a thick white smoke of phosphorous oxide. V. Merz and W. Weith, and A. W. Hofmann found that a mixture of red and yellow phosphorus is deposited on a piece of cold procelain held in the flame of the burning hemiphosphide. P. Thénard found the liquid hemiphosphide to be insoluble in water; while alcohol, and turpentine appear to dissolve the liquid, but the soln. is very unstable, and rapidly decomposes. As in the case of hydrogen dioxide, the liquid hemiphosphide decomposes in contact with different substances which act as catalysts; for instance, an indefinitely large quantity is decomposed by a c.c. of hydrogen chloride gas, or, according to A. Stock and co-workers, by charcoal, pumice-stone, wadding, etc. L. Gattermann and W. Hausknecht tried unsuccessfully to prepare compounds of the liquid hemiphosphide with aldehydes and ketones similar to those formed by hydrazine.

H. Rose[2] observed a yellow powder is formed during the decomposition of potassium phosphide by water, and G. Magnus showed that when this substance is heated, it gives off hydrogen, and he therefore called it *Wasserstoffphosphor.* P. Thénard showed that the yellow solid has the empirical composition of **hydrogen diphosphide,** P_2H, and this is in agreement with analyses by R. Schenck, and L. Amat. Mol. wt. determinations agree with the formula, $(P_2H)_6$, or $P_{12}H_6$. This compound is often referred to as *yellow or solid hydrogen phosphide.* U. J. J. Leverrier found that when phosphine is exposed to light, yellow flakes of the solid hydrogen phosphide are produced; and P. Thénard obtained a greenish-yellow residue in the preparation of phosphuretted hydrogen from alkali-lye and phosphorus, and this he regarded as an isomeric modification of the yellow solid phosphide. H. Rose, P. Thénard, and R. Schenck also observed the formation of the diphosphide in the action of water on calcium phosphide; and P. Jolibois in the action of conc. hydrochloric acid on zinc phosphide. The usual method of preparation is by the action of water on calcium phosphide. This process was employed by A. Stock and co-workers, H. Rose, M. Croullebois, R. Schenck, and P. Thénard. W. Lenger's directions are as follow :

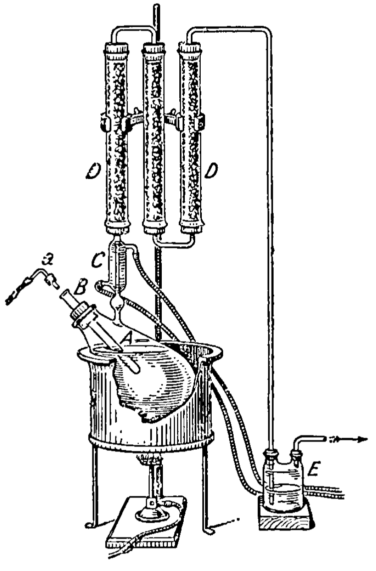

FIG. 20.—W. Lenger's Apparatus for the Preparation of Solid Hydrogen Phosphide.

A 3-litre flask, Fig. 20, three-fourths filled with water, is fitted up as shown in the diagram, and placed in a water-bath at 60°. A tube (2 cms. bore), *B*, is fitted into the neck of the flask by a rubber stopper; this tube dips below the surface of the water in the flask and serves for the introduction of the calcium phosphide. The gases first pass through a vertical condenser, *C* (about 10 cms. long), in order to remove most of the moisture, and then through three tubes (45 cms. long, and 2·5 cms. bore), *DD*, filled with fragments of calcium chloride about the size of a pea. About 200 or 250 grms. are needed to charge the tubes. The calcium chloride used should dissolve in dil. hydrochloric acid without residue. The calcium chloride tubes are protected from light by covering them with black paper. The liquid hydrogen hemiphosphide accompanying the phosphuretted hydrogen is decomposed on coming in contact with the calcium chloride. The exit tube dips below the surface of conc. hydrochloric acid in a 2-necked bottle, *E*, before it leaves the system; if the calcium chloride tube be not working properly, some flakes of yellow hydrogen diphosphide will appear in the acid. The escaping gas is thence led to the flue, and there ignited. When the calcium phosphide has been all added (about a kilogram in 6 hrs.), a stream of carbon dioxide is sent through the system by connecting *a* with the tube dipping in the flask. Most of the yellow hydrogen diphosphide will be found in the first two calcium chloride tubes, and it can be recovered by dissolving the contents in dil. hydrochloric acid (about 500 c.c.) cooled to 0°, and well stirred to prevent local heating. The solid diphosphide, floating on the surface of the acid, is washed with ice-cold water for about 5 minutes, then washed with alcohol, and finally with ether which has been distilled from sodium; and the solid is then allowed to stand for about 12 hrs. over concentrated sulphuric acid in vacuo. The yellow diphosphide must be protected from light during these operations. A kilogram of calcium phosphide furnishes from 6 to 8 grms. of the yellow hydrogen diphosphide. The dry product is best preserved in an ice-chest, since at ordinary temp. it is liable to decompose and turn a red colour.

P. Thénard showed that the solid diphosphide is formed by the action on the hemiphosphide (*q.v.*) of light, hydrochloric acid, volatile chlorides, and many other substances; and it is likewise formed under similar conditions from spontaneously inflammable phosphine which contains some hemiphosphide. D. Amato observed its formation by the partial oxidation of spontaneously inflammable phosphine at 10°–12°: $5P_2H_4+9O_2=6H_3PO_3+P_4H_2$. M. Berthelot noticed the formation of the diphosphide when phosphine is exposed to the electrical discharge: $4PH_3=5H_2+P_4H_2$; and U. J. J. Leverrier, when chlorine mixed with an equal vol. of carbon dioxide is passed into an excess of phosphine; with chlorine alone, the temp. produced is so high that phosphorus separates alone. P. de Wilde, and A. Besson observed the formation of the solid diphosphide by the action of phosphorus trichloride or tribromide on phosphine. A. Stock and co-workers added that the yields are small. A. Besson obtained the solid hydride by the action of phosphine on silicon hexachloride at —10°. F. Rüdorff showed that the solid diphosphide is formed when phosphorus diiodide is treated with water: $10P_2I_4+45H_2O=2PH_3+3H_3PO_4+11H_3PO_3+40HI+2(P_2H)$—W. Hittorf said that red phosphorus is the product of this reaction: $3PI_2+3H_2O=6HI+P_2O_3+P$. A. Stock and co-workers said the reaction is not suited for preparing the solid diphosphide. P. de Wilde noticed that the solid diphosphide is formed along with phosphine, etc., when phosphorus trichloride acts on phosphonium iodide; and J. C. Cain found it among the products of the action of chlorine on phosphonium iodide. A. Joly obtained the yellow diphosphide among the products of the action of metaphosphoric acid on phosphorous acid at 120°; and L. Amat, by heating a mixture of phosphorous acid and phosphorus trioxide. A. Colson observed the formation of the solid diphosphide when a soln. of phosphorus in turpentine is heated to 250°.

Hydrogen diphosphide, prepared by P. Thénard, U. J. J. Leverrier, and R. Schenck, is described as a canary-yellow powder without smell or taste. According to A. Stock and co-workers, the sp. gr. of the solid is 1·83 at 19°; J. Ogier found the heat of formation from yellow phosphorus to be $(4P,H_2)=35·4$ Cals. The mol. wt. determined by R. Schenck and E. Buck from the lowering of the f.p. when dissolved in molten phosphorus is 376, in agreement with 379 calculated for $P_{12}H_6$. A. Stock and co-workers found that the diphosphide can be preserved in darkness over a desiccating agent for 24 hrs. without appreciable change, but when exposed to air, it acquires an acid reaction, and gives off phosphine. They also showed that it is quickly decomposed when exposed to light; and U. J. J. Leverrier reported that when submerged in water hydrogen is evolved, and phosphoric acid is formed. According to U. J. J. Leverrier, the diphosphide decomposes into its elements when heated to 175° in a current of carbon dioxide, and in air it ignites between 140° and 150° according to its state of subdivision. It also decomposes when heated in an atm. of hydrogen, forming phosphine, and with a stronger heating, phosphorus. L. Amat said that when slowly heated to 215°, it decomposes as represented by the equation: $P_{12}H_6=2PH_3+10P$; and R. Schenck observed a slight decomposition when heated in vacuo at 100°. A. Stock and co-workers said that in vacuo gas begins to come off, and the decomposition almost ceases at 200°, but begins again at 260°, indicates the possible existence of another solid phosphide—*vide infra*. The diphosphide is inflamed when suddenly heated to 100°, or when struck with a hammer. U. J. J. Leverrier found the diphosphide is insoluble in water and alcohol; and, added P. Thénard, it is not dissolved in any liquid, other than the hemiphosphide, without decomposition. R. Schenck and E. Buck showed that it is soluble in molten phosphorus, forming a yellow liquid. A. Stock and co-workers found it is not soluble in liquid phosphine, nor in any liquid tried other than molten phosphorus, and hydrogen hemiphosphide. P. Thénard showed that the diphosphide decomposed by chlorine or chlorine-water, forming hydrogen chloride and phosphorus pentachloride in the former case, phosphoric acid in the latter case. P. Thénard found that when mixed with potassium chlorate it detonates when struck with a hammer, or when warmed a little; the diphosphide is rapidly decomposed by sulphuric acid, the acids of chlorine, and nitric acid; and, added U. J. J. Leverrier, a drop of conc. nitric acid causes inflammation, while with dil. nitric acid, it is decomposed and dissolved. R. Schenck showed that the diphosphide is blackened when treated with conc. aq. ammonia. A. Stock and co-workers, and W. Lenger found that the diphosphide dissolves in liquid ammonia at —40°, evolving phosphine and forming a red liquid, resembling $\frac{1}{20}N$-iodine soln., but in a few days becomes pale yellowish-red. When the sealed tube is opened, and the ammonia and phosphine have escaped, there remains a black solid—hydrogen enneaphosphide associated with ammonia. When the diphosphide is treated with piperidine, an energetic reaction occurs, phosphine is evolved, and there is produced hypophosphorous acid and a black solid—**hydrogen amminodiphosphide,** $P_{12}H_6.3NH_3$—which R. Schenck believes is to be regarded as **ammonium hydrotetraphosphide,** NH_4P_4H, where P_4H_2 is considered to be a monobasic acid. P. Thénard found that phosphorus pentachloride acts on the diphosphide like chlorine, but phosphorus trichloride, stannous chloride, or titanium tetrachloride has no action. A mixture of the diphosphide with silver oxide or mercuric oxide detonates feebly by percussion; and a mixture with cupric oxide detonates vigorously when heated. An alcoholic soln. of potassium hydroxide decomposes the diphosphide, giving off hydrogen and phosphine, and forming a red soln. which with water gives a yellow precipitate, and some hypophosphite is formed at the same time. The precipitate was thought by U. J. J. Leverrier to be a suboxide, and by A. Michaelis and M. Pitsch to be a tetritoxide: $P_4H_2+H_2O=P_4O+2H_2$, or, according to B. Francke, $P_4H_2+KOH=P_4HOK+H_2$, from which acetic acid precipitates solid $P_4H.OH$. U. J. J. Leverrier said that copper and silver salts are decomposed by the diphosphide; and a soln. of copper sulphate gives a black precipitate of copper, and copper phosphide.

B. Francke said that phosphorus hemiiodide is prepared by mixing the required quantities of phosphorus and iodine in carbon disulphide soln., and gradually adding the soln. to water with constant agitation. No separation of phosphorus occurs, but the aq. soln. of *phosphorus hydrohydroxyhydroiodide,* $OH.P_4H,HI$, becomes a golden-yellow colour, whilst the carbon bisulphide becomes colourless. The aq. layer is separated and heated to 80°, when it becomes colourless, deposits yellow flocks, and contains now only hydriodic and a little hypophosphorous acids. The yellow flocks are said to be *phosphorus hydrohydroxide,* $P_4H.OH$. This substance decomposes, slowly under water, more rapidly in moist air, into hypophosphorous acid, phosphorus, and gaseous hydrogen phosphide. When strongly heated in a current of carbon dioxide, the residue consists of phosphorus and phosphorus pentoxide. A. Michaelis and M. Pitsch, and K. Weidner consider these products to be the impure tetritoxide.

According to A. Stock and co-workers, and W. Lenger, indications of the formation of a solid hydrogen phosphide different from the yellow diphosphide are obtained when ammonia acts on the diphosphide—*vide supra.* They found that **hydrogen hemienneaphosphide,** P_9H_2, is formed when the diphosphide is warmed in air at 175°: $5P_{12}H_6=6P_9H_2+6PH_3$; and when the black ammonium salt—*vide supra*—is heated to 200° in vacuo, or warmed with dil. hydrochloric acid. The hemienneaphosphide is either a red flocculent powder or a red vesicular mass, according as the temp. is raised slowly or rapidly during the decomposition of the diphosphide; it is stable in dry air, but in moist air it rapidly increases in weight, acquires an acid reaction, and becomes converted into phosphine and phosphoric acid; it is darkened by contact with alkalies in the cold, and, on warming, dissolves with evolution of phosphine, but it dissolves readily in dry liquefied ammonia without the formation of phosphine. Prolonged heating in a high vacuum at 340°–360° converts it into red phosphorus.

According to L. Hackspill, when one of the alkali phosphides of the type M_2P_5 is treated with dil. acetic acid, yellow **hydrogen hemipentaphosphide**, H_2P_5, is produced; and the same compound is formed when the hemienneaphosphide is heated in vacuo at 80° for several hours The hemipentaphosphide is considered to be of an acid nature, and the phosphides M_2P_5 to be salts of that acid.

U. J. J. Leverrier, and A. Gautier noted that when phosphorus is half covered with phosphorous chloride, and exposed to air, the aq. soln. so obtained decomposes at 80° into free phosphoric acid, and yellow flocks of a substance regarded as a hydrated suboxide; B. Francke reported the same substance to be formed by gradually adding phosphorus subiodide, P_4I_2, dissolved in carbon disulphide, to water. The water becomes yellow owing to the formation of **hydrogen hydroxytetraphosphide hydroiodide.** The carbon disulphide layer becomes colourless. When the aq. soln. is heated to 80° it becomes colourless, and deposits yellow flocks of **hydrogen hydroxytetraphosphide**, $P_4H.OH$. This substance decomposes slowly under water, more rapidly in moist air, forming phosphorus, phosphine, and hypophosphorous acid. It dissolves in alcoholic potash with the evolution of hydrogen, forming **potassium oxyhydrotetraphosphide**, $P_4H.OK$, which is very quickly decomposed by water: $3P_4H(OK)+6H_2O+3KOH=6KH_2PO_2+2PH_3+4P$. The potassium salt is formed when alcoholic potash-lye acts on hydrogen diphosphide: $P_4H_2+KOH=H_2+P_4H.OK$. The action of dil. potash-lye on phosphine furnishes *potassium oxydihydrophosphide*, PH_2OK, thus: $PH_3+KOH=PH_2OK+H_2$; and this immediately decomposes: $4PH_2OK=P_4H_2+H_2+4KOH$.

§ 12. The Metal Phosphides

Phosphorus unites with most of the metals, forming phosphides. Phosphorus is electronegative towards hydrogen, and its affinity for the metals is rather less than that of sulphur. The phosphides are made by the direct union of the two elements usually assisted by heat, and in an atmosphere of an inert gas to prevent undue oxidation. In this way, at a dull red-heat, the metals iron, nickel, cobalt, copper, manganese, palladium, platinum, and iridium united with phosphorus with incandescence; and gold, silver, tin, and zinc without incandescence. Phosphides are also made by heating the metal or metal salt (halides) or metal oxide in a stream of phosphine or phosphorus halide; by passing phosphine through aqueous soln. of the metal salts, or by the action of a soln. of phosphorus in carbon disulphide on a metal salt—the phosphides of arsenic, antimony, and bismuth have been made in this way. Phosphides have also been made by reducing a phosphate with hydrogen or charcoal; and by heating the metal with copper phosphide in an electric furnace. The phosphides of the strongly electropositive metals—like potassium and calcium—behave like weak salts, and they are readily hydrolyzed by water, forming a hydroxide or hypophosphite of the metal and phosphine; on the other hand, the phosphides of the weaker electropositive metals—*e.g.* iron and copper—have characters like the metals, and are closely related with alloys; they are not decomposed by water, but some are decomposed by warming with dilute acids. Nitric and hypochlorous acids convert many phosphides into orthophosphates. The subject generally wants overhauling since many of the alleged phosphides hold a precarious position in the list of chemical individuals.

L. Troost[1] inferred that a **lithium phosphide** is formed when lithium is exposed to the vapour of phosphorus, because the product gives off phosphuretted hydrogen when treated with water; and H. Moissan made a similar observation with respect to the product of the action of phosphorus vapour on lithium carbide. Some analogous qualitative observations were made by H. Davy, J. L. Gay Lussac and L. J. Thénard, G. Magnus, H. Rose, E. Tomkinson and G. Barker, and F. Berlé on the production of **potassium and sodium phosphides** when the vapour of phosphorus, or phosphine is passed over the heated alkali metal; by P. Vigier, when the two elements are fused together under petroleum and the excess of phosphorus removed by washing with carbon disulphide; by R. Bunsen, and J. L. Gay Lussac and L. J. Thénard, when the alkali metal is heated with phosphoric acid or a phosphate. T. de Grotthus also made impure alkali phosphide by the action of phosphine on alcoholic potassium hydroxide.

According to C. Hugot, when liquid ammonia is brought in contact with a mixture of potassium or sodium and red phosphorus, the sodammonium or potassammonium first formed is decomposed by the phosphorus with the liberation of hydrogen; potassium yields a red compound, **potassium triamminopentaphosphide,** $KP_5.3NH_3$, which, when heated to 180°, loses all its ammonia, and leaves a brown mass of **potassium pentaphosphide,** KP_5. Sodium, under similar conditions, furnishes **sodium triamminotriphosphide,** $NaP_3.3NH_3$, and at 180°, **sodium triphosphide,** NaP_3. The potassium compound is not quite pure on account of the slight solubility of potassamide in liquid ammonia; this phenomenon does not occur with the sodium compound. Both phosphides are decomposed by moist air with the liberation of hydrogen phosphide.

According to A. Joannis, when hydrogen phosphide is passed into a soln. of potassammonium in liquefied ammonia, the gas is absorbed and hydrogen is evolved, a liquid being formed which does not mix with the ammonia, although not quite insoluble in it. When the action is complete, and the excess of ammonia is allowed to volatilize, *potassium dihydrogen phosphide* or *potassium phosphine,* or **potassium phosphamide,** PH_2K, is obtained in slender, white needles. When heated, it is converted into **potassium tritaphosphide,** PK_3, with evolution of hydrogen phosphide, and water also decomposes it with evolution of hydrogen phosphide. Sodammonium behaves similarly, the quantity of hydrogen liberated corresponding with the formation of **sodium phosphamide,** PH_2Na. The liquid solidifies when slowly cooled. If, however, the tube is kept at 0° and the ammonia is allowed to escape, a considerable quantity is retained by the phosphide, and the liquid does not solidify. No definite compound of the phosphide and ammonia seems to be formed, and a further quantity of the latter is evolved when the liquid is allowed to acquire the ordinary temp. If it is heated at 65°, still more ammonia is liberated, and the residue solidifies, and has the composition sodium phosphamide, PH_2Na. It decomposes in the same manner as the potassium compound, furnishing

sodium tritaphosphide, Na_3P. When nitrous oxide is allowed to act on them derivatives of phosphine, a volume of nitrogen is liberated equal to the volume of nitrous oxide employed, and the action is therefore quite different from that between nitrous oxide and the amides. If a mixture of red phosphorus and sodium be left in contact with liquid ammonia, yellow crystalline sodium phosphinotritaphosphide, $Na_3P_2H_3$, or $Na_3P.PH_3$, is formed simultaneously with phosphine, and sodamide. If an excess of sodium is not used, sodium phosphamide, PH_2Na, is produced. The phosphinotritaphosphide is decomposed by acids and by water with the liberation of phosphine, and when heated above 180°, it loses phosphine and hydrogen; at 150°–200°, less phosphine; and at 200°–300°, hydrogen alone.

H. Moissan made qualitative observations on the formation of **rubidium phosphide** by the action of molten phosphorus on rubidium hydride; and likewise on **cæsium phosphide.** L. Hackspill and R. Bossuet prepared a series of alkali phosphides with the general formula M_2P_5, by distilling successively 2–3 grms. of metal and a large globule of phosphorus into an evacuated tube, and heating the mixture to 400°–430°—with sodium, a temp. of 450° is necessary. A black mass is formed containing the free metal, but after heating for 100–150 hrs. this is volatilized, and the reddish-brown phosphide remains. In this way, they obtained **sodium hemipentaphosphide,** Na_2P_5; **potassium hemipentaphosphide,** K_2P_5, of sp. gr. 2; **rubidium hemipentaphosphide,** Rb_2P_5; and **cæsium hemipentaphosphide,** Cs_2P_5. At 0°–100°, the four phosphides resemble cadmium sulphide in appearance, but become darker at higher temp., and are almost colourless when cooled in nitrogen. They melt near 650° with decomposition and the loss of phosphorus; they decompose in air; and when treated with water yield a solid hydrogen phosphide together with a little phosphine and hydrogen. L. Hackspill found that with very dil. acetic acid, the yellow solid is hydrogen hemipentaphosphide, H_2P_5, and this is considered to be the acid parent of the phosphides M_2P_5. The rubidium salt was found by L. Hackspill and R. Bossuet to form a limpid soln. with liquid ammonia, which on evaporation at —18° deposits yellow, transparent crystals of **rubidium pentamminohemipentaphosphide,** $Rb_2P_5.5NH_3$. This phosphide effloresces with the loss of ammonia at ordinary temp.; it dissolves in liquid ammonia, and the soln. reacts with liquid ammonia soln. of the nitrates of barium, strontium, calcium, silver, copper, and lead, forming amorphous precipitates, yellow in the case of the alkaline earth metals, brown with silver, and black with the others.

W. B. Schober and F. W. Spanutius[2] have reported the preparation of salts of the phosphorus analogue of hydrogen cyanide. When phosphine is passed over heated sodium, PH_2Na, or Na_2HP, or Na_3P, is formed, the reaction is possibly analogous with the action of ammonia on sodium: $2Na+2NH_3=2NH_2Na+H_2$; when sodamide, $NaNH_2$, is treated with carbon monoxide, sodium cyanide is formed: $NaNH_2+CO=NaCN+H_2O$, and when the corresponding derivative of phosphine is treated in a similar way, **sodium phosphocyanide,** NaCP, is formed: $NaPH_2+CO=NaCP+H_2O$. The compound is very unstable, it gives off phosphine and forms formic acid: $NaCP+2H_2O=PH_3+H.COONa$, when treated with water.

Some general remarks on the combination of copper and phosphorus were made in connection with the action of phosphorus on copper—**3.** 21, 6—and **copper phosphides** with Cu : P in the at. proportions 3 : 1, 5 : 2, 2 : 1, 3 : 2, 1 : 1, and 1 : 2 have been reported at various times. These compounds, or rather alloys, were observed towards the end of the eighteenth century by A. S. Marggraf,[3] B. Pelletier, and B. G. Sage. The relation of copper to phosphorus is important because it is largely concerned with the production of the so-called phosphor-bronzes obtained by H. de Ruolz-Montchal and H. de Fontenay about 1854. The effect of copper on these alloys is discussed in connection with the properties of the alloys of tin —**7.** 46, 5. Alloys have been made by the direct union of copper and phosphorus vapour—by B. Pelletier A. S. Marggraf,, R. Lüpke, E. Heyn and O. Bauer, F. A. Abel, A. Granger, A. Schrötter, H. H. Hvoslef, etc.; E. Casoria passed the vapour of phosphorus over cuprous chloride or nitrate; by heating a mixture of copper and carbon with phosphoric acid or a phosphate—by B. Pelletier, B. G. Sage, P. Berthier, H. Schwarz, C. Künzel, P. Mellmann, etc.; by heating mixtures of copper oxide, phosphorus, and carbon—by G. Seyboth; by heating copper phosphate admixed with carbon—by P. Berthier, L. Gnétat and J. Chavanne, C. Matignon and R. Trannoy, etc.; by treating soln. of copper salts with phosphorus—by R. Böttger, A. Oppenheim, A. Joannis, etc., by the electrolysis of molten phosphates or phosphoric acid, using copper electrodes—by H. Davy, H. N. Warren, P. Burckhard, L. Dill, etc.; and by the electrolysis of soln. of copper salts—E. Goerke, R. Böttger, D. S. Ashbrook, O. N. Heidenreich, etc. T. Sidot made some general observations on the crystals; B. G. Sage, and H. de Ruolz-Montchal and H. de Fontenay, on the sp. gr. and hardness; W. R. Webster and co-workers, on the mechanical properties; A. Matthiessen and C. Vogt, on the electrical conductivity; and other observations on the properties have been indicated, **3**. 21, 6. A. Rietzsch measured the thermal and electrical conductivities. The chemical properties were discussed by A. Granger, E. Heyn and O. Bauer, H. Moissan, F. A. Abel, R. Lüpke, W. G. Otto, etc. G. Tammann and H. Bredemeier studied the rate of thickening of films produced on copper phosphide when exposed to oxygen and to the halogens. What appeared to be a **colloidal copper phosphide** was obtained by W. Straub by the joint action of copper, phosphorus, and water in air. A. Granger concluded:

> The quantity of metalloid retained by the metal augments with the duration of heating, and that it tends towards a limit established by a definite compound, which may be reached if the experiment be sufficiently prolonged. Thus the phosphide approaching Cu_2P, at the temp. of formation, can be transformed into a crystalline compound Cu_5P, perfectly distinct both in its physical and chemical properties from alloys more or less resembling Cu_3P.

And E. Heyn and O. Bauer:

> (i) Alloys with more than 15 per cent. phosphorus cannot be prepared by fusion. On the other hand, copper-phosphorus alloys richer in phosphorus are prepared by heating copper turnings and phosphorus at a lower temperature (300°–400°). A proposal is made to apply these facts to the technical production of phosphor-copper. (ii) At higher temperatures those alloys richer in phosphorus (15·0 per cent.) lose phosphorus. To every temperature corresponds a definite phosphorus content, which is reached as a limiting condition by loss of phosphorus. At 1100°, this saturation phosphorus content is 14·1 per cent., corresponding to a compound Cu_3P. (iii) In rapid heating and melting of phosphorus-rich alloys there is not sufficient time to reach the saturation phosphorus content by loss of phosphorus. To this fact is due the possibility of technically producing by fusion alloys containing up to 15 per cent. of phosphorus. The alloys with over 14·1 per cent. phosphorus form mixed crystals of the compound Cu_2P and a second compound, probably Cu_3P_2. The γ solid soln. has, with phosphorus over 14·3 per cent., the same melting point, 1022°. This temperature corresponds to the boiling point of melts which are saturated γ soln.

C. A. Edwards and A. J. Murphy measured the rate at which copper reacts with phosphorus vapour between 600° and 700°, and referred the results to the expression $dw/dt=kA/D$, where k is a constant; w denotes the number of grams converted into phosphide in the time t min.; A, the area of the exposed copper in sq. cm.; and D, the depth in cm.

	t	D	A	dw/dt	k
600°	10	0·023	7·447	0·120	0·000371
	30	0·0515	6·625	0·044	0·000345
	60	0·069	6·250	0·03	0·000331
640°	15	0·053	6·603	0·20	0·00160
	30	0·080	6·013	0·111	0·00147
	60	0·123	4·985	0·04	0·00107
700°	10	0·106	5·507	0·40	0·00770
	30	0·203	3·68	0·133	0·00730
	60	0·267	2·691	0·033	0·00327

The results for k are very fair at 600° and 640°, but not so for the 60-minute observation at 700°. P. E. Demmler gave 400° as the most satisfactory temp. for phosphorizing copper; but C. A. Edwards and A. J. Murphy showed that 640° is nearer the mark.

It has been possible to examine only a portion of the equilibrium curve because copper cannot hold much over 14 per cent. of phosphorus at a red-heat. F. A. Abel, and A. H. Hiorns worked with alloys containing up to 14 per cent. of copper. A. Granger said that phosphorus begins to act on copper at about 400°, and at about 600°, the copper can take up between 29 and 30 per cent. of phosphorus, while E. Heyn and O. Bauer made an alloy with 20 per cent. of phosphorus at 700°—but in all cases the phosphorus is expelled at a higher temp. P. E. Demmler, A. K. Huntington and C. H. Desch said that at ordinary press. 15 per cent. of phosphorus is the limit dissolved, and A. E. Tucker found that with alloys containing this amount of phosphorus, some of the red variety of that element is present in a free state. A. H. Hiorns' values for the f.p. of some alloys with up to 14 per cent. of phosphorus are as follow:

P . .	0	0·25	4·11	5·75	8·21	9·03	10·67	12·00	13·00	14·00
F.p. . .	1082°	1070°	1050°	820°	620°	650°	795°	950°	990°	1005°

E. Heyn and O. Bauer's f.p. curve is shown in Fig. 21. A. H. Hiorns gave 620° for the eutectic temp. with 8·2 per cent. of phosphorus. The f.p. of copper is steadily depressed by additions of phosphorus from the f.p. of pure copper to that of the eutectic; the f.p. curve then rises to the saturation point with 14 per cent. of copper. The eutectic alloy shows the characteristic pearlitic structure; with copper in excess, the metal shows islands of copper surrounded by the eutectic matrix; and with an excess of phosphorus, crystals of **copper tritaphosphide,** Cu_3P, also surrounded by the pearlitic eutectic matrix. The complete diagram has not been worked out, but E. Heyn and O. Bauer discussed the diagram for the case of a system of two elements, A and R, which form two compounds, V_1 and V_2, which give a complete homogeneous series of solid soln. γ. V_1 is supposed to boil without decomposition at *G*, while V_2 does not boil without decomposition. C. A. Edwards and A. J. Murphy found that there is a line corresponding with *CA* for the system: Cu–P.

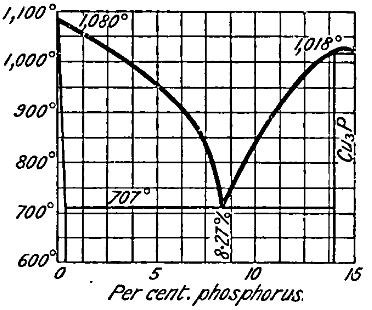

FIG. 21.—Portion of Freezing-point Curve of Copper-Phosphorus Alloys.

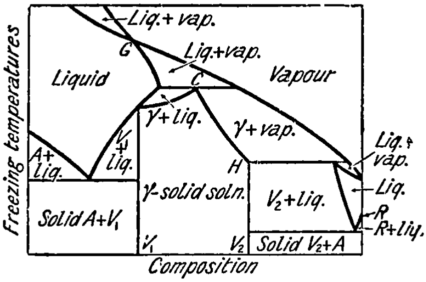

FIG. 22.—Imaginary Equilibrium Diagram of a Case like the System: Cu–P.

The tritaphosphide was analyzed by F. A. Abel, A. Granger, H. Rose, A. Schrötter, H. H. Hvoslef, and E. Rubenovitch. It is formed as indicated above, and, according to F. A. Abel, and A. Granger, when phosphorus vapour is passed over copper at about 900°. H. Rose, A. Granger, A. Schrötter, H. H. Hvoslef, and E. Heyn and O. Bauer obtained it by heating higher phosphides to say 1100°. A. K. Christomanos obtained it by the action of an ether or benzene soln. of phosphorus on an excess of an aq. soln. of cupric nitrate; E. Priwoznik, by reducing cupric phosphate with charcoal at a high temp.; and J. Riban, by heating cuprous phosphinochloride. E. Rubenovitch said that it is formed when phosphine acts on copper in the absence of air—the reaction begins at 180°–200°, and is completed below the decomposition temp. of phosphine; he also obtained it by the action of phosphine on precipitated cuprous oxide in ammoniacal soln. of various cupric salts, or cupric hydroxide ; P. Kulisch, by the action of phosphine on a mixed soln. of cuprous and sodium chlorides ; and H. Rose, by the action of phosphine on heated cuprous chloride or sulphide. The tritaphosphide is a steel-grey mass with a crystalline fracture, or a grey powder. H. H. Hvoslef obtained it as a silvery-white mass. A. Schrötter gave 6·75 for the sp. gr., and H. H. Hvoslef, 6·59. E. Priwoznik found it to be harder than copper or wrought iron, but softer than steel ; and E. Heyn and O. Bauer said it is about as hard as annealed steel. G. Pfleiderer studied the thermal and electrical conductivities of copper-phosphorus alloys. The tritaphosphide, said E. Priwoznik, can be kept for a long time in air without change, while P. Kulisch found it to be slowly oxidized by exposure to air. E. Rubenovitch said that it is rapidly oxidized in air or in oxygen at 100°. When heated on charcoal H. Rose said that the phosphorus burns with a green flame. These different observers found the tritaphosphide to be slowly dissolved by nitric acid, forming phosphoric acid ; it dissolves slowly in aqua regia ; H. Rose said that it is insoluble in hydrochloric acid, but A. Schrötter said it does dissolve slowly in that acid ; hot conc. sulphuric acid forms phosphine, sulphur dioxide, and maybe some sulphur. G. Tammann and H. Bredemeier studied the surface oxidation of copper phosphide. E. Rubenovitch found the tritaphosphide dissolves easily in bromine water ; and does not reduce potassium permanganate soln.

A. Granger made **copper dipentitaphosphide,** Cu_5P_2, by passing the vapour of phosphorus trifluoride or trichloride over copper at a red-heat ; E. Rubenovitch made the same product by the action of a slow current of phosphine (alone or diluted with an inert gas) at a low temp. on copper carbonate or hydroxide, or on cuprous oxide suspended in water ; and J. B. Senderens made it by the action of red phosphorus on a dil. soln. of cupric nitrate. This phosphide forms steel-grey, hexagonal, prismatic crystals which are transformed into the phosphate on exposure to moist air. The dipentitaphosphide passes into cuprous phosphide and free copper when heated to redness. The crystals dissolve in nitric acid, and in bromine water, and they reduce potassium permanganate. Hot conc. sulphuric acid is reduced to sulphur dioxide and sulphur. E. Rubenovitch prepared a black precipitate of what appears to be monohydrated copper dipentitaphosphide by the action of a mol of phosphine (from phosphonium iodide) on an aq. soln. of two mols of copper sulphate. E. Rubenovitch thinks that it is possible that this supposed compound is a mixture or double compound of the two phosphides Cu_3P and Cu_3P_2.

A. Granger reported the formation of **copper hemiphosphide,** Cu_2P, by passing the vapour of phosphorus, diluted with an inert gas, over copper heated to about 650°–700° ; and G. Maronneau, by heating a mixture of calcium phosphate and carbon in an electric arc furnace. The compound was reported by A. Schrötter and H. H. Hvoslef to be formed by the action of the vapour of phosphorus on heated copper, but these directions are too vague to enable the experiments to be repeated ; the same remark applies to F. Casoria's statement that the compound is formed by the action of phosphorus vapour on soln. of cupric salts, or by boiling phosphorus with soln. of these salts. The formula is in agreement with the analyses of A. Granger, and G. Maronneau. Copper hemiphosphide is a grey mass with a metallic appearance, and difficult to powder. G. Maronneau found the sp. gr. to be 6·4. It loses phosphorus when heated to bright redness. In moist air it loses its lustre, and oxidizes when heated in air. Some phosphorus is expelled at 1000° in hydrogen ; fluorine attacks it with a glow at ordinary temp., and cold chlorine, bromine, or iodine, as well as other oxidizing agents attack it. At dull redness, iodine forms phosphorus pentaiodide and a phosphide ; melted sulphur forms copper sulphide. It is soluble in hot nitric acid, the cold acid acts very slowly ; hot hydrochloric and sulphuric acids attack it slowly, forming in the latter case sulphur and sulphur dioxide. It is not attacked by cold or hot acetic or hydrofluoric acid ; and it is soluble in aqua regia, and in a mixture of hydrofluoric and nitric acids.

H. Rose reported **copper ditritaphosphide**, Cu_3P_2, to be formed when phosphine is passed over heated cupric chloride, or through a soln. of cupric sulphate. This precipitate was also observed by J. B. A. Dumas, H. Buff, and G. Landgrebe, who regarded it simply as a phosphide; E. Rubenovitch, and P. Kulisch regarded it as a mixture. R. Böttger said that if yellow phosphorus is boiled with a repeatedly renewed soln. of cupric sulphate, or acetate, a mixture of phosphide and basic sulphate or acetate is formed; when the washed product is digested with a soln. of potassium dichromate acidified with sulphuric acid, there remains the ditritaphosphide. Red phosphorus forms only a superficial film of this phosphide; a soln. of cupric chloride will not do because it is simply reduced to cuprous chloride. A. K. Christomanos obtained it by the action of a soln. of phosphorus in ether or benzene on a not too dil. aq. soln. of cupric nitrate not in excess. H. Moissan obtained it by the action of phosphorus vapour in an atm. of nitrogen or carbon dioxide, on copper at a dull red-heat; and B. Reinitzer and H. Goldschmidt, by passing phosphoryl chloride or phosphorus trichloride over copper at 250°—phosphorus pentachloride forms cuprous chloride and phosphorus trichloride; and phosphoryl chloride gives a number of by-products, cupric chloride, phosphorus pentoxide, and trioxytetrachloride. The compound was analyzed by H. Moissan, H. Rose, T. Parkman, and R. Böttger. A. K. Christomanos obtained the ditritaphosphide in black flocks, and in black, needle-like crystals; usually it appears as a black powder, which, according to G. Landgrebe, melts more easily than copper, but it is probable that the ditritaphosphide was decomposed during the fusion, for H. Rose said that when heated to redness in hydrogen it loses half its phosphorus; T. Sidot, and H. Moissan also noticed that phosphorus was lost when this phosphide is heated in a test-tube. T. Sidot gave 6·350 for the sp. gr., and found that the finely-divided ditritaphosphide burns vigorously in chlorine. R. Böttger said that when heated with iodine and water it forms cuprous iodide, and hydriodic and phosphoric acids; if the ditritaphosphide prepared at the high temp. be treated with hydrochloric acid, it does not readily dissolve, but that prepared at a low temp. dissolves more easily than copper in the presence of air; and when boiled cuprous chloride and phosphine are formed. R. Böttger said that when the ditritaphosphide is mixed with potassium chlorate it detonates when struck with a hammer. The ditritaphosphide prepared at a high temp. is not attacked by sulphuric acid, but the low temp. form is dissolved by the hot acid giving off phosphine and sulphur dioxide; with nitric acid, phosphoric acid is formed. When a mixture with potassium nitrate is heated, detonation occurs. T. Sidot found that phosphine is given off when the ditritaphosphide is acted on by an aq. soln. of potassium cyanide.

O. Emmerling prepared **copper monophosphide**, CuP, by heating the two constituents in a sealed tube; A. Granger, by the action of phosphorus vapour on copper at 600°; H. Goldschmidt, by the action of phosphorus pentachloride on copper; A. Granger, and T. Sidot, by the action of a soln. of copper hydrophosphite on red phosphorus; H. Rose, and F. A. Abel, by heating in hydrogen copper phosphate precipitated by sodium hydrophosphate; and J. Katz, by shaking a soln. of phosphorus in carbon disulphide with a soln. of cupric sulphate; washing out the carbon disulphide with ether; and washing the precipitate with water, alcohol, and ether. A. K. Christomanos' repetition of J. Katz's process yielded only the ditritaphosphide. Analyses were made by O. Emmerling, A. Granger, H. Rose, J. Katz, and A. K. Christomanos. The grey product, said A. Granger, looks like graphite. It is quickly oxidized by air, especially when heated. F. A. Abel said that when heated in hydrogen it passes into the tritaphosphide. The monophosphide is attacked in the cold by chlorine and bromine; it is sparingly soluble in hydrochloric acid; freely soluble in nitric acid; aq. ammonia in air forms phosphate and phosphite; and it detonates when admixed with potassium nitrate or chlorate and struck with a hammer.

A. Granger reported **copper diphosphide**, CuP_2, to be formed when carbon dioxide charged with vapour of phosphorus trichloride, tribromide, or diiodide is passed over gently heated copper, the diphosphide is obtained as a crystalline solid with a colour and lustre resembling that of silicon. It is readily attacked by chlorine, bromine, or nitric acid, and more slowly by hydrochloric acid. When heated out of contact with air, it yields copper phosphide and phosphorus; heated in presence of air, it oxidizes, and when mixed with oxidizing agents such as potassium chlorate, it detonates when struck. Phosphorus trifluoride, under similar conditions, yields the dipentitaphosphide.

In 1792, B. Pelletier[4] dropped phosphorus on to silver heated to redness in a crucible, and found the metal instantly melted; he continued adding phosphorus until he believed the silver to be sat. The molten mass had a tranquil surface, but, on cooling, much phosphorus was emitted, and the surface became *toute mamelonnée* owing to the spitting of the silver as it rejected the phosphorus in soln. It was estimated that the solid silver retained about 15 per cent. of phosphorus, and that it lost 10 per cent. in the act of solidification. J. Percy found a maximum of 0·293 per cent. to be retained by the solid metal. P. Hautefeuille and A. Perrey, and H. N. Warren confirmed these observations in a general way. H. André observed that fused silver phosphides absorb phosphorus vapour, and the electrical resistance then decreases regularly with a rise of temp. A direct current slowly displaces the silver, but an alternating current has no perceptible effect at low temp. In addition to the formation of a **silver phosphide** by the direct union of the elements, B. Pelletier observed that a silver phosphide is formed by melting silver with metaphosphoric acid and charcoal; and G. Landgrebe obtained a phosphide by heating silver orthophosphate with charcoal. For the action of phosphine on silver nitrate resulting in the formation of **silver nitratophosphide,** $Ag_3P.3AgNO_3$, *vide* **3.** 22, 21—the action of phosphine on silver nitrate. According to R. Fresenius and H. Neubauer, carbon dioxide charged with phosphorus vapour forms a similar product; and, according to J. B. Senderens, solid phosphorus reacts with a neutral soln. of silver nitrate, or, according to A. Oppenheim, with an ammoniacal soln. of silver oxide furnishing either free silver, or a mixture of silver and silver phosphide. O. Emmerling reported that **silver monophosphide,** AgP, is formed by heating silver and phosphorus in an evacuated sealed glass tube; when the product was heated in air, silver remained as a residue while phosphorus was evolved. A. Schrötter reported **silver hemiphosphide,** Ag_2P_3, or Ag_4P_6, to be formed by heating finely-divided silver in phosphorus vapour; the product was said to be insoluble in hydrochloric acid, but freely soluble in nitric acid. According to A. Granger, **silver diphosphide,** AgP_2, is produced when reduced silver is heated in phosphorus vapour at 400°, or when phosphorus acts on silver chloride at 400°. The diphosphide is said to give off phosphorus in a current of an indifferent gas at 500°, and to form a new phosphide at 900°. The diphosphide is soluble in nitric acid; and is attacked by aqua regia, and by chlorine and bromine. E. Boissuet and L. Hackspill treated a soln. of rubidium hemipentaphosphide in liquid ammonia with silver nitrate and obtained a brown easily oxidizable precipitate thought to be **silver hemipentaphosphide,** Ag_2P_5.

The affinity of gold for phosphorus is small. P. Hautefeuille and A. Perrey[5] noticed that molten gold absorbs the vapour of phosphorus, and spits it out again on cooling. B. Pelletier noticed that by melting gold with glacial phosphoric acid and charcoal, a yellow alloy of gold with about 4 per cent. of phosphorus was obtained; and E. Davy prepared a grey-coloured alloy with 14 per cent. of phosphorus by heating gold with phosphorus in an evacuated sealed glass tube. By passing phosphine into an aq. soln. of auric chloride, a black precipitate is obtained which C. P. Oberkampf regarded as gold phosphide, but H. Rose as metallic gold. A. Cavazzi reported the precipitation of **gold monophosphide,** AuP, when dried phosphine mixed with the vapour of ether is led into an ethereal soln. of auric chloride free from water. The brown hygroscopic powder decomposes in air, forming the acids of phosphorus; and it is blackened when kept 7 or 8 days in vacuo. It burns in air at 100°–110°, forming metallic gold; and in a current of carbon dioxide at a red-heat it loses all its phosphorus. This phosphide is decomposed by cold or hot water, forming phosphoric acid and metallic gold; potash-lye acts like water but more energetically. The monophosphide inflames by contact with fuming nitric acid; and it is decomposed by dil. nitric acid, forming phosphoric acid, and giving off nitric oxide and nitrogen peroxide. Cold conc. sulphuric has no action, but the hot acid forms gold, phosphoric acid, and sulphur dioxide. A. Schrötter reported grey-coloured **gold hemitriphosphide,** Au_2P_3, or Au_4P_6, to be formed by heating gold in phosphorus vapour, but A. Granger could not confirm this, and obtained instead what he considered to be Au_3P_4 by heating finely divided gold in phosphorus vapour to about 400°; but which decomposes at a higher temp. It also decomposes when heated in air or in carbon dioxide, and is readily attacked by aqua regia or by chlorine.

A kind of *phosphated lime*, a mixture of calcium phosphide and calcium pyrophosphate, was made by the action of the vapour of phosphorus on red-hot lime by G. Pearson,[6] S. L. Mitchill, H. Rose, J. B. A. Dumas, and P. Thénard, and used for the preparation of the hydrogen phosphides (*q.v.*). Normal **calcium phosphide,** Ca_3P_2, was made by P. Vigier by melting phosphorus and calcium together under petroleum, as in the case of the alkali phosphides. The Chemische Fabrik Griesheim-Elektron made it by heating calcium carbide with phosphoric oxide. A. Renault, and H. Moissan prepared it by heating an intimate mixture of calcium phosphate and lamp-black for 3 or 4 minutes in an electric arc furnace. The product is a reddish-brown crystalline mass, whereas the phosphide obtained by passing phosphorus vapour over calcium in vacuo at dull redness is amorphous. The sp. gr. is 2·51 at 15°. It melts with difficulty in the electric furnace, and if the action of the arc is continued too long, some phosphide is decomposed. Calcium phosphide is not affected by hydrogen or nitrogen at 900°, but at 1200° is slightly decomposed by the latter, and a small quantity of nitride is formed. Boron and carbon are without action; at a higher temp., carbon converts it into calcium carbide. Arsenic has no action at the softening temp. of glass. Chlorine has no action on the phosphide in the cold, but attacks it readily at about 100°, and bromine and iodine behave in the same way at somewhat higher temperatures. Oxygen and sulphur decompose the phosphide with incandescence at about 300°. Oxidizing agents, including nitrous and nitric oxides, attack it very readily at a red-heat, and the halogen hydracids decompose it with great energy. Concentrated nitric and sulphuric acids are without action, but in presence of water the phosphide is rapidly decomposed. Water acts somewhat slowly on the crystallized phosphide, and if it has been heated sufficiently in the electric furnace, the liberated hydrogen phosphide is not spontaneously inflammable; the reaction is complex, and all the phosphorus is not liberated in the form of hydride. J. A. Hedvall and E. Norström found that barium oxide begins to react with calcium phosphide at 331°; and strontium oxide at 447°. Calcium phosphide was found by H. P. Cady and R. Taft to be insoluble in liquid sulphur dioxide. Ordinary organic solvents have no action on the phosphide.

A. Jaboin prepared normal **strontium phosphide,** Sr_3P_2, in a similar manner, by heating an intimate mixture of lamp-black and strontium phosphate in the electric arc furnace for 3–4 minutes. The sp. gr. is 2·68, and it melts only at the high temp. of the electric furnace. Strontium phosphide burns in fluorine at the ordinary temp., in chlorine at about 30°, in bromine at 170°–175°, in iodine at a red-heat, in oxygen above 300°, and in sulphur vapour at a higher temperature. It is decomposed by carbon at a high temp., but not by sodium at a red-heat; by dilute acids and gaseous hydracids, but not by concentrated acids, nor by hydrogen sulphide or ammonia, nor by organic solvents. It alters rapidly in moist air, is decomposed by water with liberation of hydrogen phosphide, and is violently attacked by oxidizing agents. A *phosphated baryta*, analogous to phosphated lime, was prepared by J. B. A. Dumas, and P. L. Dulong. A. Jaboin obtained normal

barium phosphide, Ba_3P_2, by a method similar to that employed for the strontium compound. The product was a black crystalline mass of sp. gr. 3·183. The properties are similar to those of strontium phosphide, but it is not so active chemically; it burns in chlorine at 90°, but in bromine vapour at 260°–300°.

F. Wöhler[7] obtained an impure **beryllium phosphide** by heating beryllium in the vapour of phosphorus; the reaction proceeds with incandescence; and the grey pulverulent product develops phosphine when treated with water. More or less impure **magnesium phosphide,** Mg_3P_2, was obtained by R. Bunsen,[8] and L. Schönn by heating magnesium with dehydrated organic or inorganic substances containing phosphorus. The product evolves phosphine when treated with water. The phosphide was made by T. P. Blunt, by passing the vapour of phosphorus in a current of carbon dioxide over heated magnesium. The product was contaminated with carbon from the reduction of the carbon dioxide; accordingly, J. Parkinson, and H. Gautier used hydrogen in place of that gas. J. Parkinson, O. Emmerling, and R. Lüpke made magnesium phosphide by heating a mixture of magnesium filings and red or yellow phosphorus to redness in a glass vessel. Analyses by T. P. Blunt, J. Parkinson, and H. Gautier are in agreement with the above formula. The dark grey product is hard and brittle, and very difficult to fuse; and H. Gautier obtained small greenish-grey crystals which are rapidly decomposed by moist air. All observers noted the instability of the compound in moist air, and J. Parkinson said that phosphine is evolved and magnesium hydroxide with traces of phosphite and hypophosphite are formed. H. Gautier said that the phosphide can be preserved only in sealed tubes. J. Parkinson found that when heated in air it is oxidized superficially. H. Gautier reported that dry air and oxygen are without action at the ordinary temperature, but the phosphide burns in oxygen at a dull red-heat, and is converted into magnesium phosphate. Water very readily decomposes the phosphide, with production of magnesium hydroxide and pure hydrogen phosphide. The phosphide burns brilliantly when heated in chlorine, and also in bromine and iodine vapours at somewhat higher temperatures. Hydrochloric acid decomposes it with liberation of hydrogen phosphide; concentrated sulphuric acid slowly converts it into magnesium sulphate and phosphoric acid; nitric acid oxidizes it with incandescence, forming magnesium nitrate and phosphoric acid.

The union of molten zinc with phosphorus to form a **zinc phosphide** was observed by B. Pelletier,[9] E. A. Lewis, E. Baudrimont, and G. Landgrebe; F. Wöhler observed the formation of a zinc phosphide when zinc is heated with fused microcosmic salt; C. Trommer, when zinc and carbon are heated with phosphoric acid; H. H. Hvoslef, when zinc oxide is heated in phosphorus vapour; H. Rose, by the action of phosphine on zinc chloride; and H. H. Hvoslef, A. A. Proust, F. Selmi, and B. Reinitzer and H. Goldschmidt, by heating zinc in the vapour of phosphine diluted with nitrogen. The equilibrium diagram of the binary system has not been investigated. A. Schrötter reported normal zinc phosphide, or **zinc ditritaphosphide,** Zn_3P_2, to be formed by heating finely-divided zinc in the vapour of phosphorus. Combination sets in towards dull redness, and continues without incandescence; O. Emmerling used an analogous process. B. Renault used zinc oxide in place of zinc. P. Vigier added the phosphorus to molten zinc. R. Lüpke used a modification of this process; and P. Jolibois obtained it by heating zinc and phosphorus together in a crucible until fumes of phosphorus cease to be evolved. The product was fused from excess of zinc, either by ignition in vacuo at 600°, or by treatment with mercury or fuming nitric acid. J. J. Berzelius, and H. H. Hvoslef used a mixture of zinc or zinc oxide, phosphoric acid, and carbon; and B. Renault, a mixture of magnesium hydrophosphate, zinc sulphide, and carbon. The compound was analyzed by A. Schrötter, H. H. Hvoslef, and B. Renault. The normal phosphide appears as a steel-grey mass, which, if fused, consists of a mass of what H. Hager called *rhomboidischen Kristallen* of sp. gr. 4·72; A. Schrötter gave 4·76. P. Jolibois said the crystals are octahedral, and have a sp. gr. 4·55 at 13°. At a high temp., this phosphide may give off phosphorus without melting. B. Renault said that it melts at a higher temp. than zinc and volatilizes. P. Jolibois said the compound is infusible and sublimes in hydrogen at 1100°. It is not changed by air at ordinary temp., but if triturated in air it gives off the smell of phosphorus. If heated in air, it forms zinc phosphate. The phosphide is insoluble in zinc. R. Lüpke found that it is not attacked by water, but cold dil. hydrochloric and nitric acids were found by P. Sabatier to develop phosphine of a high degree of purity; and with nitrososulphuric acid it gives the blue soln. of nitrosodisulphonic acid.

H. H. Hvoslef heated a mixture of molten sodium hexametaphosphate and zinc turnings to redness in a retort; some phosphorus distils off, and there is formed a dark brown sublimate which is digested with boiling hydrochloric acid, and there remain grey plates with a metallic lustre with the composition of **zinc diphosphide,** ZnP_2. B. Renault obtained it by heating barium phosphide with zinc chloride; and by heating zinc oxide in phosphine. H. Rose seems to have obtained a similar product by the action of phosphine on zinc chloride. P. Jolibois made it by the action of phosphorus vapour on the normal phosphide at 400°, and digesting the product with dil. hydrochloric acid. The black powder has a sp. gr. 2·97 at 15°; it does not take up any more phosphorus at 400°, and at 500° it breaks down into phosphorus and the normal phosphide. It is not affected by conc. sulphuric acid, but it is slowly decomposed by conc. hydrochloric acid, forming gaseous and solid hydrogen phosphides.

B. Renault also claimed to have made *zinc monophosphide*, ZnP, in needle-like crystals during the preparation of the normal phosphide; *zinc tetratritaphosphide*, Zn_3P_4, as a red residue by treating the oxyphosphide with hydrochloric acid; and *zinc tetraphosphide*, ZnP_4, according to the analysis, as a yellow residue when the normal phosphide is treated with dil. hydrochloric acid. B. Renault also reported a *zinc oxyphosphide*, ZnP_2O, in orange-red needles in the sublimation of the normal phosphide, or of a mixture of zinc sulphide, carbon, and a phosphate. P. Vigier, and H. H. Hvoslef both considered the needle-like crystals to be phosphide not oxyphosphide.

According to E. Drechsel and E. Finkelstein, when a current of dry phosphine is passed into a soln. of zinc ethide in absolute ether, which must be cooled by a mixture of ice and salt, the separation of a white pulverulent precipitate is observed, which gradually increases in quantity. The precipitate was collected on a filter, washed rapidly with absolute ether, and dried in vacuo over sulphuric acid. The body thus obtained continually exhales phosphine when exposed to the air; its analysis corresponds with **zinc hydrophosphide.** The zinc hydrophosphide is decomposed at once by cold water, with evolution of phosphine and formation of zinc hydroxide. It is especially interesting for the ease with which it is attacked by chlorides and iodides; acetyl chloride acts upon it energetically, but the product of the reaction has not been thoroughly examined. By heating together the zinc hydrophosphide, ethyl iodide, and ether to 150°, ethyl-phosphine was produced.

F. Stromeyer,[10] and P. Vigier obtained a **cadmium phosphide** by the union of molten cadmium with zinc; while P. Kulisch obtained a phosphide by the action of phosphine on an ammoniacal soln. of cadmium sulphate. These products were not analyzed, but their chemical behaviour was characteristic of the metal phosphates. P. Drawe also found a cadmium phosphide in the residue obtained by the ignition of cadmium hypophosphate. O. Emmerling reported **cadmium hemiphosphide,** Cd_2P, to be formed when cadmium is heated for 12 hrs. with phosphorus. The grey or silvery-white mass consists of needle-like crystals associated with some red phosphorus. The product is soluble in hydrochloric acid with the evolution of phosphine. A. Oppenheim boiled cadmium oxide with an excess of phosphorus in potash-lye, and obtained pale brown, crystalline **cadmium ditritaphosphide,** Cd_3P_2. B. Renault obtained the same compound by the action of phosphorus vapour at a red-heat on cadmium, cadmium oxide, or cadmium carbonate; and A. Brukl obtained it as a black, unstable, flocculent precipitate by the action of phosphine on an ammoniacal soln. of cadmium sulphate. Dil. acids form non-spontaneously inflammable phosphine. He also obtained **cadmium diphosphide,** CdP_2, by heating ammonium phosphate, cadmium carbonate, and carbon; and as small red crystals in the preparation of the ditritaphosphide. Treatment of the diphosphide with acids gives phosphine, solid hydrogen phosphide, phosphoric acid, and a cadmium salt of the acid.

The affinity of mercury for phosphorus is small. According to D. Gernez,[11] molten phosphorus dissolves mercury, forming a colourless liquid which remains colourless until the temp. is raised, when the soln. blackens. B. Pelletier obtained a compound of mercury and phosphorus by heating mercury or mercuric oxide with phosphorus; H. Davy obtained a combination of the two elements by the action of phosphorus vapour on mercurous chloride; P. Boullay, by heating mercuric chloride with phosphorus; T. Thomson, by the action of phosphine on an aq. soln. of mercurous nitrate; and H. Rose, on solid mercuric chloride. A. Brukl obtained **mercurous phosphide,** Hg_3P, as a black, amorphous precipitate when hydrogen phosphide is allowed to react on a soln. of mercurous sulphate in dil. sulphuric acid; it is rapidly oxidized by the oxygen of the air, and gradually by dil. nitric acid. Phosphine is gradually evolved by the action of cold conc. hydrochloric acid, but much more rapidly by the action of the hot acid; with conc. sulphuric acid, sulphur dioxide is evolved. The compound is not explosive. A. Brukl also obtained **mercuric phosphide,** Hg_3P_2, by the action of a soln. of mercuric chloride in ether on hydrogen phosphide; it is a dark brown solid, becoming grey on exposure to air. In the cold, water, alkalies, and some dil. acids are without action, but on warming phosphine is evolved; it is oxidized in the cold by dil. nitric acid. A. C. Vournasos obtained a phosphide by heating the two constituents under molten paraffin; and A. C. Christomanos, by treating an ethereal or benzene soln. of phosphorus with mercurous or mercuric nitrate. A. Granger, and A. Partheil and A. van Haaren reported the formation of **mercury tetratritaphosphide,** Hg_3P_4, as a result of heating a mixture of mercury and phosphorus diiodide for 10 hrs. in a sealed tube at about 300°; and also by leading the vapour of the diiodide in a stream of inert gas over mercury; but it is not formed by the action of phosphine on dry or on an ethereal soln. of mercuric chloride. A. Partheil and A. van Haaren found that when phosphine is passed over dry mercuric chloride, the hydrogen chloride which is evolved does not correspond with the formation of mercury ditritaphosphide. T. de Grotthus obtained an impure phosphide by the action of phosphine on a mercury salt. According to A. Granger, the tetratritaphosphide forms brown rhombohedral crystals, which are stable when cold, but decompose into their constituents when heated. It inflames when heated in air, and in chlorine at ordinary temp. Mixed with potassium chlorate, it detonates by percussion. Nitric and hydrochloric acids separately have no action, but it is easily soluble in aqua regia. A. Partheil and A. van Haaren heated the phosphide with alkyl iodides in a sealed tube, and obtained tetralkylphosphonium compounds, *e.g.* $P(C_2H_5)_4.I\cdot 2HgI_2$; $P(CH_3)_4.I\cdot 2HgI_2$; etc. They also found that when purified phosphine is passed into a 2·5 per cent. alcoholic soln. of mercuric chloride, a dark brown precipitate is formed which is ultimately obtained free from chlorine; its composition is that of a **mercury oxyphosphide,** $Hg_5P_2O_4$—it is unstable. Some complex phosphides have been indicated in connection with the action of phosphine on mercury salts.

According to H. Moissan,[12] phosphorus does not react with amorphous boron at 750°; but G. Dragendorff obtained what appeared to be a compound of these elements by heating a mixture of borax and phosphorus; and A. Vogel obtained evidence of the existence of a compound of the two elements by heating boron phosphate, BPO_4, with sodium. H. Moissan, and A. Besson prepared **boron monophosphide,** BP, by heating the addition product, $PBr_3.PH_3$, to 300°, or boron phosphoiodide, BPI_2, or BPI, to about 500° in a stream of hydrogen. Boron phosphide is a maroon-coloured powder, insoluble in all the solvents which were tried; it is decomposed by boiling conc. alkali-lye with the evolution of phosphine.

Boiling water has no action on the phosphide, but it is decomposed by steam at 400°, forming boric acid and phosphine; conc. hydrochloric, hydriodic, or sulphuric acid has no action in the cold; hydrogen fluoride attacks the phosphide at a dull red-heat; and hydrogen iodide at a still higher temp. Boron phosphide inflames in conc. nitric acid, and fused alkali nitrates attack it with deflagration; it burns in oxygen at 200°, forming boric and phosphoric oxides; fused sulphur has no action, but it is attacked by sulphur vapour; hydrogen sulphide at a dull red-heat also attacks it, forming boron sulphide and hydrogen phosphide; chlorine reacts in the cold with incandescence; bromine when heated; and iodine has no action at dull redness. Nitrogen does not attack the phosphide at 500°; but the phosphide inflames when heated to 200° in ammonia gas, forming boron nitride and phosphorus. When heated with finely-divided metals, the phosphide is attacked. When boron phosphide is heated to about 1000° in a current of hydrogen, **boron tripentitaphosphide,** B_5P_3, is formed; this compound does not inflame in chlorine below a dull red-heat; it is not attacked by nitric acid, but it is attacked by fused nitrates.

According to H. Moissan, melted phosphorus acts with great energy on boron triiodide, and if red phosphorus is heated in the vapour of the iodide, decomposition takes place with incandescence. If, however, a soln. of the iodide in carbon disulphide is mixed with a similar soln. of phosphorus, great care being taken to avoid the presence of moisture, the reaction takes place more slowly. The mixture is sealed up in a flask and kept at the ordinary temp.; it is at first clear, but has a red colour. In a few minutes a brown precipitate begins to separate, and the reaction is complete in about three hours. The product is filtered through glass wool, washed with carbon disulphide, and dried in vacuo, the apparatus being filled with carbon dioxide until the latter is removed by the pump. The product is **boron phosphodiiodide,** BPI_2, an amorphous, homogeneous, deep-red powder. When heated in a vacuum, it melts at 190°–200°, and will remain in superfusion at the ordinary temp. for a long time; in a vacuum, it begins to volatilize at 170°–200°, and condenses on the cold part of the tube in distinct red crystals. It is only very slightly soluble in carbon bisulphide, and seems to be completely insoluble in benzene, phosphorus trichloride, and carbon tetrachloride. It is extremely hygroscopic, and decomposes very rapidly in moist air. In presence of a large excess of water, it becomes yellow, without apparent development of heat, and hydriodic, phosphorous and boric acids are formed, a small quantity of phosphine being evolved, and a small quantity of a yellow substance with an odour of phosphorus being deposited. With a very small quantity of water, the yellow precipitate is produced in larger quantity, and a distinct quantity of phosphonium iodide is formed. When boron phosphodiiodide is heated in hydrogen sulphide, it yields boron sulphide, phosphorus sulphide, and hydrogen iodide without any free iodine. Dil. nitric acid yields phosphoric acid and boric acid, whilst strong nitric acid produces the same result, but with incandescence. Ordinary or fuming sulphuric acid has no action in the cold, but, on heating, free iodine, hydrogen iodide, and sulphur dioxide are evolved. Phosphorous trichloride and carbon tetrachloride have no action even in sealed tubes at 100°. Chlorine produces incandescence with formation of boron chloride, iodine chloride, and phosphorus pentachloride. When heated in oxygen, the compound burns and yields iodine, boric anhydride, and phosphoric anhydride. Sodium has no action in the cold, but decomposition takes place near the m.p. of the metal. Powdered magnesium reacts with incandescence. When thrown into mercury vapour, the phosphodiiodide takes fire at once. In the presence of carbon bisulphide the behaviour of metals is different; magnesium or sodium at the ordinary temperature produces a red compound, PBI, whilst silver or mercury in the cold, or more rapidly at 100°, yields a maroon-coloured compound with the properties of boron phosphide, BP. When boron phosphodiiodide is heated in an atm. of hydrogen, **boron phosphoiodide,** BPI, is formed as an amorphous, red powder, somewhat less hygroscopic than the diiodide. It volatilizes in a vacuum at 210°–250° without previous fusion, and condenses in orange-yellow crystals. Strong nitric acid decomposes it with development of heat and without incandescence, iodine being liberated. Conc. sulphuric acid has no action in the cold, but, on heating, iodine, sulphurous anhydride, and boric acid are formed. When heated out of contact with air, it decomposes at a temp. below dull redness with evolution of vapour of iodine and boron phosphide. Mercury in excess, in presence of dry carbon disulphide, yields mercuric iodide and boron phosphide at the ordinary temp.

Some unanalyzed aluminium phosphides were obtained by F. Wöhler[13] by burning aluminium in the vapour of phosphorus; but O. Emmerling could not make the phosphorus vapour attack the red-hot aluminium. H. Fonzes-Diacon, and C. Matignon ignited a mixture of red phosphorus and aluminium powder in a crucible and observed a lively reaction. Yellow crystals of phosphide were obtained; and L. Franck obtained needle-like crystals by heating a mixture of aluminium and phosphorus in an atm. of air or hydrogen in a sealed tube at a red-heat. A. Rossel and L. Franck prepared **aluminium pentitatriphosphide,** Al_5P_3, as a grey crystalline mass, by passing the vapour of phosphorus over aluminium at a high temp., and heating the product until phosphorus is no longer evolved. L. Franck obtained **aluminium tritaheptaphosphide,** Al_3P_7, by heating an intimate mixture of aluminium powder and red phosphorus to a white-heat in a current of hydrogen. The grey crystalline mass is pulverulent; it can be heated in air without change; it gives off phosphine when treated with water or dil. acids; and it is decomposed by exposure to moist air, forming aluminium hydroxide, etc. If the mixtures be heated in an electric furnace, L. Franck found that **aluminium tritaphosphide,** Al_3P, and **aluminium monophosphide,** AlP, can be produced. These phosphides have both metallic appearance and crystalline fracture, and give off phosphine when treated with water. L. Losana examined the effect of a little phosphorus on the mechanical properties of aluminium—they are improved by up to 0·1 per cent. additions, but higher proportions reduce the tenacity and elongation.

A. Lamy[14] said that thallium unites directly with phosphorus, but E. Carstanjen found that no **thallium phosphide** is formed either when the two elements are melted together in a closed crucible, or when pieces of phosphorus are projected into molten thallium in an atm. of carbon dioxide. H. Flemming said that phosphorus vapour passed over molten thallium produces a thin layer of a black substance. E. Carstanjen did not obtain thallium by passing hydrogen over molten thallium phosphate; or by heating a mixture of thallium phosphate and carbon. H. Flemming found that phosphorus does not act on the thallium salts, but with aq. soln. of thallous hydroxide, a black deposit of thallium appears; and when phosphorus is heated with a thallous hydroxide soln. in a sealed tube, a little phosphine appears, a black substance is formed and some phosphoric acid passes into soln. W. Crookes said that when phosphine is passed into an ammoniacal soln. of thallous sulphate, a black powder of thallium phosphide is formed which is stable in air. P. Kulisch said that phosphine is without action on neutral and acid soln. of thallous salts, and thallium is precipitated from alkaline soln. Hence only small quantities of the phosphide can be obtained by W. Crookes' process. Only a small quantity of a precipitate was obtained after passing phosphine through the soln. for a day; this precipitate gave off a little phosphine when treated with acids. Thallic salts are incompletely reduced by phosphine to thallous salts.

T. Thomson[15] thought that he had obtained what he called a *carburet of phosphorus*—or carbon phosphide—when impure calcium phosphide is decomposed by water, and the lime removed by hydrochloric acid: the residual carbon phosphide was collected on a filter and quickly washed. It was said to be a brownish-yellow, soft, tasteless, inodorous, infusible powder, which suffers no alteration in dry air below 100°, but takes fire at a red-heat when the phosphorus burns to phosphoric acid while the carbon is not changed. It attacks moisture from the air, forming a hydrocarbon, and carbon dioxide. The properties of the alleged phosphide correspond with those of a mixture of carbon and phosphoric acid with perhaps a small proportion of phosphorus. J. J. Berzelius said that a similar substance remains when crude phosphorus is pressed through chamois leather. J. B. Trommsdorff obtained what he regarded as *Phosphorkohlenoxydgas*, or *hydrogen carbophosphide* which existed in the gaseous state at ordinary temp. during the distillation of phosphoric acid with charcoal. T. de Grotthus said that *phosphorcarburetted hydrogen gas* is obtained by dissolving phosphorus in an alcoholic soln. of potassium hydroxide. There is nothing to show that the gaseous product is any different from a mixture of hydrogen, carbon monoxide, and a little phosphorus vapour. A. Bor attempted unsuccessfully to effect *la combinaison du phosphore du carbone.*

J. J. Berzelius[16] said that red-hot silicon does not take up phosphorus vapour; and O. P. Watts was unable to prepare a **silicon phosphide** by reducing phosphoric acid with carbon and silicon in an electric furnace, or by using copper or copper silicide as a flux, or by the action of phosphor tin on silicon. J. Gewecke, however, said that silicon tetrachloride reacts with phosphine, forming silicon phosphide. According to R. Chenevix, a white, brittle, granular **titanium phosphide** is produced when titanium phosphate mixed with charcoal and a little borax is strongly ignited. H. Rose also obtained the phosphide; and F. Wöhler said the phosphide is not obtained by heating a mixture of titanic oxide, phosphoric acid, and carbon in a graphite crucible over 1400°, but it can be prepared by passing titanium phosphinochloride vapour mixed with phosphine through a red-hot glass tube when a layer of grey titanium phosphide appears on the glass. H. Moissan also found that at 1000°, phosphorus vapour covers titanium with a film of a dark-coloured phosphide. J. Gewecke investigated F. Wöhler's reaction, and found that when titanium tetrachloride is treated in the cold with phosphine, it forms a yellow crystalline substance which when heated decomposes into phosphine, hydrogen chloride, and a little titanium phosphide, TiP, which appears in the form of a brittle mass with a metallic lustre, and sp. gr. 3·95 at 25°/4°. A. E. van Arkel and J. H. de Boer made titanium phosphide by passing the vapour of the metal chloride and phosphorus over a heated tungsten filament; and F. P. Venable and R. O. Dietz, by passing the phosphine over the heated chloride. R. Chenevix said that the phosphide did not melt before the blowpipe, and seemed not very fusible. According to H. Moissan, the phosphide is a conductor of electricity, and burns when heated in air, or when fused with potassium nitrate. It is insoluble in dil. or conc. acids or alkali-lye; and is oxidized only to a small extent when boiled with aqua regia, or when heated with fuming nitric acid at 250°–300°. When heated in chlorine, the phosphide burns, forming white fumes of titanium tetrachloride and phosphorus pentachloride which condense as a complex titanium phosphoenneachloride, $TiPCl_9$. According to J. Gewecke, when zirconium tetrachloride is treated with phosphine, it behaves as in the case of titanium tetrachloride, yielding **zirconium diphosphide**, ZrP_2, which resembles titanium monophosphide in its general chemical and physical properties. The glistening grey mass has a sp. gr. of 4·77 at 25°/4°. When zirconium tetrachloride is sublimed in a current of hydrogen over heated potassium phosphide, there is formed a black mass containing potassium chloride, zirconium, phosphorus, and possibly oxygen derived from the presence of some zirconium oxychloride. A. E. van Arkel and J. H. de Boer made zirconium phosphide, and also **hafnium phosphide**, by the process used for titanium phosphide. J. J. Berzelius[17] noticed that when thorium is heated with phosphorus, the two elements unite with incandescence. J. Gewecke could not prepare **thorium phosphide** by the action of phosphine on thorium tetrachloride, even at a high temp., although H. Moissan and H. Martinsen obtained the phosphide by heating thorium tetrachloride to redness in a stream of phosphorus vapour; A. E. van Arkel and J. H. de Boer made thorium phosphide by the process used for titanium phosphide.

Experiments on the formation of **tin phosphides** were made by B. Pelletier,[18] O. Emmerling, C. Künzel, R. Lüpke, etc., who obtained a silvery-white alloy with 13–14 per cent. of phosphorus by heating the two elements together. Indefinite tin phosphides were made by A. Schrötter, and P. Vigier, who passed phosphorus vapour over the heated metal. G. Landgrebe melted tin with fused microcosmic salt; P. Berthier heated tin dioxide, tin, carbon, bone-ash, powdered quartz and borax; P. Mellmann, and J. L. Seyboth, heated phosphatic materials sand, tin or stannic oxide, and carbon; S. Natanson and G. Vortmann, metaphosphoric acid, carbon, and tin; A. Granger, by the action of phosphorus trichloride on tin at 500°; and T. von Grotthus, by the action of phosphine on tin salts. Commercial *phosphor-tin* contains 10 per cent. or more phosphorus, and is used extensively in making phosphor-bronze. The applications of phosphor-tin were discussed by F. von Friese, P. F. Nursey, W. G. Otto, etc. Phosphor-tin is very brittle and has a very pronounced crystalline fracture; a polished surface, etched by immersion in dil. nitric acid (0·5 per cent.), shows under the microscopic plate-like crystals immersed in a matrix of tin. The crystals can be obtained in the form of hexagonal plates by the action of dil. nitric acid or of mercury in which they are insoluble; the mercury can be removed by heating the crystals to 400° in a stream of carbon dioxide. L. Losana said that a small proportion of phosphorus has a deleterious effect on the mechanical properties of tin.

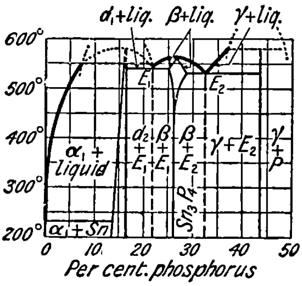

FIG. 23.—Equilibrium Diagram of the Binary System: Sn–P.

P. Jolibois considers that only tin triphosphide and tritetritaphosphide are chemical individuals; and that the other phosphides which have been reported are solid soln. or mixtures. A. C. Vivian found that when a mixture of phosphorus and tin is heated in sealed tubes, two conjugate soln. appear to be formed, and two definite layers of molten liquid are present. The maximum amount of phosphorus alloying with tin is 8 per cent., and the product melts at about 485°; if phosphorus vapour be absent, about 2·5 per cent. of phosphorus is retained by the tin at about 485°. The first approximation to the equilibrium diagram is shown in Fig. 23, where E_1 and E_2 represent the two eutectics; and Greek letters, solid soln. There is evidence of the formation of tin triphosphide, SnP_3, a compound prepared by P. Jolibois. This phosphide commences to dissociate at about 480°. There is also evidence of the formation of tin tritetritaphosphide, Sn_4P_3, isolated by J. E. Stead. The composition of the crystals from an alloy with 0·4 per cent. of phosphorus corresponds, according to J. E. Stead, with **tin ditritaphosphide,** Sn_3P_2; and, according to M. Ragg, the crystals obtained from a 5 per cent. alloy, correspond with **tin hemiphosphide,** Sn_2P. W. Gemmell and S. L. Archbutt found that phosphor-tin with 5 per cent. of phosphorus is vigorously attacked by aqua regia giving off phosphine; the action is less vigorous with nitric acid of sp. gr. 1·2, and no phosphine is given off. P. Jolibois found that alloys of tin with up to 13 per cent. of phosphorus contain **tin tritetritaphosphide,** Sn_4P_3, which can be isolated by making one of these alloys the positive pole in a soln. of sodium polysulphide—the uncombined tin dissolves, the silver-white crystals of the tritetritaphosphide remain unchanged. This phosphide has a sp. gr. 5·1810, and begins to dissociate at 480°. It is oxidized by nitric acid, and decomposed by hydrochloric acid and by sodium hydroxide. Alloys with more than 13 per cent. of phosphorus can be obtained by heating the mixtures under press., and when these alloys are treated first with hydrochloric acid, then with warm soda-lye, and finally with nitric acid at 50°, the monophosphide is obtained. A. Schrötter, S. Natanson and G. Vortmann, and O. Emmerling prepared crystals corresponding with the monophosphide by heating finely-divided tin with phosphorus vapour to a dull red heat; and S. Natanson and G. Vortmann prepared the same compound by heating a mixture of metaphosphoric acid with carbon and tin. The monophosphide has a sp. gr. of 6·56; it is soluble in hydrochloric acid; and not attacked by ordinary nitric acid, but it is attacked by the fuming acid; and, according to P. Jolibois, it dissociates when heated to 415°, forming the tritetritaphosphide. When tin is heated with a great excess of phosphorus in an evacuated tube,

A. Schrötter, and O. Emmerling found evidence of the existence of **tin diphosphide,** SnP_2, of sp. gr. 4·91; this substance is not attacked by hydrochloric acid, but aqua regia decomposes it with a series of explosions and the development of phosphine. P. Jolibois obtained **tin triphosphide,** SnP_3, by heating a mixture of tin and red phosphorus in a sealed tube for 10 hrs. at 620°. The product contained 40 per cent. of phosphorus, and it was purified by treatment with hydrochloric acid, followed by a hot dil. soda-lye, and by nitric acid of sp. gr. 1·2 at 50° and diluted with an equal vol. of water. The crystals have the appearance of elemental silicon. The sp. gr. is 4·10 at 0°; it dissociates into phosphorus and the tetratritaphosphide at 415°; it is insoluble in hydrochloric acid; slowly attacked by dil. nitric acid; and reacts with incandescence with fuming nitric acid. H. Rose reported **tin pentaphosphide,** SnP_5, to be formed as a yellow powder by the action of water on tin phosphinotetrachloride. L. C. Glaser and H. J. Seemann studied the system: Cu–Sn–P.

According to B. Pelletier,[19] molten lead can take up about 1·5 per cent. of phosphorus; and a similar alloy is obtained when lead filings are heated with glacial phosphoric acid, or when phosphorus is heated with lead chloride. A. Stock and F. Gomolka, and A. C. Vournasos obtained a phosphide by projecting pieces of molten phosphorus on molten lead. It contained needle-like crystals of lead and phosphorus in the molar proportion 3 : 7—possibly *lead diphosphide*, PbP_2. G. Linck and P. Möller said the crystals are monoclinic with the axial ratios $a:b:c = 1·651:1:1·46$, and $\beta=72° 40'$; the sp. gr. is greater than 3·2; and the crystals are less soluble than lead in nitric acid. A. C. Vournasos obtained a similar product by melting lead and phosphorus together under paraffin. P. S. Braucher used an alloy with 0·25 per cent. of phosphorus. P. Hautefeuille and A. Perrey said that lead heated in phosphorus vapour below the m.p. absorbs only a little phosphorus, and the phosphorus dissolved by molten lead is rejected on solidification. A. Granger could not get phosphorus and lead to unite directly, nor indirectly by the action of phosphorus on lead chloride or oxide, and he considered *l'existence de ces phosphures est donc douteuse.* T. von Grotthus, and H. Rose obtained a brown precipitate by passing phosphine into a soln. of lead acetate. P. Kulisch said that acid soln. of lead salts give no precipitate when treated with phosphine; a black precipitate is readily obtained by passing phosphine into lead acetate dissolved in a soln. of potassium hydroxide or aq. ammonia; A. Brukl worked with an alcoholic soln. of potassium hydroxide and obtained a precipitate of normal **lead phosphide,** Pb_3P_2. The precipitate is so unstable that it is liable to decompose, leaving a film of lead on the glass walls of the containing vessel. Water and alkali-lye decompose it slowly, forming lead, phosphine, and phosphoric acid. Dil. acids give phosphine; conc. nitric acid partially oxidizes the phosphide. R. Bossuet and L. Hackspill treated a soln. of lead nitrate with rubidium dipentitaphosphide in the same menstruum, and obtained black, amorphous **lead pentaphosphide,** PbP_5. It spontaneously inflames in air; and at 400°, in vacuo, it gives off much phosphorus; water attacks it slowly; nitric acid gives lead nitrate and phosphoric acid; and dil. sulphuric acid and hydrochloric acid form solid hydrogen phosphide, and lead sulphate or chloride respectively.

H. Rose [20] prepared **chromium monophosphide,** CrP, by passing phosphine over heated chromic chloride; C. A. Martius, by the action of phosphorus vapour on potassium dichromate; and J. J. Berzelius, by heating a mixture of charcoal and chromic phosphate in a graphite crucible. The monophosphide was made by A. Granger by heating phosphorus with chromium or chromic chloride in a glass tube in an atm. of nitrogen at 900°. G. Maronneau also made a chromium phosphide by heating copper phosphide with chromium filings in an electric furnace. The phosphide is a dark grey crystalline powder of sp. gr. 4·68–5·71. J. J. Berzelius found that it fuses with difficulty, and conducts electricity. The phosphide is decomposed by potash-lye, or molten potassium hydroxide; it is insoluble in acids, but it is very slightly attacked by aqua regia, and dissolved a mixture of hydrofluoric and nitric acids.
